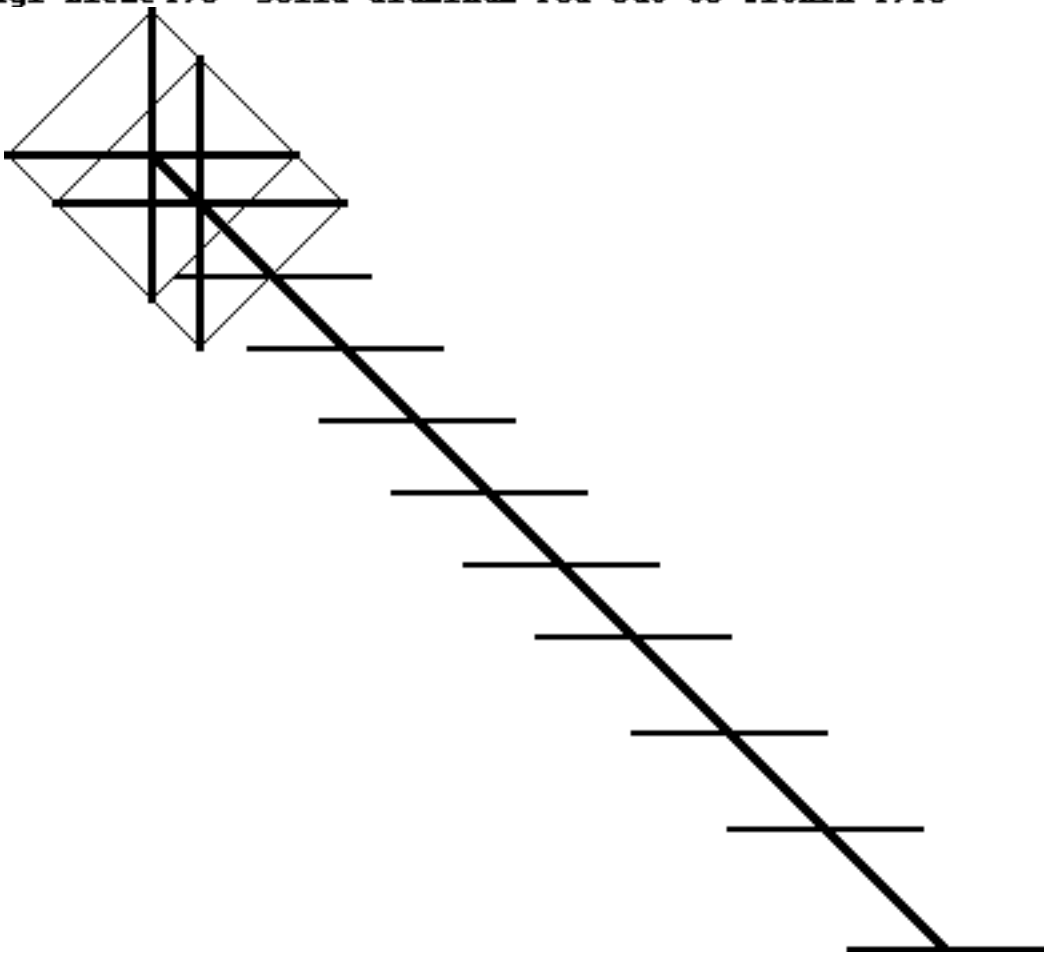
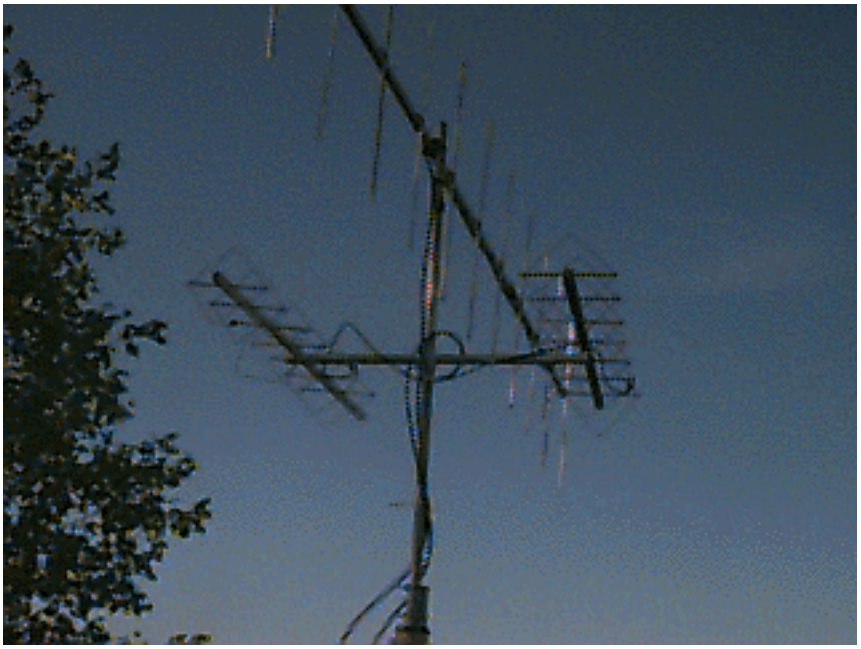
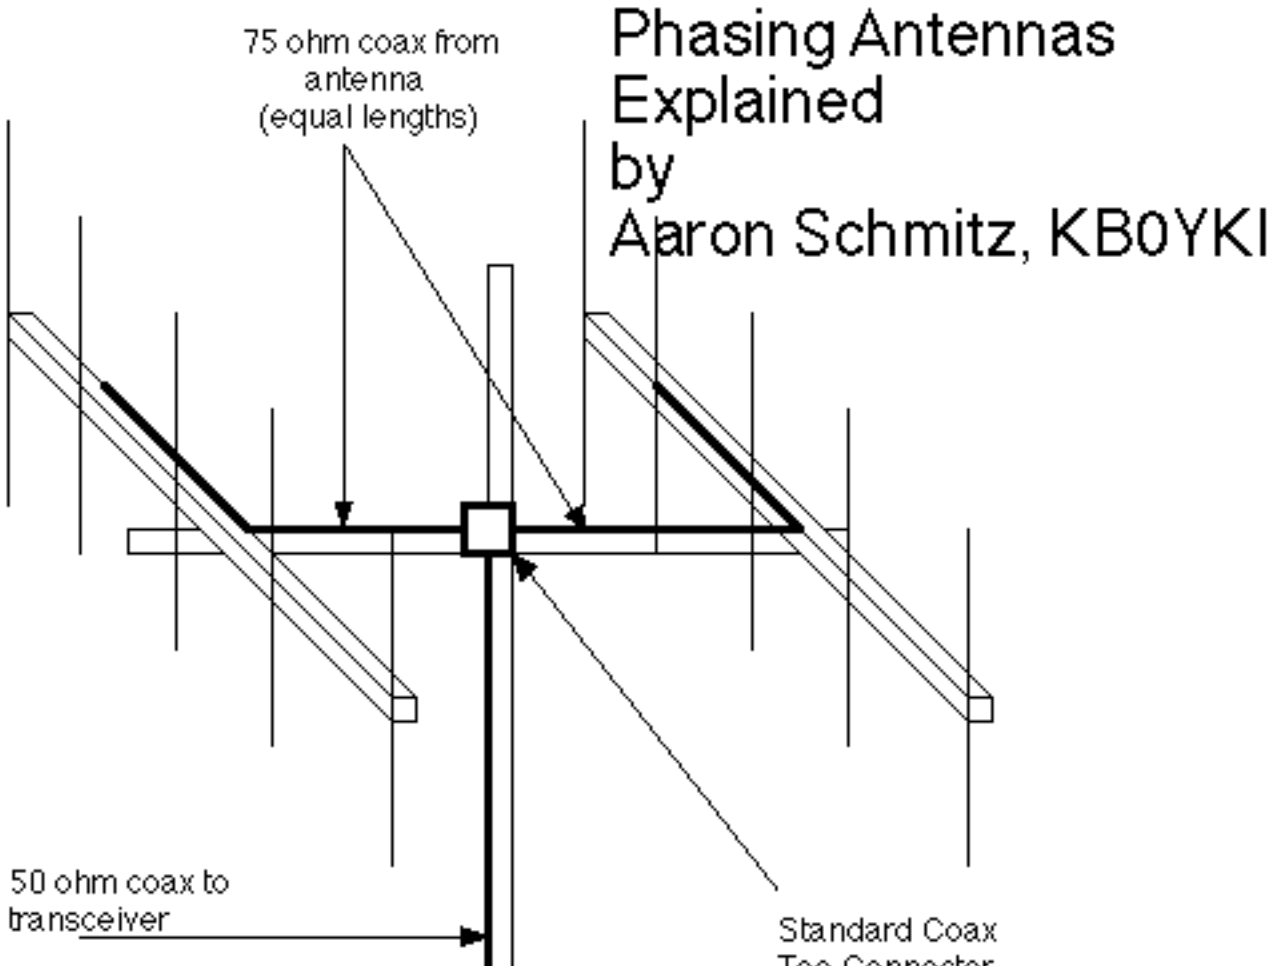
Boom- Nonconductive material such as wood or fiberglass
Quad Eleme made from 12 guage insulated copper wire
Yagi Eleme 1/8" solid aluminum rod cut to within 1/16"



My Stacked Quads



The picture above is of my 440 MHz stacked quads. The spacing between the antennas is approximately 80-90% of the boom length. RG-59 (75 ohm) cable was used on the phasing harness. An almost perfect 1:1 SWR was achieved at 446 MHz after installation. Any other questions on this can be forwarded to me.



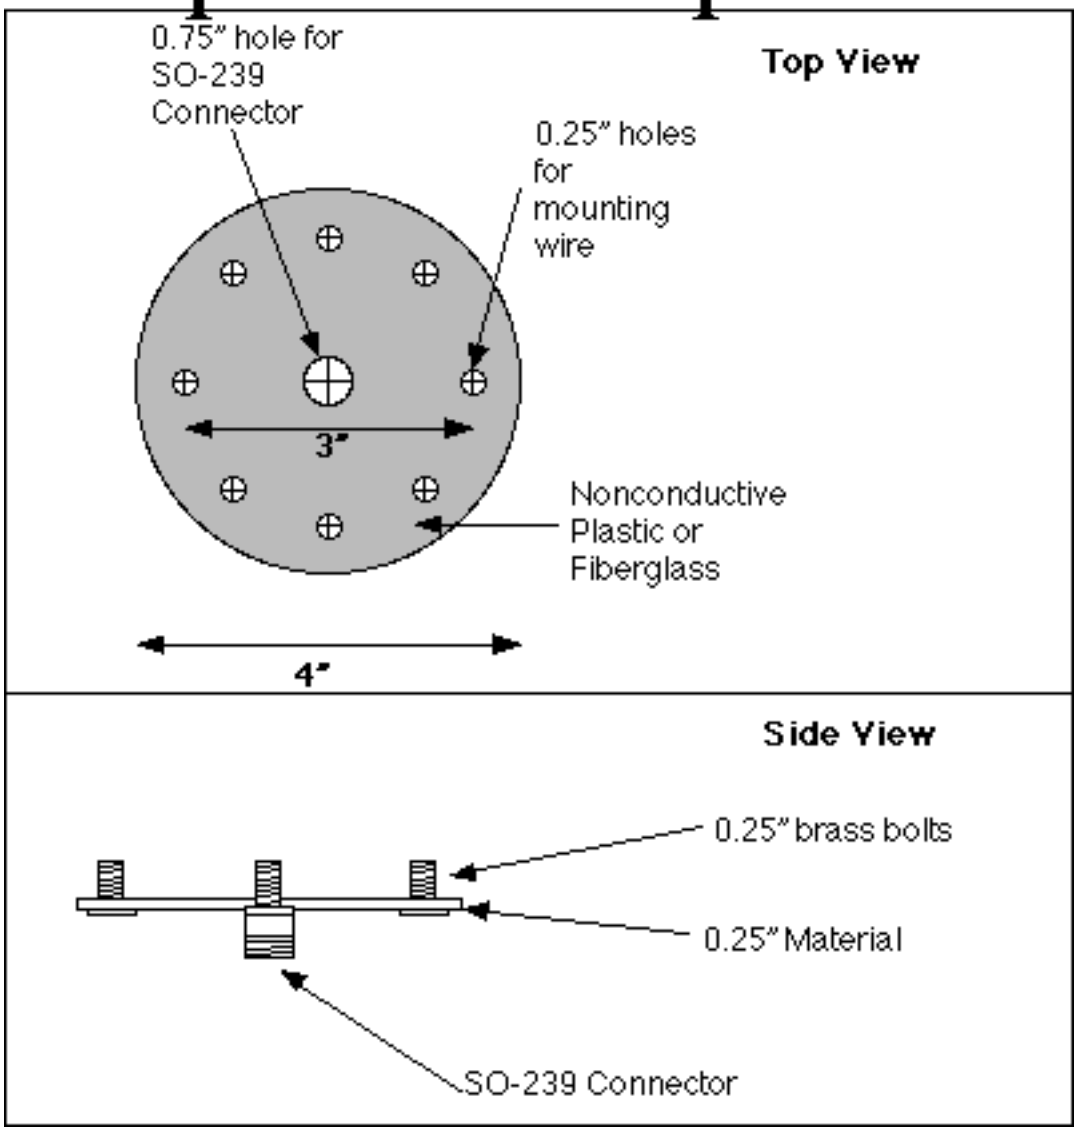
Standard Coax
Tee Connector

Steps to build a Phasing Harness
1) Build the antenna and cross support
2) Determine the length of coax that you need to run from the antenna feedpoint to the connector.
3) See how much coax will work for the phasing harness.
f=146.520 MHz
λ/4=234/f=234/146.52=1.5 ft=18 inches (Physical λ/4)
RG-59 Coax Velocity factor is 66% the speed of light.
(18 inches)X(0.66)=12 inches (Electrical λ/4)

Example: Your setup needs approximately 6 feet of cable to get from the feedpoint to the Tee connector.
The only problem is that 6 ft would be an even quarter wavelength (not good). All you have to do is go to 7 feet of RG-59 coax and you have 7 electrical quarter wavelengths(Fantastic). You should be pretty close to having a low SWR reading. That is not guaranteed, but it should be close.

4) Get your 75 ohm coax and cut it off pretty close to amount of coax needed(in this case 7 feet for each side.)
5) Solder on your PL-259 connectors with the appropriate reducer to the 75 ohm coax coax.
6) Hook everything up. If you are using a gamma matched antenna, adjust the gammas to get a low SWR reading.
7) Get on the air and have fun!!!

Dipole Feedpoint



This is the big rooftop tower that I built a few months ago. At that time I could not find any in my area for a price I felt I could afford. It is made of 1 inch square tubing for the legs and uses a 2 1/4" inch pipe for holding the rotor. It is welded throughout and has two coats of enamel primer and two coats of flat black paint.

The tower has with stood the 50 mile per hour winds that have roared through Missouri in the month of April and May of 1997. If you would like a set of plans for this, feel free to email me.

GO TO HOME PAGE

A ROTARY DIPOLE FOR 17 AND 20

After assembled a two element Quad, Mario (ik7zcq) needed an antenna for 17 and 20, so he asked me to build a 17/20 dipole; I hote rotary dipoles and traps..but why don't try it!

THE PROJECT

I hote projects because I never find all I need: so always I do the best I can with what I found.
At the beggining my project was:
1) Grounded-driven element;
2) Gamma-match feeding;
3) Traps with coax-cable;
After first test I decided to use a direct-feeding with no Gamma-match: the Gamma will give best results with single-band feeding. Dipole will be no more grounded.

THE DRIVEN ELEMENT

Driven element is tapered and I use 8 aluminum pipes with the following diameters:

Diameter	Length	thickness	N.part
30 mm	162 cm	2 mm	2
25 mm	164 cm	2 mm	2
20 mm	131 cm *	2 mm	2
16 mm	28 cm	1 mm	2

*** here will be the trap (108 cm + insulator + 23 cm)**

I suggest you to reduce thickness for tips (2 - 1,75 - 1,5 - 1 mm).

First part (diam. 30 mm) is center-insulated with a nylon bar (diam. 25 mm);

outside I used PVC (diam. 40mm, 5 mm Thickness); there are two screw bolt (3mm diam.) for feeding the dipole (See Picture 1).
The mast to boom attachment is an home-made steel plate (15x30x0,35 cm) (See Picture 2).

Second part (diam. 25 mm) is easy to assemble;

Third one is a little bit difficult: cut a 20 mm aluminum pipe (lenght 131 cm) at 108 cm so to obtain two pipes (108 e 23 cm).
Put a PVC bar (5cm) into and between them, then use fibreglass to block them and put over them an insulated support (See Picture 3) (TNX Antonio,ik7ytx).
Than make two 3 mm-holes (for traps-feeding).

Last part is a 28 cm length (diam. 16 mm) aluminum pipe, used for 20 mt tuning.

TUNING

Radiation resistance for an half-wave dipole will be around 69-70 ohm (free space); if you put it 0,5/0,75 lambda high resistance will be lower so you don't need to match it; I only used 20-25 turns of coax-cable as balun.

THE TRAPS

At the beginning I believed traps was the more difficult thing to build, so i bought two RF capacitor (See Picture 4) but that was not true!
Using a dip-meter check the resonance: 8 turns of RG58 on a 27 mm support will resonate at 18.1 (See Picture 5).
When tuned, cover the traps with RF glue (See Picture 6) so that water can't enter in and then cover all with PVC tape (See Picture 7).

ASSEMBLING

I tested the dipole on my garden, on a 10 mt pole, with no objectes near it.
At first assemble first two partes (with no traps) and tune it on 17 mt; than add traps and 20 mt part and tune it on 20: S.W.R. will not change.
On my garden S.W.R was 1,2:1 on 17 and 1,5:1 on 14.200, 2:1 on 14.000 and

14.350; when assembled in the qth of Mario it was 2:1 on 17 and 1,1:1 on 14.200 (but there are some objects near it, see Picture 8)!

The length (half-dipole) is the following:

Tips (18 MHZ)	Trap	Half-Dipole (18 e 14 MHZ)
46 cm	Trap	394 cm

WEIGTH

Dipole's weigth is less than 6 Kg but you can reduce it reducing the thickness for aluminum pipes.

73 de iz7ath, Talino

RUBBER DUCK ANTENNAS

RACES BULLETINS 023-025, 1986

Rubber duck antennas on hand-held radios are a severe compromise on efficiency. On the plus side is their short size and flexible forgiveness to brutish handling. On the negative side is their terrible radiation inefficiency, probably worse than many of you expected.

When did you last replace your helical spring antenna we call the rubber duck? On testing a hundred or so portable radios that had been out on the fire lines for a few weeks we found a typical 60 percent failure rate. Most of the antennas looked fine. The only way you can detect an invisible rubber duck failure is by measuring the microvolts per meter with a calibrated receiver over a measured range under controlled conditions, such as done routinely by the Boise Interagency Fire Center. Since this is difficult for most to do, it might not be a bad idea to replace rubber ducks as a matter or course when they show signs of wear or if they are a year old. You might want to consider using a telescopic antenna under non-violent conditions to vastly improve the range of your hand-held.

The National Bureau of Standards ran some tests that proved what we had long suspected. The efficiency of a hand-held is dependent upon how much antenna it has and how good the ground plane. Most portables have very poor ground planes; the more metal the better. Also the more antenna the better. Hence the rubber duck is a woeful but often necessary compromise. But if a portable is not going to be subjected to the abuse of fireground or street cop utility, you should consider the telescopic quarter-wave antenna if range is important. Compare the figures and discussion that follows.

Be aware that the telescopic antenna is nowhere as rugged as the rubber duck but it will talk circles around it. You might say that the quarter wave whip is to the rubber duck what a 106 inch CB quarter wave whip is to a 36 inch whip on a base loaded coil to compromise range for low garages. Our reference antenna in the Public Safety high band and 2-meter Amateur radio measurements below is a quarter-wave telescopic antenna, extended, and held at face level: One-quarter wavelength extended and at face level = 0 dB One-quarter wavelength collapsed and worn at belt level = -40dB Rubber duck held at face level = -5dB Rubber duck worn at belt level = -20dB Translated, this means that a 5-watt hand-held with a rubber duck worn on the belt has an effective radiated power not of 5 watts but only .05 watt. Held at face level the radio has an ERP of 1.6 watt. 15dB is quite a difference!

In the material above we gave you facts and figures of the quarter-wave telescopic versus the rubber duck for Public Safety VHF Highband and 2-Meter Amateur handhelds. The 40 dB down for the nested telescopic relates to those commercial models where the telescopic disappears within the radio. Such an antenna won't break when it's nested but it won't receive worth a whoop either. In those radios where the collapsed quarter wave is external to the radio they break very easily. For that reason we recommend the style that has a spring at the base. The spring makes it very forgiving of elbows and other bum raps. We

have not researched or measured five-eighth wave antennas because they are too long for most public safety use and because they typically require too many telescopic sections. The more sections the more chance of troubles. Few people take the time to correctly telescope any hand-held antenna. They should never be whacked down with the palm of the hand on top and push. They should be pulled down with the thumb and first two fingers.

If you are interested in the figures for 450 MHz, using the table above, they are respectively 0dB, 30dB, 5dB, and 30dB. One more reference for the technically inclined-the loss of a telescopic antenna compared to half-wave dipole: VHF -5dBd and UHF -20 dBd. Telescopic antennas should be changed at least annually and whenever they become the slightest bit loose. Any looseness can mean a poor RF connection inside the antenna where you can't see it or fix it. Simply change it.

The Slinky that became a Antenna

LOWER PRICE WAS $35.00 *NOW* $29.95

Fun with Helitrix ™, the stretchy helix.-- Helitrix ™ is a flexible springy helix with a 2-3/4 inch diameter. Each Helitrix ™ weighs approximately 7 ounces. When collapsed it is only 2-1/4 inch long, but it can be stretched without deforming into a helix as long as 15 feet in length. An antenna made from a Helitrix™ is light, simple to suspend and extend, and easy to put out of sight when not in use.

Helitrix™ Antenna Basics.-- For a forty meter dipole, use a full Helitrix™ coil on each side of the feedpoint. Stretch to 15 ft. For 75 meters put two coils on each side and stretch the whole to about 30 feet in length. Presto! You will have an 80 meter dipole that fits in most attics or even in a motel room. A quick twenty meter dipole, can be made by stretching out a single coil to a length of 7 ft and feeding it with a delta match in the center.

Helitrix Antenna Performance.--Is Helitrix a wonder antenna? No. But it works. In a test on a state-wide 75 meter phone net, a 30 foot 80 meter Helitrix™ dipole at 20 ft received signal reports on average 1-1/2 S-units lower than a TNT Windom at 35 feet. That's not bad for a 1/8 wavelength antenna. The Helitrix dipole would have compared better had it been equally high, but it would not outperform the full size dipole. On the same occasion a comparison was made with a Hustler mobile whip. Compared with the whip, Helitrix performance and bandwidth were outstanding--better by several S-units for state-wide coverage. So, considering that you can even install a Helitrix ™ antenna for 80 meters inside a motel room, the Helitrix antenna promises some good moments.

1. The simplest way to obtain multi-band results is to take a pair of Helitrix™ coils, one on each side of your feedpoint, stretch them as far as space permits, and clip on the feedline. Here you have a compact version of the good old "center fed Zepp". Feed it through an antenna tuner. This simple antenna will play on all bands 7 MHz and above. In a pinch it will permit QSOs on the 80 meter band. The ready-to go QRV Helitrix 40-10 antenna (see description below) is an aesthetically pleasing and easy to use version of this basic doublet.
2. Helitrix™ antennas are best suited to indoor or portable deployment. If you wish to put your Helitrix ™ antenna outside on a more or less permanent basis, you should solder all connections well, then paint the whole antenna with spray enamel. This is actually quite easy to do, so don't shy away from trying it.
3. For a given Helitrix™ antenna, performance is best at the frequency of natural resonance and on the next harmonic because the coils act increasingly like an RF choke on the higher harmonics.

Have Fun with a Helitrix! But be careful the kids don't run off with it. They could slink around with it like a toy. But they'd miss the big fun. Could they imagine talking into one and having someone from Japan answer them on 15 meters? Or think of checking into MARS and RACES nets with a Helitrix™ on the bedroom wall? Only in amateur radio can you get a bang like this out of a stretchy helix.

Antennas & More has put together what you need to get off to a fast start with Helitrix™ experimentation. Check out the items listed below and turn a weekend with a Helitrix™ into the most fun you've had since you were a kid .

Helitrix™ Antenna TechNote 123D $7 ppd.
This frequently updated Technote reviews Helitrix™ experiments performed to date. Gives detailed information on the electrical properties of Helitrix™ coil antennas. Describes instruments used & designs tested. Reports

unpublished experiences of numerous contributors. Shows how to get the most out of a Helitrix™ with or without an antenna tuner. Reviews what works and what doesn't. Use this to study out the principles and plan your installation.

QRV Helitrix™ Dipole $29.95

This is the fully refined and ready to use QRV Helitrix™ system, all set to go for instant motel, attic, or portable use. Coaxial feedline is decorator white. Quick attachment clips make it a snap to hook up fast. Support line lets antenna slide in and out of action instantaneously. Unique design assures unerring and quick return to correct position whenever desired. Mounting tabs, coax feedline, and unobtrusive installation easy, whether for long or short term utilization. Manual shows proven methods for working 40 thru 10 even without an antenna tuner. With tuner work 80 meters.

Includes Feedline

Helitrix 40-10M Dipole antenna $29.95us

Helitrix 80M Extension $8.95us

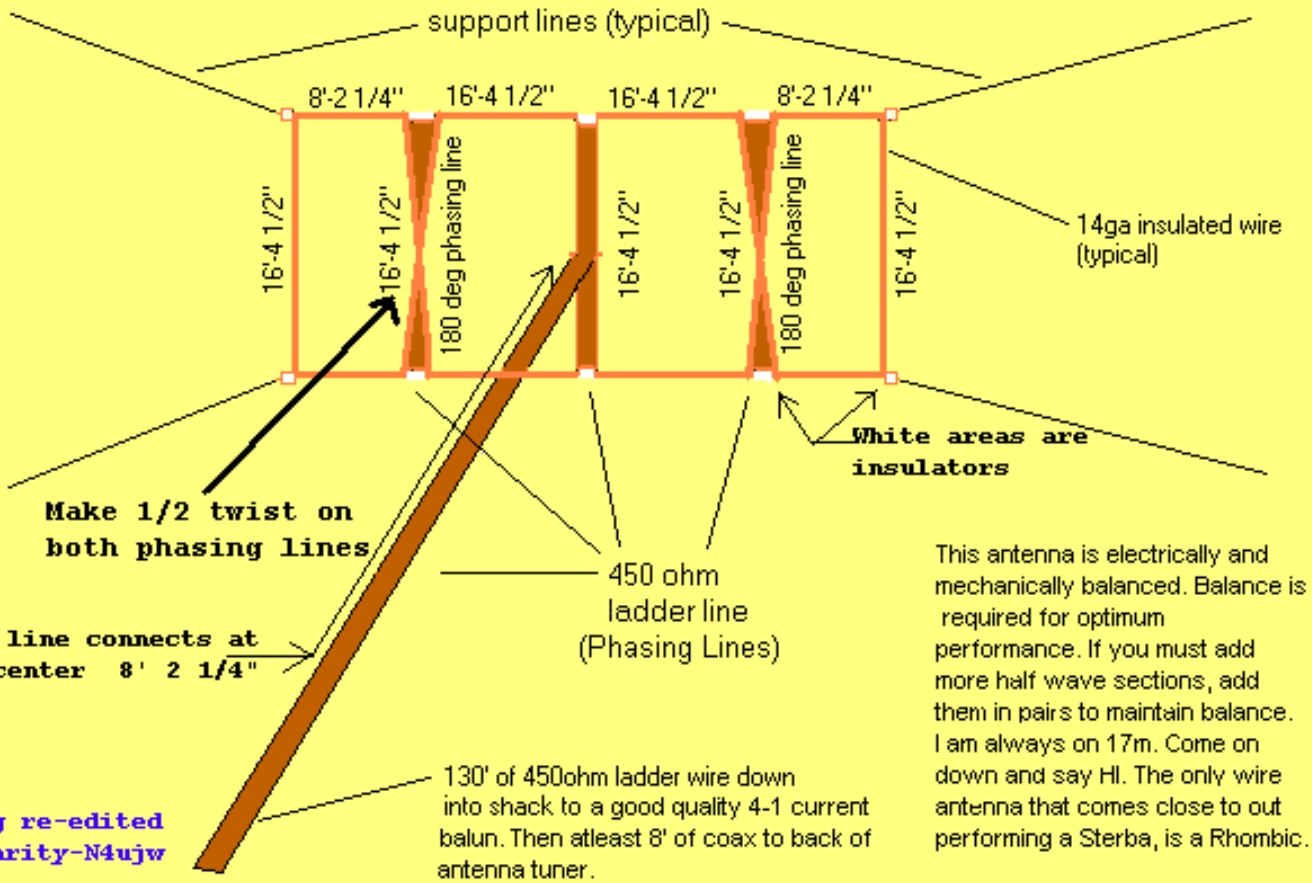
160m-10m Sterba Curtain

IF YOU COULD ONLY PUT UP ONE ANTENNA...THIS WOULD BE IT!

By NØKHQ - ST.LOUIS.MO

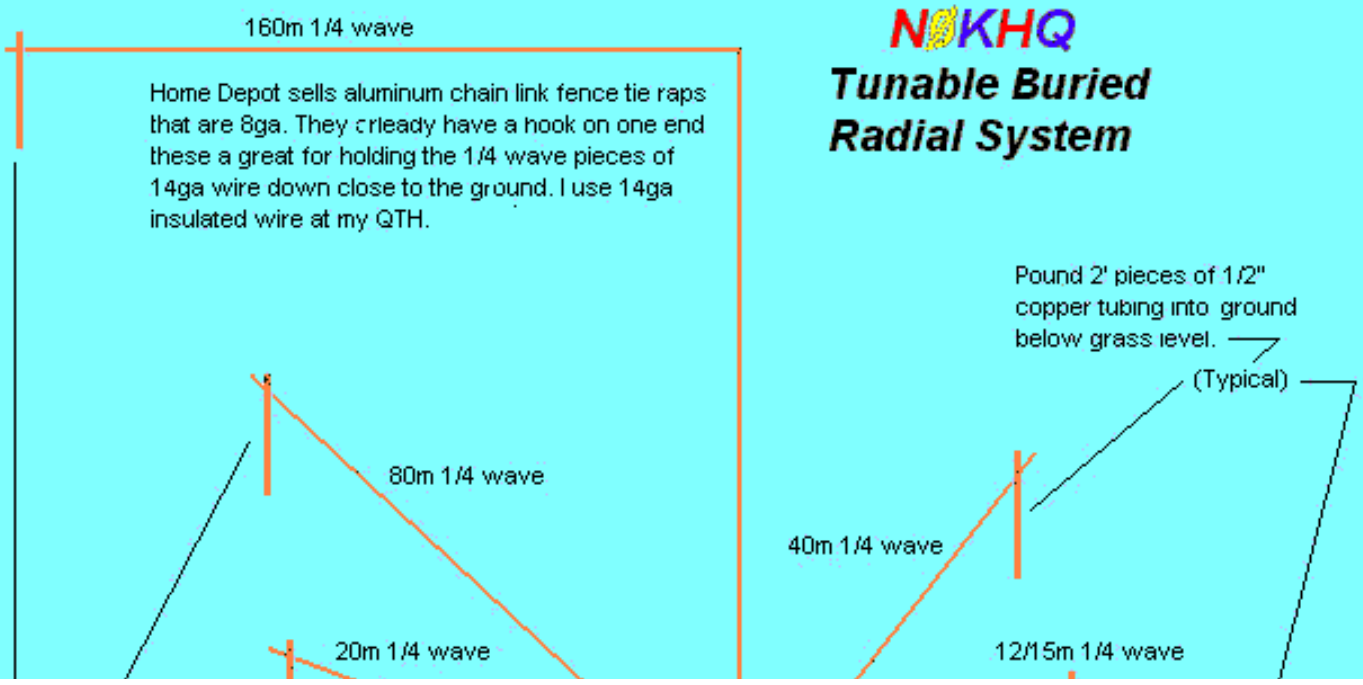
The Broadside Curtain Aray

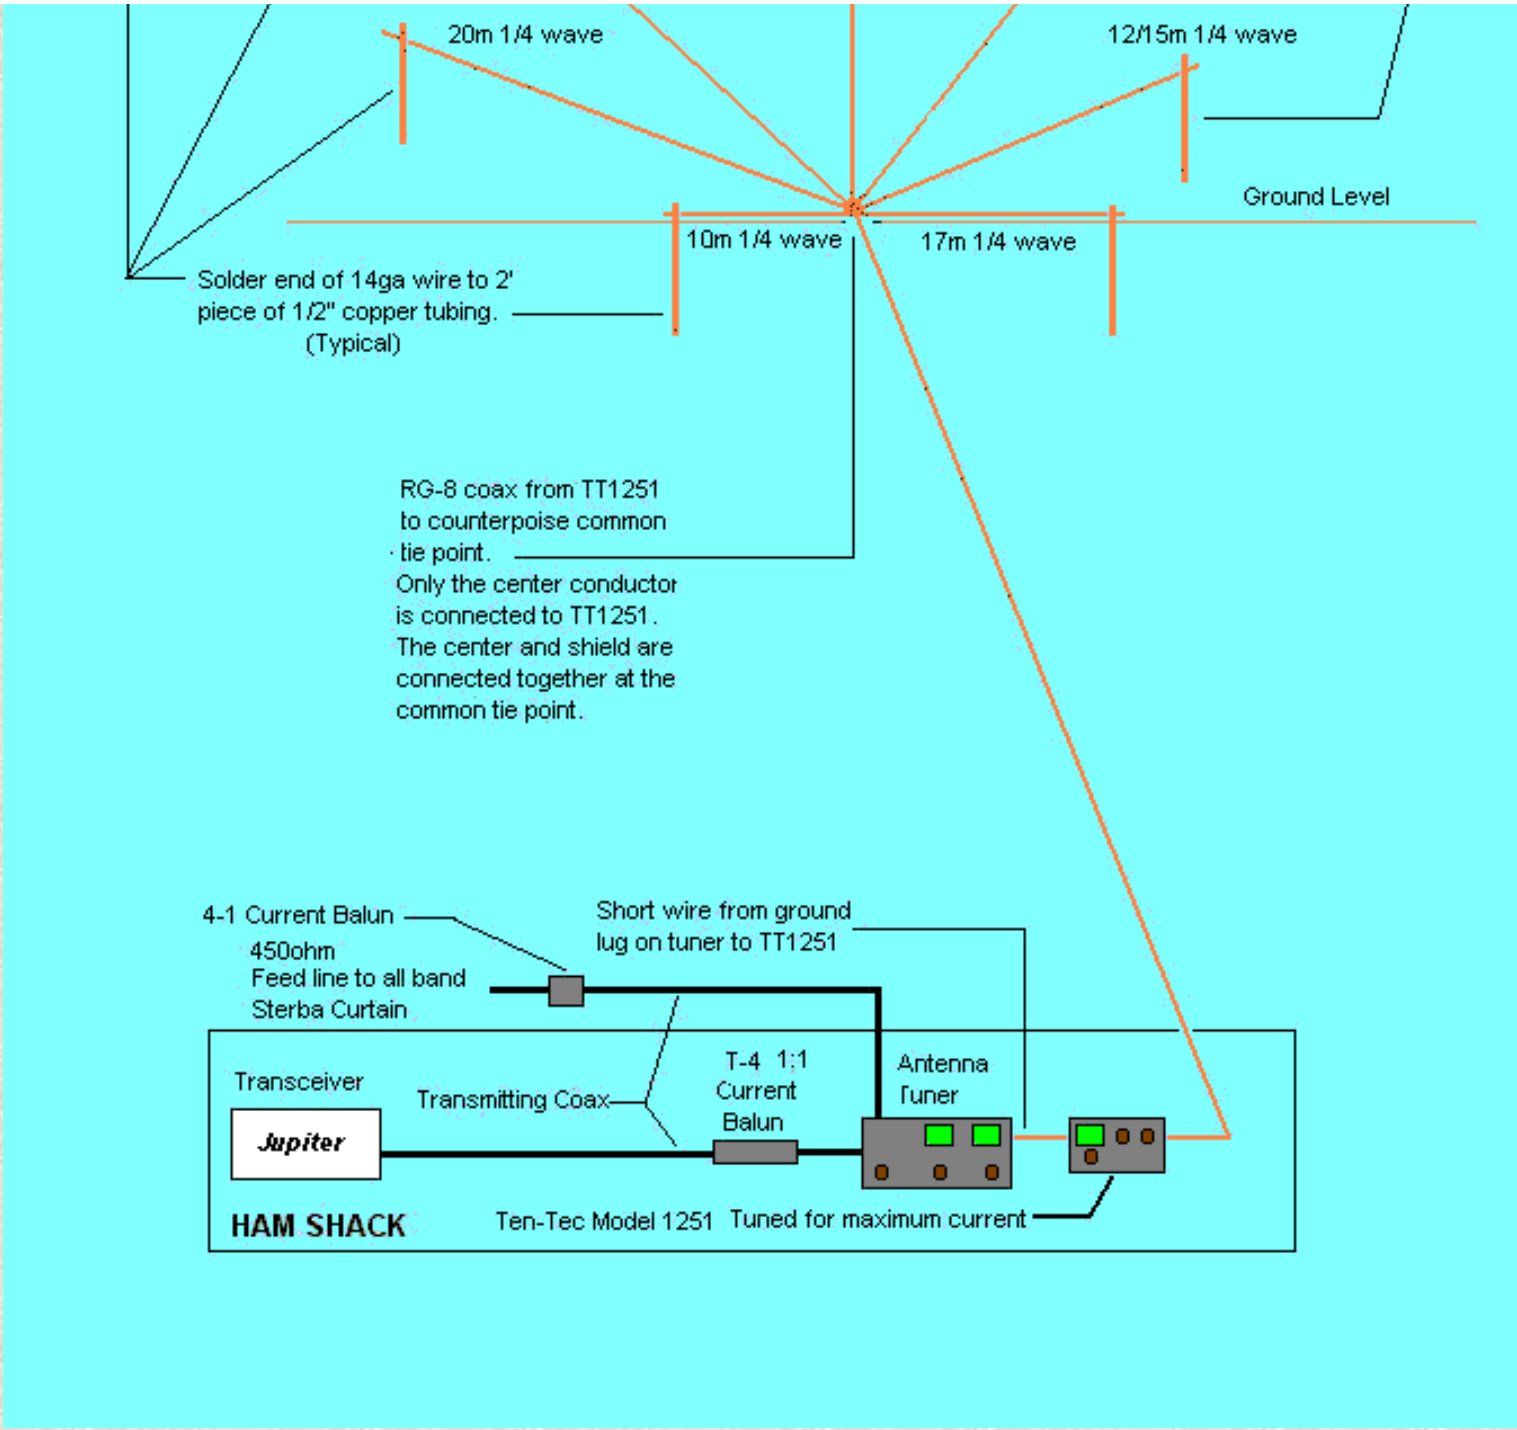
You can build them better than you can buy them!



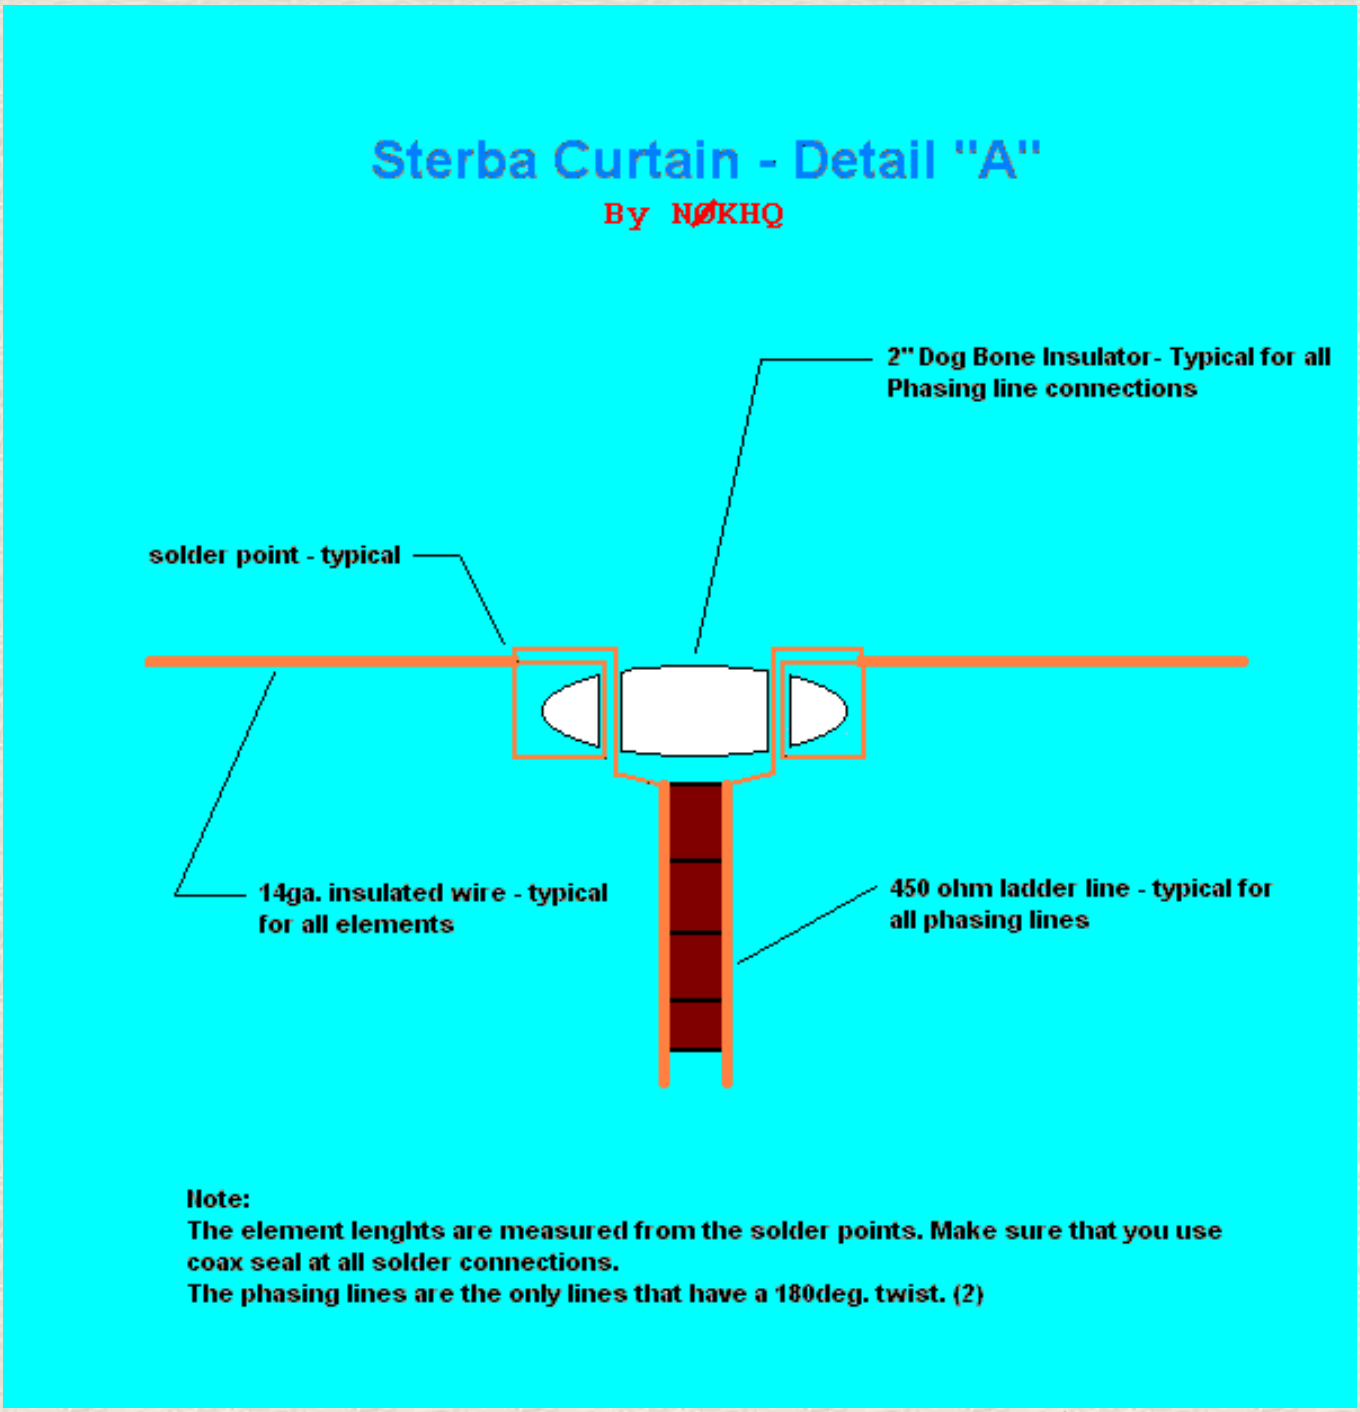
Drawing re-edited for clarity-N4ujw

This antenna is electrically and mechanically balanced. Balance is required for optimum performance. If you must add more half wave sections, add them in pairs to maintain balance. I am always on 17m. Come on down and say Hi. The only wire antenna that comes close to out performing a Sterba, is a Rhombic.





20m 1/4 wave
12/15m 1/4 wave
Ground Level
10m 1/4 wave
17m 1/4 wave
Solder end of 14ga wire to 2' piece of 1/2" copper tubing. (Typical)
RG-8 coax from TT1251 to counterpoise common tie point.
Only the center conductor is connected to TT1251. The center and shield are connected together at the common tie point.
4-1 Current Balun
450ohm
Feed line to all band Sterba Curtain
Short wire from ground lug on tuner to TT1251
Transceiver
Jupiter
Transmitting Coax
T-4 1:1 Current Balun
Antenna Tuner
HAM SHACK
Ten-Tec Model 1251
Tuned for maximum current



"I live on a very small residential lot 65' wide x 100' deep. I have a tree in the front yard and a tree in the back yard.
The sterba is hung directly over the top of my house.
the bottom element of the array is up at 35'.
The design frequency for maximum gain was 28.5mhz
THIS DESIGN IS FOR ALL BAND USE.... 160 THRU 10 using a Tuner!.
The standard formulas below were used
468/freqmhz = 1/2 wavelength section
234/freqmhz = 1/4 wavelength section.

My antenna elmer is W1VDE, Roger, He was part of the team that built the dishes at Arecibo, Puerto Rico years ago. I am attaching the other half of my antenna system(John is refering to the Tunable Radial System in pic below) for your review and comments. This system adds approx. 3db to 6db of additional gain to the Sterba.
If you need further information please do not hesitate to call.
Hams that have installed the curtain have liked it so much they have put up more than one."
73

John / N0KHQ / St. Louis
Always on 17M
Antennas:
You can build 'um better than you can buy 'um.

This taken from recent email from John, N0KHQ
Hi Don,
Okay, here we go. Here's an example for 17 meters.
The Sterba is approx. 50' long x 16' high.

Example Gain on 17m:
17m squared / 12.56 (4pi) = 23 sq. meters of aperture

50' / 3.28 (1 meter) = 15.24 meters
16' / 3.28 (1 meter) = 4.878 meters

15.24m x 4. 878m = 74.34 sq.meters

74.34 / 23.00 = 3.24 log x 10 = 5.09 db + 1.64 (gain over dipole) = 6.73 db gain on 17m.

If you are running 150w x 6.73 = 1009.5 watts of effective radiated power output on 17m.

On 10m (the design frequency) the gain is 10db +/-
The above formula can be used for calculating aprox gain on other bands

I need to clear up something that I may not have explained very well. This design allows a ham to use this array on all bands 10m through 160m, on 160m the swr bandwidth is pretty narrow.. There is no need to build arrays for different bands.
I have not tested other Sterba's designed for other bands as to their performance from 10m through 160m.

ABOUT FEEDLINE LENGTH
The reason the 450 ohm feed line is 130' is because it is about 1/4 wave length on 160m which is a high current point. So, what ever is tied to the end of the feed line.....is going to get out!.
For the feed line length (130') I have tried different lengths but 130' seems to be the minimum optimum length to get on 160 m.
Example:
I used 935/1.931=484.2' / 4 = 121.0' . This is a 1/4 wavelength at 1.931mhz, in the example. Some have said that 450 ohm ladder wire is actually 400 ohm. Some have said the velocity factor is not .95. Man, who really knows?

This antenna serves me well. Since I only have room for one.
A good thing to remember is the phrase "Volumetric Efficiency".

I have sent this design to a number of hams, the design has made it all the way to Europe. If you would like to contact a friend of mine that is running this array his call sign is KB4CCM, Bill. He liked it so well he put up two!

(Bill, KB4CCM WRITES THIS ABOUT THE DESIGN..... TAKEN FROM AN EMAIL)

"If hams interested in the Sterba wish to contact me, (see email address below)
I would be glad to answer any questions that I can and
give tips on construction. As John has told you, I

have taken down all of my other wire antennas (dipole, extended double Zepp and Half square) due to the performance and versatility of the all band Sterbas.

By the way, you may be interested in an article I wrote which is published in the ARRL Antenna Compendium # 7 now on sale. It is entitled 'The ODD QUAD' and details instructions on how to build a strong and cheap (using locally available materials) two element Quad that can be installed and rotated without a man made vertical structure. This Quad, along with the Sterbas, may be the only antennas I will ever need or use for the rest of my ham career."".....Bill KB4CCM

BACK TO THE PROJECT

The buried radial system that is used with the Sterba adds approx. 3db to 6db of gain. Once you add this gain to the gain of the curtain, the total gain of the antenna system is 9db to 12db of gain on 17m.

A good reference book that is available that will help hams to understand the importance of a good buried radial system is "Low Band DXing" by ON4UN cost $30.
Hams running the low bands are experts on antenna systems.
I call it my antenna bible.
Hope all this helps.....my head hurts!!!!!!!

RADIAL SYSTEM INFO

The Sterba Curtain, as designed is non resonant.
There are a couple of bands where the swr will drop to 3:1.

The installation of the tunable buried radial system will help on 160m, 80/75m and 40m.
If I were you I would put out radials for those bands only.

4 for 160m
4 for 80/75m
4 for 40m

Remember, the radials should be cut at .15 of a wave not .25. There is a 10% shortening factor when radials are either on the ground or buried just below the grass level. By installing the radial system you will add 3db to 6db of gain to the gain on the curtain now. (ref. ON4UN - Low Band DXing)

I bought a HedgeHog from Lowes to dig the trenches $50 and used, what I call chain link fence wire ties, the aluminum wire ties are already bent in the shape of a "U" and hold the wire down very nicely.

You wont need to run an amplifier with the antenna for good performance.

"Curtains for You"

As Forty Meters has traditionally been the most productive band on CW for our Club Field Day efforts, I would like to put up more than the usual dipole this year. The most attractive antenna appears to be a Sterba Curtain. I would ideally like the antenna design to center on 40, but this may not be practical. Perhaps we could design it for 30 Meters- that would be close enough to tune it and enjoy most of the benefits and gain of the Sterba.

My plan would be to put up the 2 section Sterba, run ladder line to a tuner in a temporary "dog house" to protect the antenna tuner in it, adjust the tuner at the center of the 40 Meter CW band, and run the needed length of feed line with coaxial cable to the Transceiver. Once tuned, we should be able to operate the whole 40 meter CW band without having to retune.

A two-section Sterba would be a full wavelength from end to end, and a half wavelength in height. Ideally, the bottom should be a half wavelength off the ground. At lower heights, it still has to be a lot better than a dipole. The 2 section Sterba should fit nicely between the stadium light poles. Provisions could be included to rotate the array.

Required materials would include:

1. A full wavelength of 450 ohm ladder line. For 40 meters this would be approximately 133 feet. For 30, this would be about 90 feet. Added to this would be a short section to the dog house.
2. 3 full wavelengths of wire. For 40 meters, about 400 feet, for 30, about 300 feet. I have been collecting wire, this should be no problem.
3. 8 Insulators (can be fabricated)
4. Tuner and Coax.
5. Rope- undetermined amount.

The Sterba Curtain: What is it, and what makes it so great?

The Sterba is a gain antenna, with the gain depending on the number of dipoles pairs. The unique signature of the Sterba is the use of ladder line with a half turn to provide the proper phase to the dipoles.

The basic Sterba unit is 2 parallel half wave dipoles with a half wave phasing harness between them. You may add as many units as you have wire and room.

The amount of wire in this antenna alone makes it a great receive antenna.

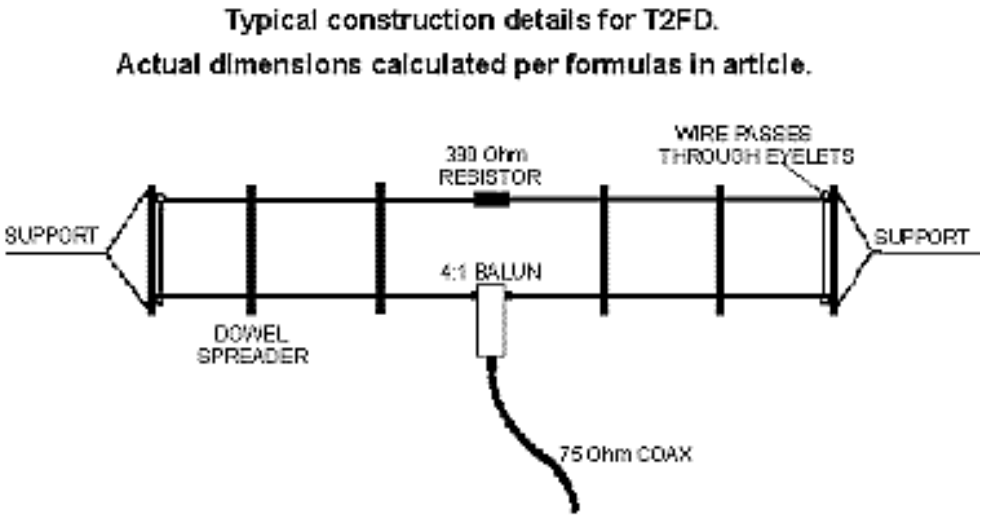
More on the T2FD
- Main
- Design
- Feeding
- Compare
- Opinion



The formulas for calculating T2FD dimensions are as follows.

1. The length of each leg ("A") from the center is equal to 50,000 divided by the lowest desired operating frequency (in kHz) and then multiplied by 3.28. The answer is in feet.

2. The spacing between radiating wires ("B") is equal to 3000 divided by the lowest desired operating frequency (in kHz) and then multiplied by 3.28. The answer is in feet.

3. The sloping angle for a non-directional pattern should be on the order of 30, but 20–40 is acceptable.

Example:
To design a T2FD for the center of the 90 meter band (3300 kHz) and up:

	Desired frequency	Spacing
Leg "A"	(50.000 / 3300) x 3.28	49.70 feet
Leg "B"	(3000 / 3300) x 3.28	2.98 feet

Total length of the antenna would be 99.4 feet (2 x 49.7), and the width would be 2.98 feet ("B").

The total wire used to complete the loop equals 204.76 feet (4 x 49.7)

NX7U Mobile Pages -- Check This Out

From The News Groups:
Someone asked me to post the following summary of three California 75m Mobile Shootouts:

Bugcatcher/Screwdriver with top hat	**0 dB reference**
Bugcatcher/Screwdriver, no top hat	**-3 dB, -50%**
Hustler	**-7 dB, -80%**
Outbacker	**-9 dB, -88%**
Hamstick	**-12 dB, -94%**
Whip with autotuner	**-14 dB, -96%**

Considering that the top legal 75m mobile antennas are only 5%-10% efficient to begin with, a Hamstick radiates ~0.6 watts in the far field with 100 watts input. 75m Hamstick users must really enjoy QRP. :-)

TELREX ANTENNA TRAP REPAIR -- FROM N6KI

Rod,

I just wrote up this Telrex antenna Trap repair procedure for Bob, K6XX. If you have room somewhere on your web page maybe you could include it somewhere so other Telrex owners around the world can keep em ticking!

73, Dennis N6K

Hi Bob, Yes Telrex traps do tend to toast but not since I modified the 15 and 20 mtr traps on the driven element of my 7 element Monarch which covers 40 thru 10 mtrs. Never had a problem with the 10 mtr traps. I marked where the driven elements assemblies were inserted into the short stub coming off the boom and was able with my tower cranked down and another person on my patio roof supporting and pushing up on the ends of the driven element, to remove the 2 sides. (I borrowed my neighbors pool cleaning poles and mounted a donut shaped piece of aluminum to the end of the pole and had my friend capture the end of the element so he could lift and take the weight off my end near the boom).

The failure mechanism is that even though the doorknob cap used in the trap is rated at 5 to 7 kV ACROSS the cap, Telrex, in their infinite wisdom, had laid the doorknob cap directly on top of and touching the coil section of the trap! So, the caps appear to flash right up through the SIDE of the cap from the coil! The object of this repair exercise is to remove the old burned out doorknob cap but replace it with 2 doorknobs in series, allowing you to lift the straps that the ends of the doorknob cap is attached to. Two advantages of this type of repair are:

1. You now have double the voltage protection across the two 5 kV doorknobs caps.

2. The doorknob caps no longer lie directly on top of the trap coil. Now, on my Monarch, the value of the doorknob happened to be 33pF (Since they seem to burn one side of the driven element at a time, I was able to chisel off the goop on the corresponding good trap on the other side of the driven element and read the value, maybe yours are different value.) Ok so here's the drill on extracting the old burned doorknob and then resealing the trap. Once you get the element on the ground I went to a machinist (who happened to be my father) and he made me a small sharp chisel shaped piece of metal. I used it and a small ball peen hammer and I CAREFULLY chiseled off that brownish colored goop used to seal the the trap. I exposed the doorknob capacitor (or what was left of it) and I also exposed the flat metal straps on each side all the way down to and including the nut and screw end of the straps.

Be very carful when chiseling around the coil not to dig the end of the chisel INTO the coil or flat

metal straps. If you do hit the coil by accident, although you won't cut through the coil you will nick it pretty good. Take a file to it later and file off any sharp edges or burrs you create. Using a small wire brush, be sure to remove ALL traces of the black burnt carbon and other debris that the burned out doorknob capacitor deposited in and around the coil.

You may need a small chisel tool to clean in between the coil windings. Since it's hard to find the exact 32.XX to 33.XX pF cap I replaced the original cap with 2 doorknob caps in series using a short piece of threaded rod to screw then together. (Changing the value of the combo of caps by just a few tenths of a pF moves the resonant point quite a bit. 0.5pF too much or too little could move you 150 kHZ if I remember right!) I found plenty 50 to 75 pf 5 kV doorknob caps on the surplus market and put 2 caps in series of various values and was able to fine tune my antenna resonance points to exactly which part of the band I wanted. (This is NOT the fun part, as I started with some series combination value around 32.5 pF using my hand held capacitance meter, then, before sealing the traps, I reinstalled the driven element and cranked the tower up and measured resonant frequency.)

Changing the value of the combo of caps by just a few tenths of a pF moves the resonant point where I wanted it. I originally tried to use a grid dip meter t0 measure the resonant freq of the good corresponding trap on the opposite side of the driven element but that didn't work out for some reason (It's been a few years since I did the repair.) For some reason and maybe because I lifted the caps off of and away from the coil, my notes indicate that I wound up using combinations of caps that yielded capacitance in the 30 to 31.5 pF range, nowhere near the original 33 pF (marked value) they replaced!!

The opposite ends of the dual doorknob caps assembly are now connected to each strap and now it is easy to position the caps at least 1/4 inch away from the coil. Once you get the antenna resonant where you want it, seal the repair by first wrapping the coil from end to end with Kapton Tape which should be available from industrial electrical supply companies. I utilized a 1/2' width tape and applied 2 layers to the coil using an overlapping wrap. Then apply Dow Corning 738 Electrical Sealant to cover all exposed areas of the coil and doorknob capacitors. 738 is UV stable and has a dielectric property of 400 to 500 Volt per 0.001 inch. That will give you plenty of arc protection now that you have the caps 1/4" off the coil! (The sealant did NOT affect the resonant point, luckily!)

Unfortunately 738 only comes in white which makes for a very ugly repair, but up at 50 ft or more, who's going to see it except the birds! It also has only a 6 month shelf life so a lot of places won't stock it and you may have to special order it. There's an industrial supply company in San Diego called Yale Enterprises (619 299-7710) that used to sell it in 3 OZ small tubes but you may have to buy the caulking gun size. I believe that one 3 OZ tube will easily have enough sealant to redo 2 traps. The small tubes used to cost @ $7 and @$20 for the caulking gun size. There's also a place in San Jose area called Anderson Supply that carries it but may make you buy the larger amount to meet minimum order. Caveat Emptor if you use any other type of sealant, make sure it's UV impervious, temperature stable and has enough electrical dielectric strength, voltage wise.

Also, a different type of sealant might shift the resonant point !!! After you repair the burned trap,

go back and chisel out the remaining good trap doorknob and replace it or I can guarantee that in the dead of winter when your tower is covered with ice, the other side WILL fail. My Telrex Monarch continues to provide good reliable service, contest after contest on 40 thru 10 meters, pumping 1.5 kW into it for 48 hrs at a time! (I just found a note showing I repaired it 8 years ago!) If this 200 lB beam wasn't such a killer antenna on 40 mtrs with 3 almost full size elements, I probably would have not gone through this much trouble to repair it. BTW, it is was originally rated for 100 MPH wind and 5 KW and cost over $2000 in 1982. So who says a trapped antenna can't compete!

73, Dennis Vernacchia N6KI / ZF2AR

AA3RL Transmission Line Calculator

Introduction:

There are a variety of programs available to the Radio Amateur that will calculate virtually every transmission line parameter that one may need. However, I have found the routines to be inconveniently scattered among many different programs. In addition, the programs usually require the data to be entered in serial form in order to obtain the calculated output. If another calculation is desired, all the data must be re-entered. As a result, I felt the need to create a spreadsheet style program where all input values are displayed and multiple "what-if" data changes may be implemented quickly with the click of the mouse.

Initially I used the spreadsheet to design Stub and Series Section Line Matches. Since then other utility functions were added that has enabled it to replace the Smith Chart, the pocket calculator, and the many computer programs for transmission line design applications. I hope you will find it equally useful.

Caution:

All formulas assume lossless transmission lines, but these results are usually within the measurement tolerance achievable by the amateur in normal situations. However, as line loss increases, i.e. with high SWR or long transmission line lengths, these approximations will diverge from the actual values. An excellent program to check the results for lossy lines is TLA, which is included with recent versions of the ARRL Antenna Book.

Format:

The spreadsheet is divided into convenient functional areas. Each area performs one of the calculations listed below. All sections share a common layout. The input data is grouped on the left side of the page, and the output data is grouped to its immediate right. Output values are shown in bold type. On the far right side of each section there are areas that are used for computational purposes, in order to break complex formulas into more manageable chunks. If these cells are disturbed or over-written the calculations may be cease to function properly. I have learned from experience to keep a backup copy of the spreadsheet for when this eventually happens.

Contents:

The program performs the following calculations:
Length Conversion: Wavelength, Degrees, Feet
Series and Parallel Equivalent values
Capacitance and Inductance required for given reactance (X)
Air Wound Coil construction
Reactance and Length of Stubs
Stub Matching - Impedance (Z) over a 180 degree cycle along a lossless transmission line.
Impedance (Z) at any single point on a lossless transmission line (for stub matching)
Series Section Line Transformer (analytic solution) for impedance matching

Length Conversion: Wavelength, Degrees, Feet

In the screen shot below, we want to make a transmission line 1/8 (0.125) wavelength long, using 50 ohm line with a velocity factor of 0.78, and operating at a frequency of 7.0 MHz. This data is entered on the left side. The output indicates that the length should be 13.7 feet, which is 45 degrees. Alternatively, the reverse calculations may be performed.

Sheet1 Sheet2 Sheet3 Sheet4 Sheet5

Capacitance and Inductance required for given reactance (X)

At any given frequency, input the desired inductive reactance (+X) or capacitive reactance (-X). The spreadsheet calculates the required inductance (uH.) or capacitance (uF and pf).

32						
33	**Capacitance and Inductance required for Reactance = X**					
34						
35	**INPUT DATA:**			**OUTPUT DATA**		
36	Freq (MHz.):	3.50				
37						
38	Reactance, Ind (+X)	800	------>	Induct (uH)	**36.38**	
39						
40	Reactance, Cap (-X	500	------>	Capac (uF)	**0.000091**	
41				Capac (pF)	**91**	
42						

Reactance and Length of Stubs

Another way to obtain a desired reactance is with the use of transmission line stubs. Input the desired inductive reactance (+X) or capacitive reactance (-X). The spreadsheet calculates the required length of stub: open for -X, shorted for +X.

Alternatively, given a stub of any length in feet which is less than ¼ wavelength, the reactance will be calculated. Results may not be accurate if the electrical length is greater than 90 degrees.

Stub Matching

Using tuning stubs to match an antenna and transmission line is quite popular and useful. While the theory of stub matching is beyond the scope of this article, the following example illustrates how it may be performed using the AA3RL TLCalc spreadsheet.

We wish to match a 50 ohm feedline to an antenna with Z = 61 + j80. These values are entered as inputs. We immediately notice that the SWR is 3.88. Next, scan the third Column of the OUTPUT DATA to find where the parallel equivalent resistance, R(p), approaches 50 ohms. We see that this occurs somewhere between 80 and 90 degrees. A good initial guess would be 85 degrees. We also note that R(p) is not changing too quickly at this point so that measuring the stub insertion point will not be overly critical.

96										

Next move to the spreadsheet section for computing the impedance at a **single point** along a transmission line. Enter the same

inputs: Z = 61 + j80, Frequency = 21 MHz., TL = 50 ohms, velocity factor 0.78. Start with the guess of 85 degree length. Adjust this value until you obtain a parallel equivalent R(p) = 50 ohms. This turns out to be 86 degrees, which at 21 MHz and vf 0.78 equals 8.73 feet. Thus the stub is inserted 8.73 feet from the antenna. The stub (or discrete component) must provide +34.44 ohms (inductive) reactance in order to cancel the - 34 ohms parallel equivalent (capacitive) reactance at the stub insertion point. This can be accomplished with a 3.74 foot shorted stub as shown above.

Series Section Line Transformer (analytic solution) for impedance matching

While the theory of Series Section Line Transformer matching is beyond the scope of this article, the solution provided is analytic and straightforward. The same example used above for stub matching illustrates how it may be performed using a SSLT. In this case we elect to use 450 ohm ladder line with a vf = 0.95 for the matching section. The output indicates that a 0.96 foot length of ladder line should be inserted 5.03 feet from the antenna.

Setting up shop

Some of the interesting shots of the W5AJ Rohn 25G tower

This installation is taking place in 2003.

And the gasoline driven digger was low cost compared to what it would have cost in time to recover.....

This is shot of project start.

Gasoline powered. Less pain then posthole diggers in WTX soil

AJ plate on Left Rohn plate is on the right

just south of the Crank up tower (see tower #1 page) Tower sections moved to location.

Hinged base. 1st ten feet in place

Concrete on base & guy posts was hand mixed 5000psi premix from hardware store. the 5000# version would setup to something like 2400psi strength in 3 days.

After getting ten feet up the section is laid over and another 20 feet added.

Setting the lower guys.

Bigger saw horse being put into place

Add another 30 feet & now 60 feet done - is ten open ?

note date on picture (I think 26th was highest SFI for the eleven year cycle)

Assembly of A4 with 40 meter kit.

that is a WTX Apple tree behind the A4

From the hinged end

20 feet of 25G on ground to right.

Note antenna assembly platform (some think this a trampoline)

Early Saturday morning SS SSB 2003

With the help of my wife the 20 foot tower for lift cable is raised

and everything is in place for a lift shortly after 8 am

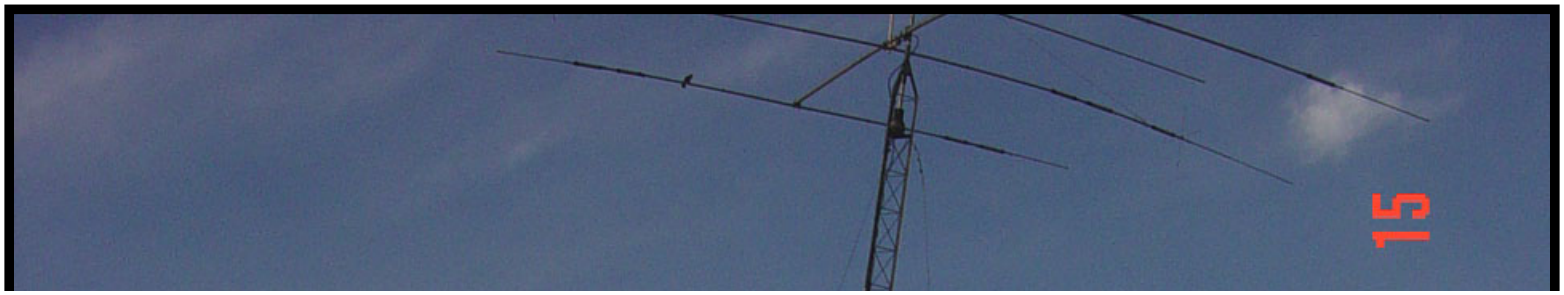
had planned this to be one person setup but had a guywire problem on the 20 foot tower.

tnx to the wife for bailing me out on that one.

there's another story there about always carrying a cell phone ....

The lift begins as the tower comes off the sawhorse

Stopped at this point to double check lift cable



Almost vertical - note bird already checking out the A4

The manual (no computer) calculations showed at this point the tower could be hand pulled

vertical

Wasn't a cake walk either

Taken just before sunrise Monday morning after SS SSB weekend

small print - this is not a design page - this shows the installation of a rohn 25G using a hinge plate similar to Rohn's. Hours of calculations were done to match conditions, tower & equipment and insure nothing was over stressed.

Work going on inside the shack building upper shelf

KO4BB's Tower Building Project

Last Updated:

NOTE: This is a description of how I built my tower. It is provided in the hope that it will be useful but without any warranty of any kind. Make sure to get the necessary permits for your area, if applicable and if you have any doubt, talk to a professional civil engineer even if not required by local regulations.

Even though a permit was not required in my county and subdivision (not required for ham towers under 75'), I thought about getting one for the piece of mind. However, in my county, the tower and antennas would have to be rated 140 mph to get a permit, something few ham radio budgets can afford, and something unnecessary in my case since the tower folds. Further, I had access to persons knowledgeable about building codes and permits and the final design takes into consideration the advice I got informally from these qualified individuals. While this is not as good as "money in the bank", or a building plan certified by a professional engineer, I felt is was sufficient for my purpose. Your mileage may vary.

If you intend on using information on these pages to build a permanent (non-folding) tower, make sure you understand the differences and protect yourself accordingly, both from safety and legal stanpoints.

Pictures: taken during construction, the finished tower and antennas.

Useful tower building resources:

- N1LO's home page contains a tremendous amount of information on tower building and anything related.
- K7NV's page on wind load calculations (this page has not proven to be reliably available, so you may want to check the links below).

Here is a link to his YagiStress software (download the demo version).

- WB6WUW's very informative page, which was featured in July 2003 QST.

This page would not be complete without the deepest thanks and appreciation for the members of the Playground Amateur Radio Club PARC, W4ZBB who came in droves to help with the tower raising party.

My Tower Project

I bought this folding Rohn 25 tower used from a local ham who had it attached to the side of his house. For extra safety (we are on the Florida coast, and we do have hurricanes and strong winds), he also had installed guy wires.

The guy wires were going from just below the hinge to the top of 7' high, 3" diameter schedule 40 steel pipes instead of directly to the ground because there was not much room where his tower was located and the guy wires would have been too steep to be effective.

I thought this would be a neat idea to reduce the risk of someone (like a kid) running into the guy wires. With the normal mounting scheme, guy wires leave the ground around 45 degree angle and that means that shrubs or a fence have to be installed to prevent accidents, and I certainly did not want to loose that much real estate. I also wanted to put the tower as close to the fence as possible. With the guy posts, I loose much less real estate and the guy wires take off from the tower closer to horizontal by about 15 degrees, so they should do a good job. The guy posts are at about 25 feet from the base of the tower.

So I did the same thing, except that in my case, the tower is detached from the house and squarely in the middle of my backyard.

To stiffen the guy posts, another EHS guy cable runs from the top of the guy post to a J bolt about 1.5' from the base of the post. This does little for ultimate strength but does stiffen the pipes and reduces flexing in the wind.

The pipes are also filled with concrete all the way to the top to make sure they do not collapse under extreme stress. The concrete makes them stronger and prevents moisture and water from getting inside the pipe and causing corrosion. The concrete also dampens the tubes, so they don't sing like a bell when something hits them.

Because it is a folding tower (it folds approximately in the middle, a design no longer offered by Rohn unfortunately), there are 4 guy wires instead of the usual 3 so that the fulcrum that allows to fold and raise up the tower has clearance.

Note: I read that Rohn stopped making the folding type tower because hams were overloading them and having problems. The tower is certainly very vulnerable when it is being cranked up and down, particularly when it is at a 90 degree angle. I wanted to take it down during moderate winds at one time, and the effect of the wind on the structure when the tower is folded is significant. You do not want to leave it like that very long. However, when the tower is straight up and properly rigged, it is as strong as a normal Rohn 25 tower.

The guy posts are actually 12' long 3" diameter schedule 40 steel pipes (structural grade, not just "pipe") with 5' in the ground, in concrete. The guy post holes are therefore 5'6" deep, and 1.5' x 2.5' and filled with 3000 lbs rated strength, fiberglass reinforced concrete. The post base also holds the J bolt for the post guy. Place a brick at the bottom of the hole so the post is at least 3" off the dirt. I poured concrete up to about 3" under the ground surface, so that if and when I move out of the house, I just have to cut the pipes flush with the concrete and cover the hole with dirt and grass.

The tower concrete base also is filled with 3000 lbs rated, fiberglass reinforced concrete. I selected the fiberglass reinforcement because the tower base is bolted down in the concrete using 4 J bolts, instead of just burying a tower element as I have seen it done often. The fiberglass gives the concrete an extra measure of strength around the J bolts and only adds about $5.00 per cubic yard to the cost of the concrete. In total, I used 5 cubic yards of concrete, in addition to what I used to fill the posts (I used regular Quickrette for that). 5 yards was the minimum quantity for which there was no delivery charge from all the vendors in the area.

Please note that fiberglass reinforcement does not allow to get rid of the rebar cage unfortunately.

To make sure the concrete hardens and does not just dry, keep it covered from the sun and keep it moist. I used an old piece of carpet laid over the concrete pad, and covered with a large piece of cardboard. I waited until the next day in the morning, when the concrete surface was already somewhat hard. Then twice a day I would hose the carpet and cover it with the cardboard so it did not dry too quickly. I took carpet and cardboard off after about 4 days of that regiment. The concrete looks pretty hard to me. I pounded on it with a hammer and could not chip it.

I let the concrete cure for two weeks before putting up the tower. The concrete was plenty hard enough by then and we had absolutely no problem, even though it was

interesting when two of us were hooked up to the tower at about 20' up in the air before we had the guy wires attached (please note we had rope guys for safety while we were doing that, but these don't do much to stabilize the tower to the point I felt I needed for peace of mind.)

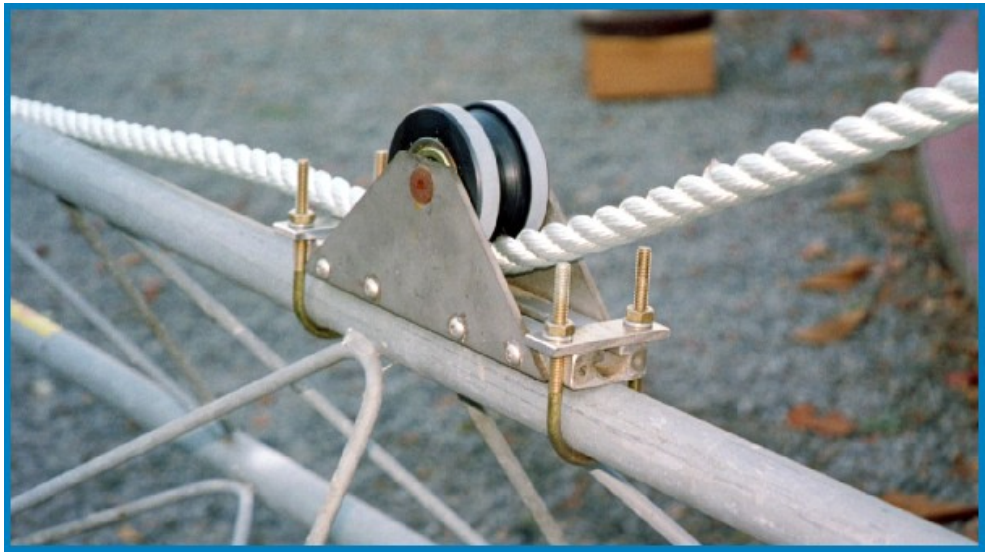
You need a level, elevated, surface to assemble this antenna. This is how I did mine.

I used a Carpenters bubble level with a riser block on each side to verify that all elements were in plane. (Level not shown)



I made this pulley to support the mid section
while raising the assembly.

The top of the tower is fitted with this larger pulley.

You can see how this works. There is a double pulley (2 grooves side by side) on the roof.

The other end of the ropes is attached to the Blazer. The rope is a loop as you can see by the previous photo.

We used an extension ladder at the right height to support the tower and keep the antenna off the ground. The ladder is lashed to the tower and follows the tower as it is raised to this point.

Art, K6XT does all the finishing touches to the assembly, here he is RTVing the Balun to weather proof it.

We are read to raise the Tower assembly, we think!

The Assembly is about 45 degrees up at this point.

The Assembly is almost vertical now. Damon is getting ready to nest the tower into a roof eave bracket we made to hold it in place.

First contact 3D2CY Conway Reef!

Coming soon, an interactive calculator to determine the force required to upright your tower and antenna. I'm looking for assistance to do this.

This is intended as a guide only, The Web Master (N9XT) is not responsible for accidents that may occur through miscalculations, faulty gear or poor procedures.

This is it, The vintage is mid 70's Drake and Alpha. Some day we may upgrade to the state of the art stuff. But you know what, they answer every time I call so what's the point? N9XT

MARC SOFTWARE

Champion Radio Products is the exclusive dealer for MARC - the Mast, Antenna and Rotator Calculator. It will automatically calculate the mast bending moment of any antenna system. Put in the wind speed, select the antenna info from the antenna table, add the spacing -- MARC does the rest. It'll give you the mast bending moment and tell you what yield strength and wall thickness of mast is required. It'll even recommend suitable rotators for the installation. For PC. Requires DOS 2.0 or above or Windows and comes on 1.4 Mb diskette. **Only $10.00**

SPECIAL ANTENNAS

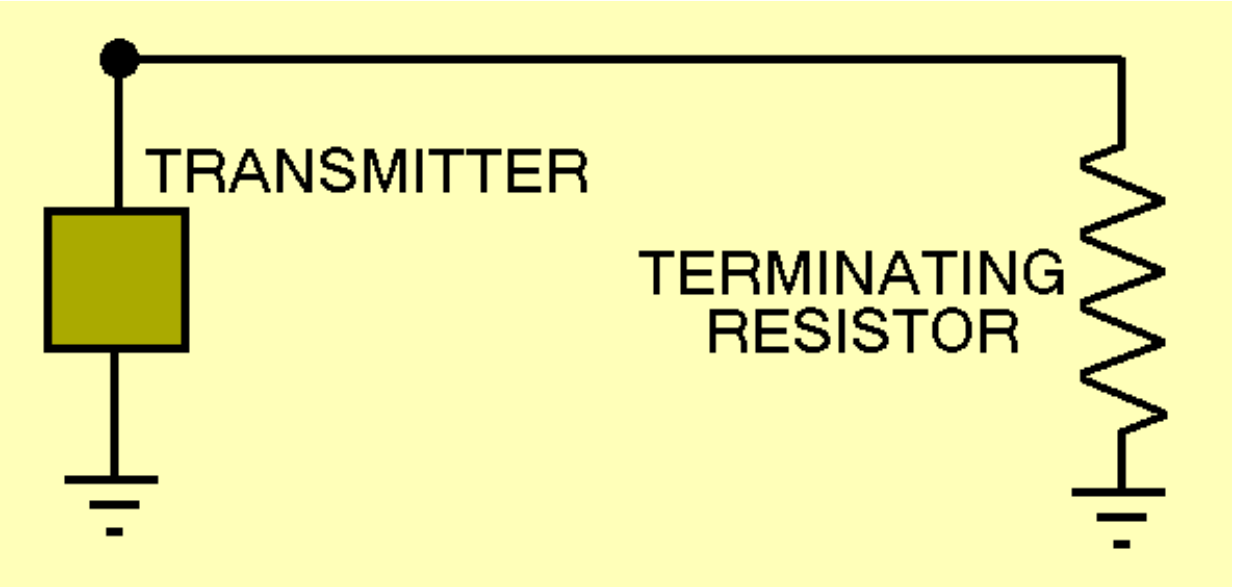
In this section we will cover some special communications and radar antennas. Some of these antennas we touch on briefly since they are covered thoroughly in other courses.

Previously discussed antennas operate with standing waves of current and voltage along the wires. This section deals principally with antenna systems in which the current is practically uniform in all parts of the antenna. In its basic form, such an antenna consists of a single wire grounded at the far end through a resistor. The resistor has a value equal to the characteristic impedance of the antenna. This termination, just as in the case of an ordinary transmission line, eliminates standing waves. The current, therefore, decreases uniformly along the wire as the terminated end is approached. This decrease is caused by the loss of energy through radiation. The energy remaining at the end of the antenna is dissipated in the terminating resistor. For such an antenna to be a good radiator, its length must be fairly long. Also, the wire must not be too close to the ground. The return path through the ground will cause cancellation of the radiation. If the wire is sufficiently long, it will be practically nonresonant over a wide range of operating frequencies.

LONG-WIRE ANTENNA

A LONG-WIRE ANTENNA is an antenna that is a wavelength or longer at the operating frequency. In general, the gain achieved with long-wire antennas is not as great as the gain obtained from the multielement arrays studied in the previous section. But the long-wire antenna has advantages of its own. The construction of long-wire antennas is simple, both electrically and mechanically, with no particularly critical dimensions or adjustments. The long-wire antenna will work well and give satisfactory gain and directivity over a frequency range up to twice the value for which it was cut. In addition, it will accept power and radiate it efficiently on any frequency for which its overall length is not less than approximately 1/2 wavelength. Another factor is that long-wire antennas have directional patterns that are sharp in both the horizontal and vertical planes. Also, they tend to concentrate the radiation at the low vertical angles. Another type of long-wire antenna is the BEVERAGE ANTENNA, also called a WAVE ANTENNA. It is a horizontal, long-wire antenna designed especially for the reception and transmission of low-frequency, vertically polarized ground waves. It consists of a single wire, two or more wavelengths long, supported 3 to 6 meters above the ground, and terminated in its characteristic impedance, as shown in figure 4-34.

Figure 4-34. - Beverage antenna.



Q.44 To radiate power efficiently, a long-wire antenna must have what minimum overall length? **Answer**

Q.45 What is another name for the Beverage antenna? **Answer**

V ANTENNA

A V ANTENNA is a bidirectional antenna used widely in military and commercial communications. It consists of two conductors arranged to form a V. Each conductor is fed with currents of opposite polarity.

The V is formed at such an angle that the main lobes reinforce along the line bisecting the V and make a very effective directional antenna (see figure 4-35). Connecting the two-wire feed line to the apex of the V and exciting the two sides of the V 180 degrees out of phase cause the lobes to add along the line of the bisector and to cancel in other directions, as shown in figure 4-36. The lobes are designated 1, 2, 3, and 4 on leg AA', and 5, 6, 7, and 8 on leg BB'. When the proper angle between AA' and BB' is chosen, lobes 1 and 4 have the same direction and combine with lobes 7 and 6, respectively. This combination of two major lobes from each leg results in the formation of two stronger lobes, which lie along an imaginary line bisecting the enclosed angle. Lobes 2, 3, 5, and 8 tend to cancel each other, as do the smaller lobes, which are approximately at right angles to the wire legs of the V. The resultant waveform pattern is shown at the right of the V antenna in figure 4-36.

Figure 4-35. - Basic V antenna.

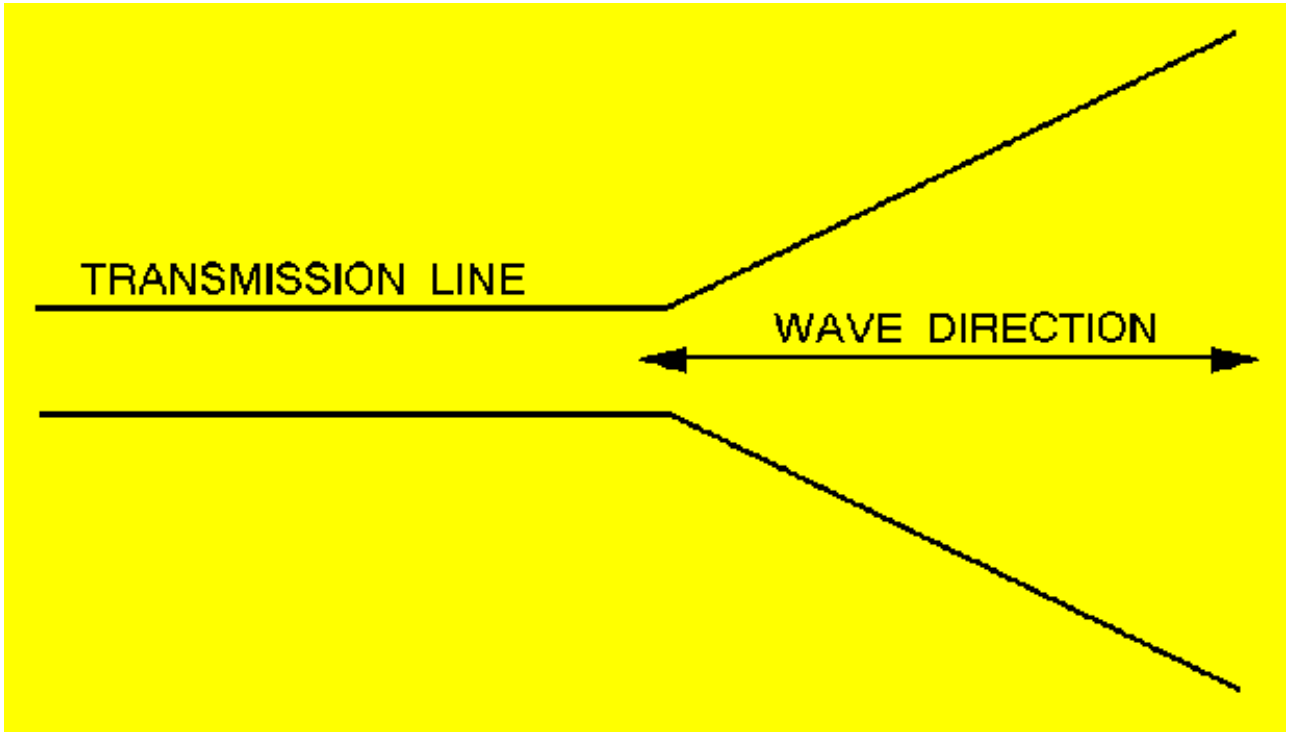


Figure 4-36. - Formation of directional radiation pattern from a resonant V antenna.

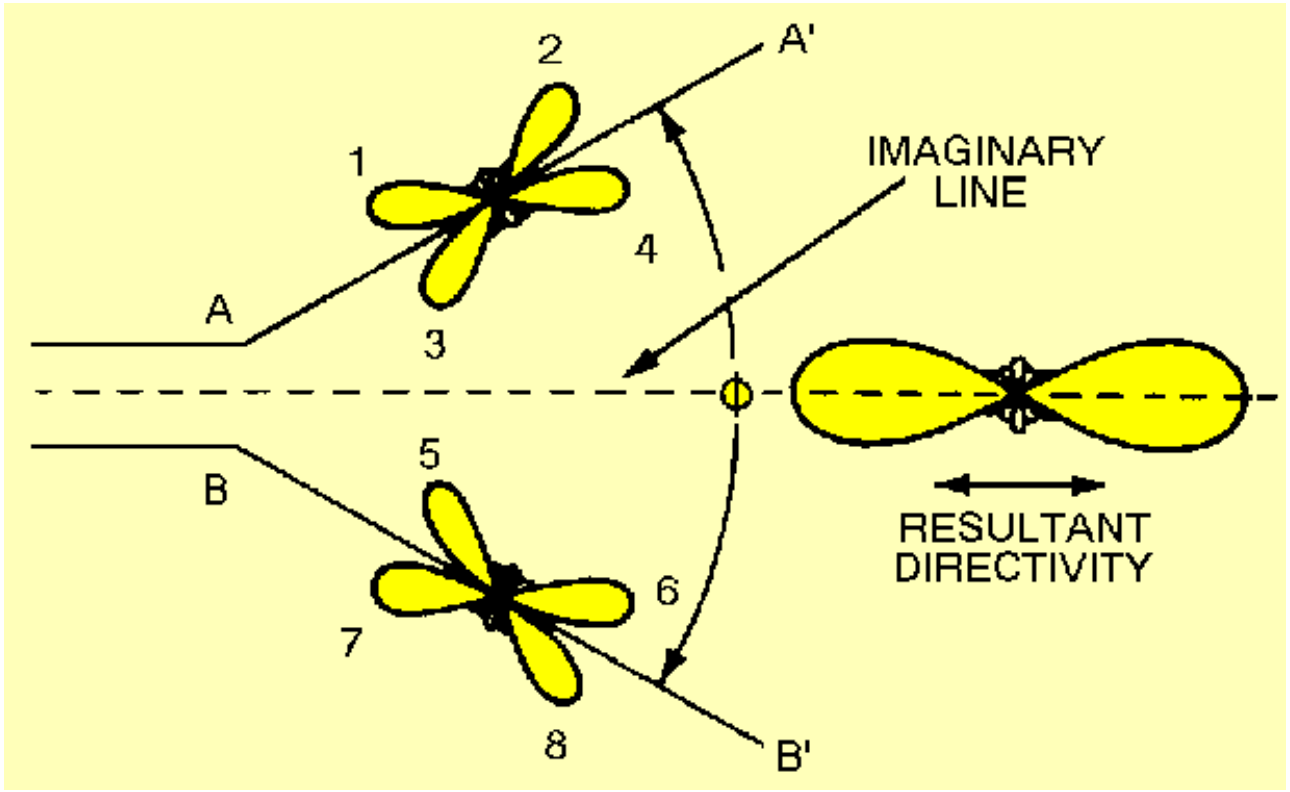

Q.46 What is the polarity of the currents that feed the V antenna? Answer

The RXO Unitenna

by R. D. BROWN G3RXO
email: standardtrees@btconnect.com

WHILST touring New Zealand some years ago, I needed a portable all band HF antenna and conceived the following design concept which produced surprisingly good results. Back in the UK, I did have time to construct and test it and it worked surprisingly well. It is extremely cheap, extremely light, and works continuously over an extremely broad bandwidth. It is non-resonant, vertically polarised and out-performs a ground plane throughout a 3:1 frequency range. Accepting a loss of some 3 dB from a ground plane, its useable frequency range is some 5:1. It has very low angles of radiation throughout the range, requires no radials, and is not susceptible to static.

My thinking was along the following lines:

(1) Consider a vertical dipole, it's current distribution and resultant polar diagram.

(2) Consider it as a folded dipole.

(3) Consider it's current distribution and polar diagram if it is fed off centre. The dissimilar currents in the two elements of the dipole are within one evanescent induction field and therefore cumulative as to radiation which can give rise to an overall current distribution and polar diagram which changes very little with change of frequency.

(4) By feeding at approximately one third of the way along the dipole the current distribution and polar diagram vary approximately from that of a vertical dipole to that of a vertical quarter wave over a frequency range of some 3:1; for example from 7 MHz through to 21 MHz.

(5) Above the antenna's maximum useable frequency the polar diagram becomes split and of high angle.

(6) As the applied frequency is reduced below its normal range the polar diagram remains much as for a vertical quarter wave, but with diminishing efficiency, although still useful over a frequency range of some 5:1.

(7) Since the antenna is a closed loop it is less susceptible to static.

(8) It requires no radials and therefore incurs no ground losses.

(9) It is fed with a tuned line which should be as perpendicular to the antenna as possible.

(10) Variation of the feed point to about 25 per cent from the antenna's end results in slightly better current distribution, but reduced bandwidth. The optimum point is around 30–35 per cent from the end.

(11) It is cheap to produce, lightweight, portable, unobtrusive and has virtually no power limits.

The original antenna was made of regular single core conductor taped down each side of lengths of plastic waste pipe and guyed with bricklayer's line. For example; practical dimensions are a 9.2 m dipole, fed 3 m from base and about 1 m above ground; coverage 7 MHz to 21 MHz continuously with full efficiency. Pro-rata for other frequency ranges.

I found the antenna to be surprisingly quiet with respect to background noise and very effective at low angles and long range. I hope that others will give this design a try and would be most interested to learn of their results with it. βi

TRANSPORTABLE VERTICAL ANTENNA

This vertical was built for me by Luis, CT1BYR, a skilled ham and homebrew fan - everything from smd component level to large antenna array construction.

The vertical's slim silhouette stands almost 10 metres high.

After numerous conversations with Luis regarding transportable antennas he came up with this solution for me to take on my trips to the Azores. Knowing that I often use an automatic SGC-230 antenna coupler and so tuning would not be a problem, he suggested combining this with a random length vertical. Operating away from home is also about having redundancy plans - this antenna can also be used if the SG-230 is unavailable as a standard quarter wave vertical, on most of the HF bands, simply by altering its length.

The antenna stands over 9 metres high when fully erected and has four levels of guying cables to withstand the harsh weather associated with this part of the world. Built from stainless steel, instead of aluminium, this provides added weather resistance and durability. As does its slim silhouette for minimum wind resistance. Thin walled stainless steel piping was easier to find at our local hardware store and although slightly heavier than aluminium this was not a problem as it is still easily carried by one person. The base is made from a nylon block with a deep circular recess to accommodate the bottom section and isolate it from ground. A couple of bolts are also screwed to this same block to attach the antenna's RF ground wires - the more the better.

To allow transportable operation and easy set-up, Luis used a telescopic solution for the

CT1BYR preparing to raise the vertical.

vertical element. Five 2 metre pipes all slotting inside each other reminds us of a car radio antenna on a larger scale. Each of the lower four section ends have a guying clamp to affix three guy ropes and when tightened, give the vertical rigidity and prevent the slimmer elements from slipping back inside the larger ones. This gives us a total of twelve guy wires which may be reduced for calm weather operating. In fact, the bottom level of three guy ropes are practically only used to facilitate raising the remaining upper sections by a single person. It saves him having to hold the bottom section vertically steady while telescoping out and tightening the remaining four sections.

Details of the telescopic antenna sections with guying clamps.

Lowering the antenna is just as easy as raising. For storage or travel, the vertical element, ground wires and guy cables fit inside a 2 metre long cardboard or plastic tube making it easily transportable and an ideal antenna for emergency, field-day or dxpedition use.

These are DOS-executable self-contained programs each occupying a single binary file. No use is made of external software. This ensures portability between DOS/Windows machines.

There is a brief one-line description following each program's name.

Approximate file sizes are from 25 to 70 kilobytes. Download, or run without downloading, in a few seconds. Just click on a program's underlined name.

Download from here to a Windows Desktop icon or collect programs in a common Windows folder of your own chosen name. There's no un-zipping inconvenience. Programs can be run immediately after download.

To run a program click on its desktop icon. If the program does not entirely fill the screen then look along the top tool bar and click on the button which expands the display outwards.

The mouse is not available when the program is running full screen. Close the program from within by hitting either the 'E(xit)' or 'Q(uit)' key when displayed in the menu on bottom line 25. You will be immediately returned to the desktop.

If the program aborts into DOS due to entry of 'impossible' data, to return to Windows Desktop type the DOS command 'EXIT' against the C>prompt followed by the enter/return key. Or to run the program again type the program's name alongside the C>prompt. No harm will have been done to your computer, operating system or to the program itself.

Remember, when in DOS, the DOS 'EXIT' command, followed by the 'Enter' or 'Return' key, will always return you to the Windows DeskTop. No need to get lost!

RJELOOP1 *
Performance of Transceiving, single-turn, magloop antennas of various regular shapes.

RJELOOP2 *

Performance of Transceiving, single-turn, magloop antennas of rectangular shape.

RJELOOP3 *
Analysis of receiving, multi-turn, square, loop (or frame) antennas, ELF to HF.

HELICAL3 *
Continuously-loaded, helically-wound HF antennas, top-capacitance loaded with a rod.

TOROID *
Ferrite & iron-dust cored, toroidal coils. Dimensions, Core permeability, Turns, uH, pF, Freq.

VERTLOAD *
Base-fed vertical antennas, coil-loaded at any height, with coil design.

RADIOETH *
DC, power freq & RF characteristics of a single shallow-buried ground wire.

EARTHRES *
Ground electrodes. Resistance msmnts and predictions, rods, wires, plates, mats,

TANT136 *
LW & MW performance of small T-antennas above a system of buried ground radials.

ENDFEED *
HF performance of Inverted-L antennas above a system of buried ground radials.

LINEAR1 *
Models simple Class-AB, Push-pull, Bipolar Linear RF power amplifiers up to 30 MHz.

BALUN4 *
Design and performance of HF transmission line ferrite-core transformers, Z-ratio 4-to-1.

RJELINE1 *
Performance of openwire lines, Power freqs up to UHF, for any complex termination.

RJELINE2 *
Full analysis of balanced-twin lines, 20Hz-1GHz, for any complex termination.

COAXPAIR *
Full analysis of coaxial lines, Power freqs to UHF, for any complex termination.

RJELINE3 *
Full analysis of balanced lines with facilities for HF line xfmr design.

TRAPDIP *
Design and performance of 2-band trapped dipole antennas including trap design.

PHASENET *
Design of T & Pi phase-shifting networks for use with antenna arrays.

TPINET *
Design of T & Pi impedance-matching and phase-shifting networks.

SWR-FREQ *
Compare simple & folded dipoles. Input Z. Feedline VSWR vs freq. Bandwidth.

SOILSKIN *
Enter soil R and K characteristics. Display a table of skin depth vs frequency.

COAXRATE *
Power ratings of solid polythene coax cables vs dimensions and SWR. 0.3 to 3000 MHz.

ZL_ZIN *
Compute antenna feedpoint impedance from measured line input impedance, known Zo & length.

SOLNOID3 *
Single-layer, air-core coils of all proportions. Dimensions. Turns. Temp rise vs applied volts.

MAGLOOP4 *
Performance of regular-shaped magloop antennas versus height and type of ground.

PADMATCH *
T, Pi and L resistive matching-pad design using standard-range resistor values.

MIDLOAD *
Design of very short, centre-loaded dipoles above lossy ground. With coil design.

LCR *
Full analysis versus frequency of behaviour of an L+C+R parallel-tuned circuit.

SWRMETER *
Modelling, design, calibration & operation of HF SWR meters using a ferrite current xfmr.

LOADCOIL *
Design of short vertical antenna + loading coil. Slide coil up/down to maximise effncy.

PI_TANK *
Design Pi-match output cct for RF power amp. Effncy, harmonic suppression, phase shift.

ZOC_ZSC *
Calculate Trans-line Zo,L,C,R,G,dB,VF from open and closed input impedance measurements.

Pi_L_Net *
Design Pi and Pi-L output networks for RF Power amps. Effncy, harmonics, phase delay.

TETRODE1 *
Design of Class A, AB1, AB2 and C RF Power Amplifiers, using beam tetrodes or pentodes.

TOPHAT2 *
Short vertical antenna with Top-capacity-hat made with N radial wires. L-tuner values.

RJELINE4 *
Analysis of balanced-pair transmission lines. Line xfmrs with complex terminations.

T_TUNER *
Design & power efficiency, etc., of T-match tuning networks for transmitting antennas.

GRNDWAV3 *
Groundwave propagation. Field strength vs pathlength, terrain and frequency, VLF to HF.

DIFFRAC1 *
Radio propagation. Diffraction over a single obstruction. Tx output to Rx input.

DIFFRAC2 *
Radio propagation. Diffraction over two successive obstructions. Tx output to Rx input.

LINOSITE *
Simple Line-of-sight radio links. Approximate aperture, beamwidth, propagation loss etc.

MATCHSEC *
Impedance matching by inserting in antenna feedline a short section of different Zo.

BOTLOAD2 *
Inductance and bottom-loading coil design, or tune pF, for vertical or sloping antennas.

L_TUNER *
Calculate coil & capacitor values of an L-Network to match any pair of complex impedances.

WIRESKIN *
Skin resistance vs frequency of a single wire, an open-wire line and a dipole.

SELECT_1 *

Simple receiver preselector is a tapped parallel tuned circuit. Also coil design.

TWOCOILS *
Design & position two common-axis solenoids for desired coupling and mutual inductance.

DIPOLE3 *
A dipole at any height + balanced line + balun + coax line + L-match tuner L & C values.

DIPCAGE2 *
Cage dipole of N wires, resonant length, bandwidth vs SWR, end-effect, feedpoint impedance.

ADDALOAD *
Location and value of L or C loading component needed to resonate an antenna wire.

TRIODE1 *
Triode RF power amplifiers. Class-A, AB, C. Tuned tank or Pi-match output cct component values.

MULTILAY *
Design of multilayer coils wound in bobbins or other formers. 3 MHz and below.

WINDOM2 *
Performance of 1/2-wave horizontal dipole fed off-centre via vertical single-wire feedline.

FEEDPOWR *
Crude estimate of power radiated from coaxial line feeding 1/2-wave dipole without a balun.

COAXTRAP *
Design of antenna trap using length of coaxial line wound as solenoid on a coil former.

TWINTRAP *
Design of an antenna trap using length of twin-line wound on coil former. (Experimental)

OSCTRACK *
Superhet receivers. Optimum tracking of RF and oscillator tuned circuits. L & C values.

STUMATCH *
Match antenna input impedance to feedline with stub line xfmr. Balanced or coaxial lines.

STUBTUNE *
Match antenna input impedance to twin feeder with stub line xfmr. Includes xfmr efficiency.

LPF_HPF *
Simple L and C High and Low-pass filters. T and Pi Sections. Insertion loss vs freq.

BANDPAS1 *
Simple L and C bandpass filters. T and Pi Sections. Insertion loss vs freq.

INV_VEE *
Performance of resonant 1/2-wave Inverted-Vee and Dipole antennas including feedlines.

RHO_SWR *
Exact values of Rho and SWR on mismatched lines. Compare with measured values.

WHIP_1 *
Signal strength received on whip antenna + un-un transformer + coax line + receiver.

TWOHOPS *
Skywave Trigonometry and insight into how losses are proportioned along a radio path.

HARM_GEN *
Simple single-transistor harmonic generator. Performance and behaviour vs frequency.

R_X_SWR *
Feedpoint Impedance and SWR of an antenna in the vicinity of resonance.

CHOKEBAL *
Design and performance of a choke balun in conjunction with feedline and antenna.

BALCHOKE *
Better, recommended, version of program ChokeBal above. Changes in input data.

XTL_SET *
Design, performance, of crystal set, or preselector, using two coupled tuned circuits. From Tx to phones.

RADIALS2 *
Performance of a set of shallow-buried ground radials considered as transmission lines.

Short Vertical Antennas and Ground Systems - VK1BRH

* *Copyright (c) Ralph Holland 1995, Copyright (c) Amateur Radio 1995.*

Introduction

There have been a number of articles discussing the merits or otherwise of various types of ground systems. The analysis of such systems is complicated by the facts that practical ground system parameters are difficult to quantify, antennas are situated in less than ideal locations, and literature, that may provide insight into what is happening, often does not present the information in a practical or applicable form. Often the reader is left to extrapolate beyond the bounds of presented data and arrive at the incorrect conclusion. Some folk-lore has been generated as a result of these types of difficulty; one such lore is 'the higher the better', which is an over-generalisation if said without qualification.

Activities

I am interested in 160m operation; it is a challenge to develop reasonably efficient antennas for this*'top band'.* I am also interested in mobile and portable work so I constructed antennas and experimented a bit. It was difficult to quantify the results and performing alterations was rather tedious, so I turned to computer simulation.

After performing several different simulations I developed the feeling that it should be possible to optimise the efficiency of an antenna by altering its earth currents and through the interactions with the mutual impedance of the antenna and its ground image. This turned out to be a very fruitful study, although I initially thought the results were dubious!

Simulations

Fortunately non-ideal antennas have been under analysis by various organisations and many papers have been written covering the theoretical aspects. One organisation of note is the Lawrence Livermore National Laboratory (LLNL), which was commissioned by the U.S. Department of Defence to perform theoretical and practical analysis of various antenna systems. Some of this material has been declassified and is now publicly available.

During this period several computer-based antenna simulation programs were developed; of note is the Numeric Electromagnetic Code (MINI-NEC, NEC-2 and NEC-3 and now NEC-4).

NEC-81 is the name of the earlier PC version of NEC-2. NEC-81, NEC-2 and MINI-NEC are available through the Applied Computation Electromagnetic Society (ACES); contact Dr R.W. Adler, ECE Department, Code EC/AB, Naval Post Graduate School, 833 Dyer Rd, Rm. 437, Monterey California, 93943-5121, U.S.A or Fax 1 408 649 0300 or E-mail 554-1304@mcimail.com, for the conditions, membership and handling fees if you want to obtain these programs.

Post publication note: public domain software now available at Unofficial NEC2 pages.

NEC-2 can model antennas in proximity to lossy ground. The lossy ground analysis is based on work by Sommerfeld; and appears to yield realistic feed-point impedances and reasonably quantifiable losses.

System Performance

The simulation goal was to determine the relative merits of elevated groundplanes for short vertical systems, ie up to 0.25 wavelengths.

Traditionally, it has been convenient to measure the feed-point impedance of the lossy antenna system and compare it with the ideal (theoretical) case. The feedpoint resistance for vertical antennas is called the base resistance (Rb); Rb is composed of the useful radiation resistance (Rr) and the collective loss resistance (Rl). Rr can be evaluated theoretically, it would be the Rb of an antenna over ideal infinite ground.

Rr can be obtained by the additional simulation of the ideal ground model, effectively doubling the simulation time to obtain results. Fortunately, NEC-2 calculates the amount of power radiated around the region of the antenna and divides this by the applied power. This ratio depends upon whether the model is simulated in free space or over ground.

The radiation region of an antenna in free-space is a solid sphere so this ratio should be unity. The radiation region is a hemi-sphere when the antenna is situated against an infinite ground, in which case the value should be close to two; this is due to the ground reflecting power into the upper hemisphere (effectively up to 3dB of gain). This ratio is a also used to gauge the stability of the model; if its value greatly exceeds the expected value then the model has failed.

Post publication note: an antenna may exhibit up to 6dB of gain over its free-space radiation pattern due to ground refelection in some directions.

It is a simple means to use this power ratio to determine the antenna's efficiency. Note that the radiation resistance can be dervied via: Rr = Rb / efficiency; I used this analysis to cross-check the results of some simulations.

Results

The term displacement is employed for the height of the groundplane above ground; this avoids confusion with antenna element lengths. All lengths, heights and displacements are measured in wavelengths (lamda) unless otherwise indicated.

Resistance versus Groundplane Displacement

Figure 1 shows the effects of various displacements upon a 0.10 wavelength vertical antenna with three 0.10 wavelength radials at 1.825MHz. I chose the average ground parameters: relative dielectric constant 13 and conductivity of 5 milli-Siemens per meter (13,5); which are typical for dry clay and indicative of the Canberra region.

Note that the Rb is high at zero displacement, much higher than Rr, so Rb is largely composed of loss resistance at this point, and the antenna is primarily heating the ground! Notice how difficult it is to determine the optimal displacement from the Rb and Rr curves on this graph.

Efficiency versus Displacement

Figure 2 shows the antenna's efficiency over the same range. Notice that there is an initial peak at fairly low displacements. Advantage will be taken of this effect.

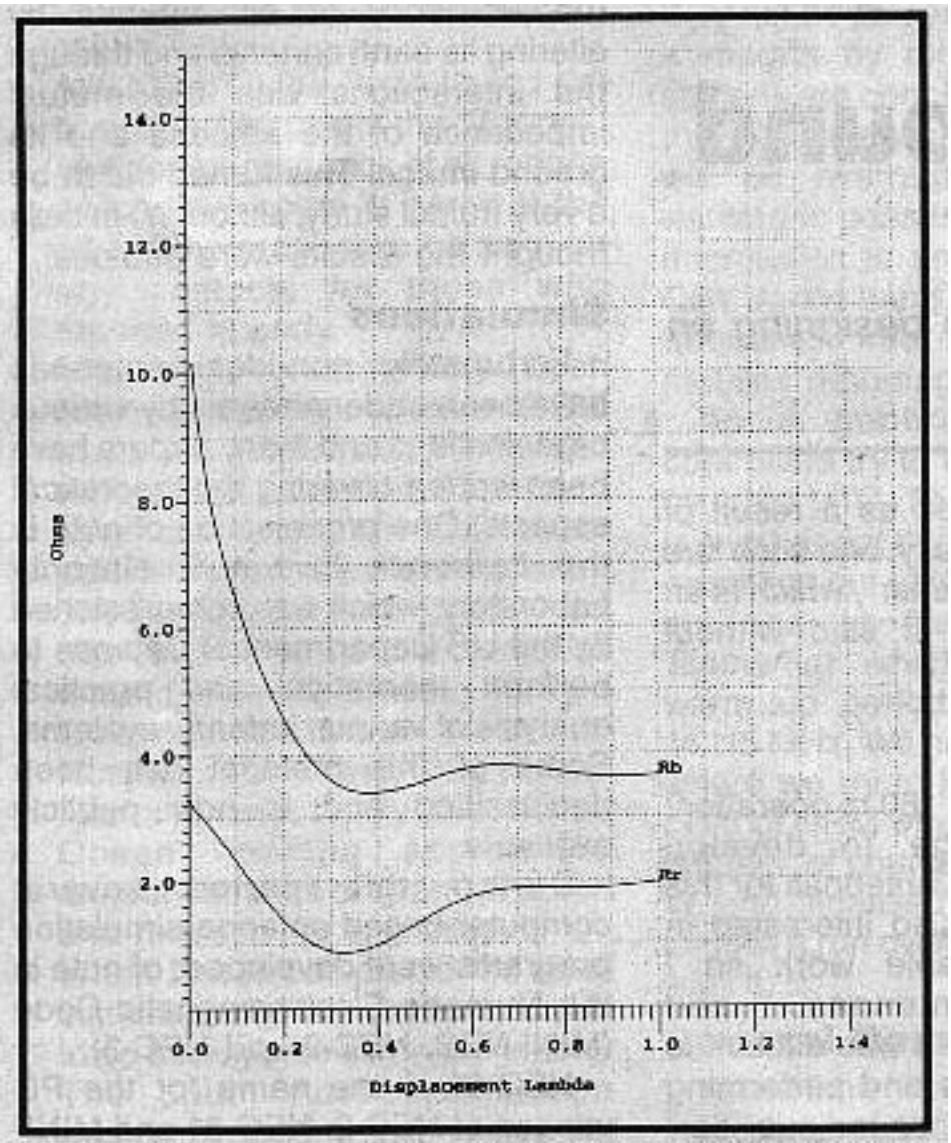

Fig 1 — 0.10 wave radiator/radials ` 3 @ 1.825 MHz (13,5).

Fig 1 - Resistance vs Displacement

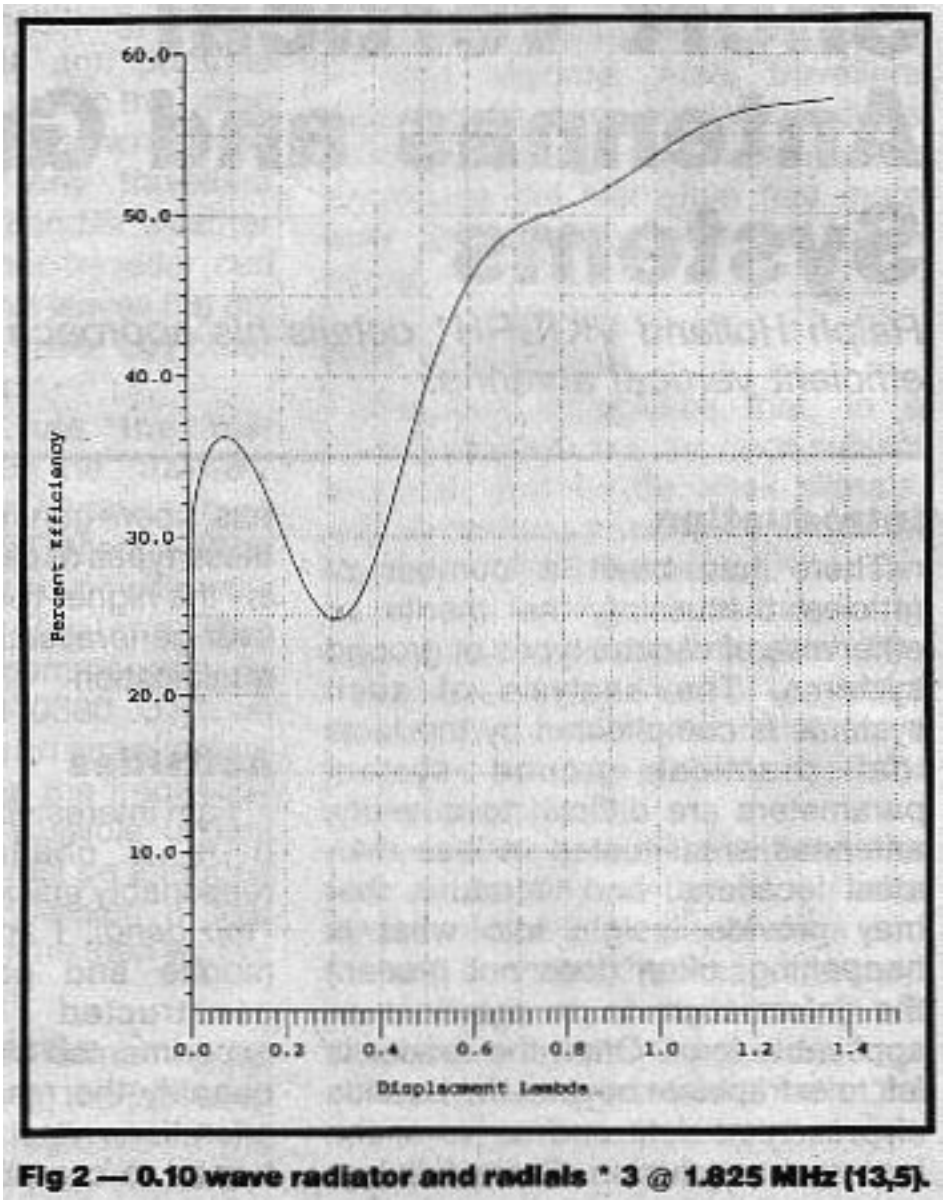

Fig 2 - efficiency versus displacement

Displaced Antennas versus the Number of Radials

Figure 3 is the comparison between the conventional groundplane, situated on or in the ground, and the elevated groundplane. The simulation parameters are 1.825Mhz, 0.25 wave radiator and radials, and ground parameters (13,5). The integer simulation points are joined to form curves (I did not actually simulate a non-integral number of radials).

Notice that the elevated curves are asymptotic to a horizontal line about 37 percent efficiency. The elevated curves are more than satisfactory at the three to four radial mark; the traditional ground screen doesn't even get near this at 32 radials. Recall that the typically quoted commercial design figure is to strive for 120 ground-based radials.

Variable Radiator, Radial Length and Displacement versus Number

of Radials

Figure 4 illustrates the effect of radiator and radial lengths. The simulation is at 1.82MHz and for ground parameters (13,5). The top curves represent the elevated groundplane, while the bottom curves are for ground-based antennas.

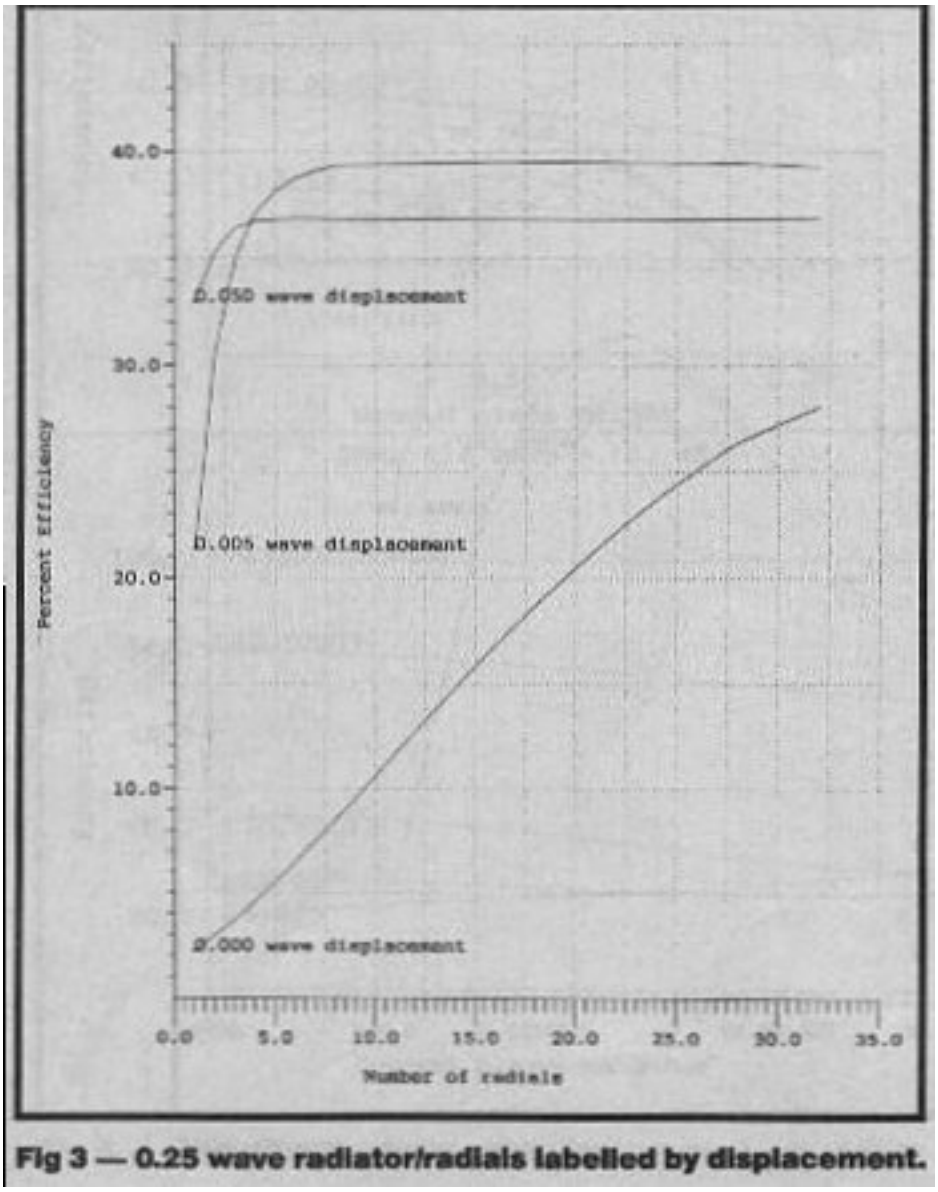

Fig 3 — 0.25 wave radiator/radials labelled by displacement.

Fig 3 - Comparison between tradition and elevated elevated groundplane

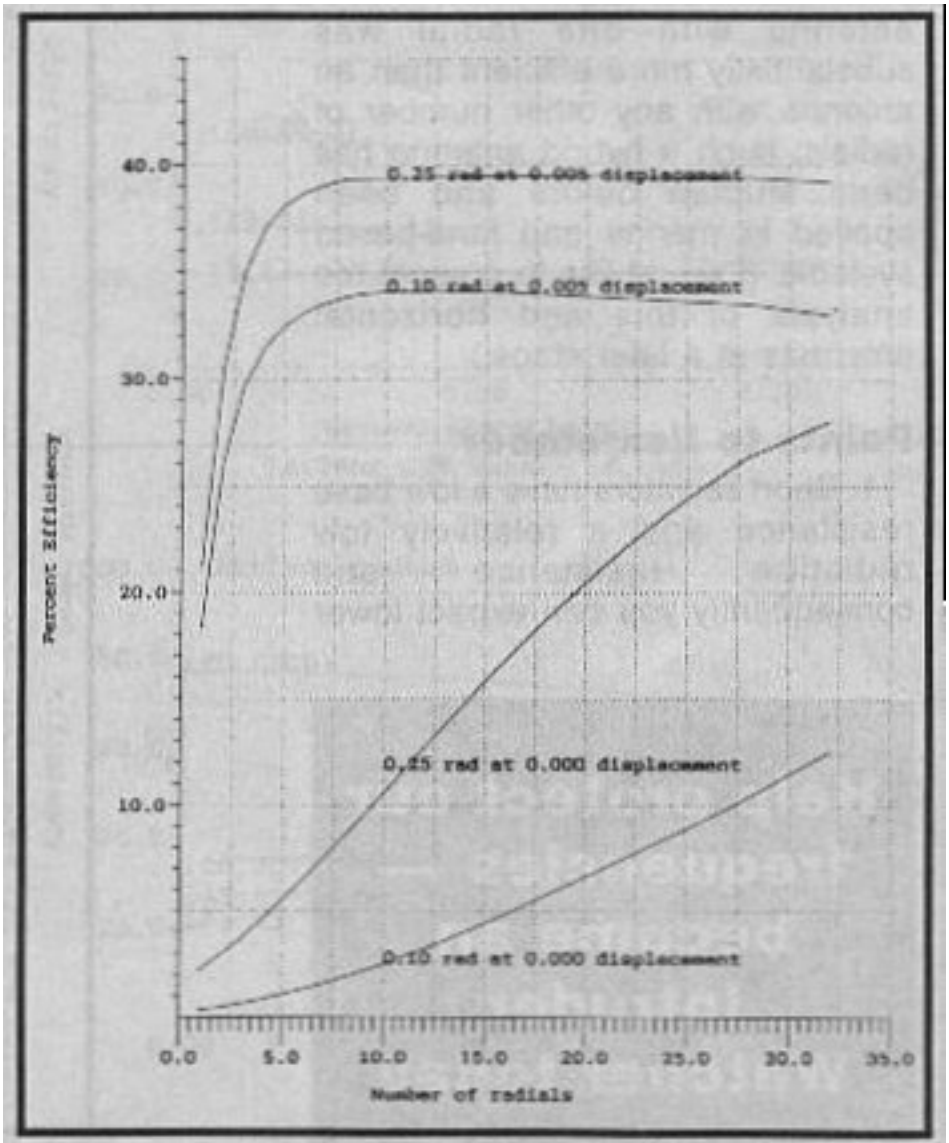

Fig 4 — Radiator/radial length and displacement.

Fig 4 - Efficiency versus number of radials at various heights and lengths

Variable Radiator and Radial Length at a constant Displacement

Figure 5 is the graph for a 1.825Mhz vertical, which was simulated for Eric, VK3AX. This simulation was based on 3 radials mounted at 20' (woolshed height) over typical clay soil (13,5). We were interested in the affect of the antenna height and radial length. The radiator length was labelled on the graph in wavelengths and feet. You will notice that short radiators performed quite well with radial lengths of 0.15 wavelengths and appear worthwhile constructing. When the radiators are lengthened from 0.06 wavelengths to 0.15 wavelengths, the efficiency improves by 5 percent; not much gain results from extending radiators up to the full 0.25 wavelength, in fact, this length was noticeably less efficient than the 0.148 wavelength radiator. In all curves there is an optimal radiator and radial length. Notice how the optimal radial lengths are noticeably less than a quarter wave for the shorter radiators.

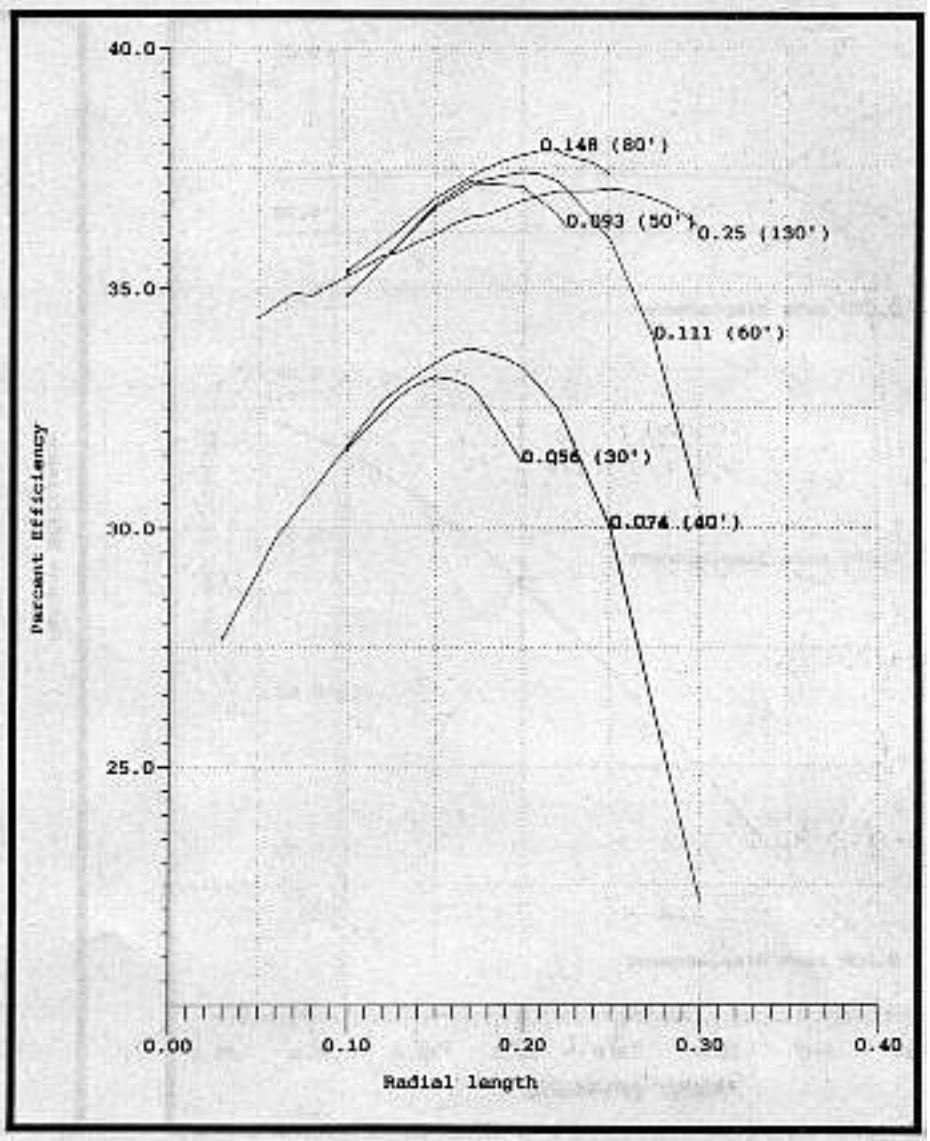

Fig 5 — Fixed displacement at 1.825 MHz 20' (13,5).

Fig 5 - 1.8 MHz antenna with 3 radials at 20'

Efficiency of Elevated Groundplane and Frequency

Figure 6 shows the effects of changing frequency. The analysis has been performed for the 160m, 80m, 40m and 20m bands so you can apply these results to your favourite band. All radiator and radial lengths were 0.25 wavelength, in all cases only three radials were employed.

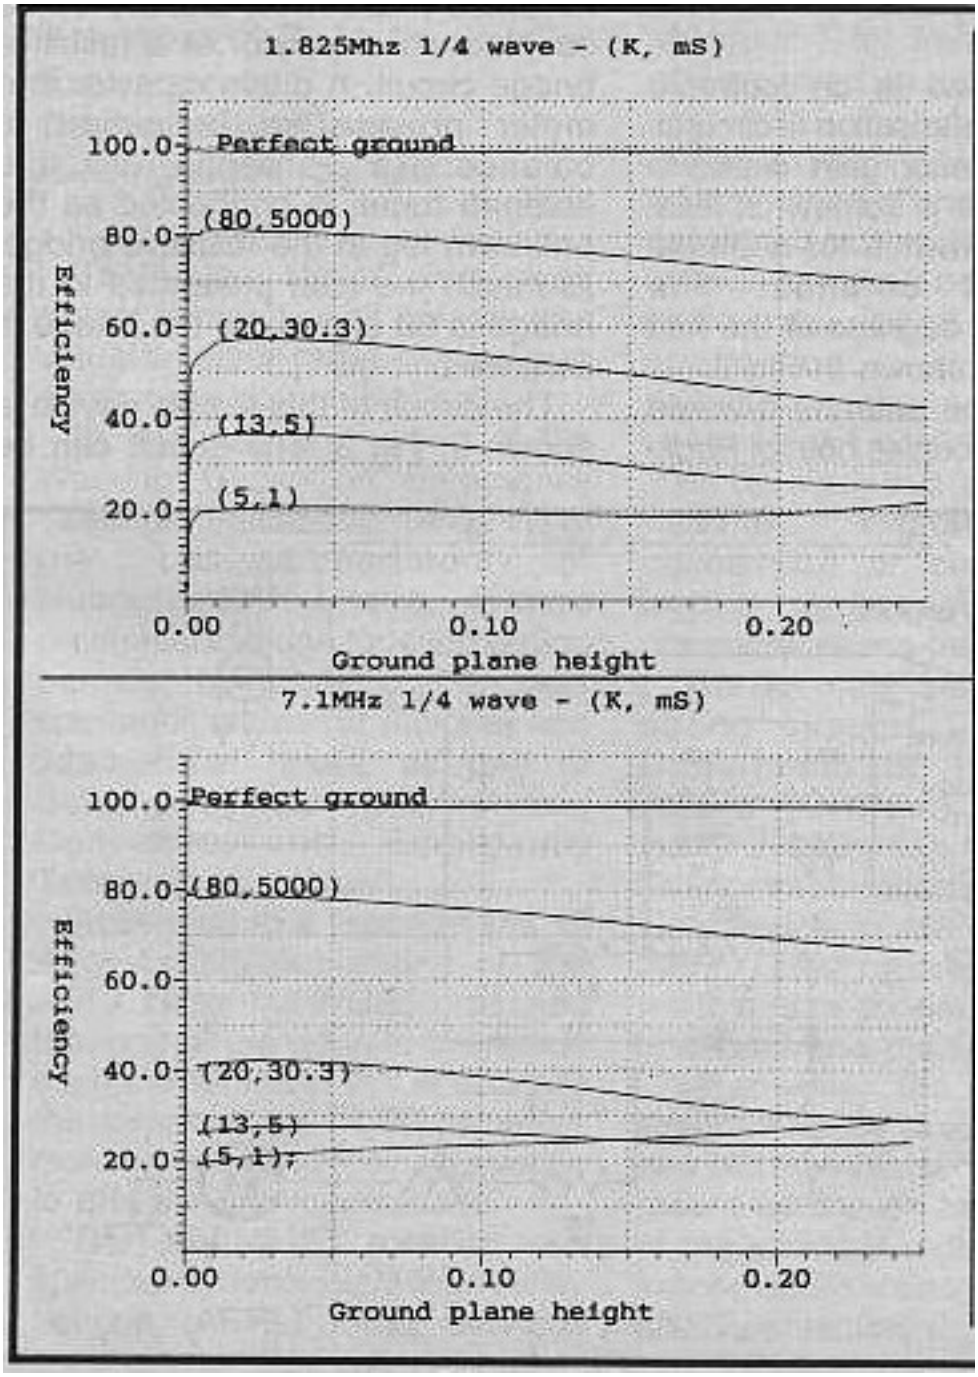

Fig 6A - The effects of changing frequency.

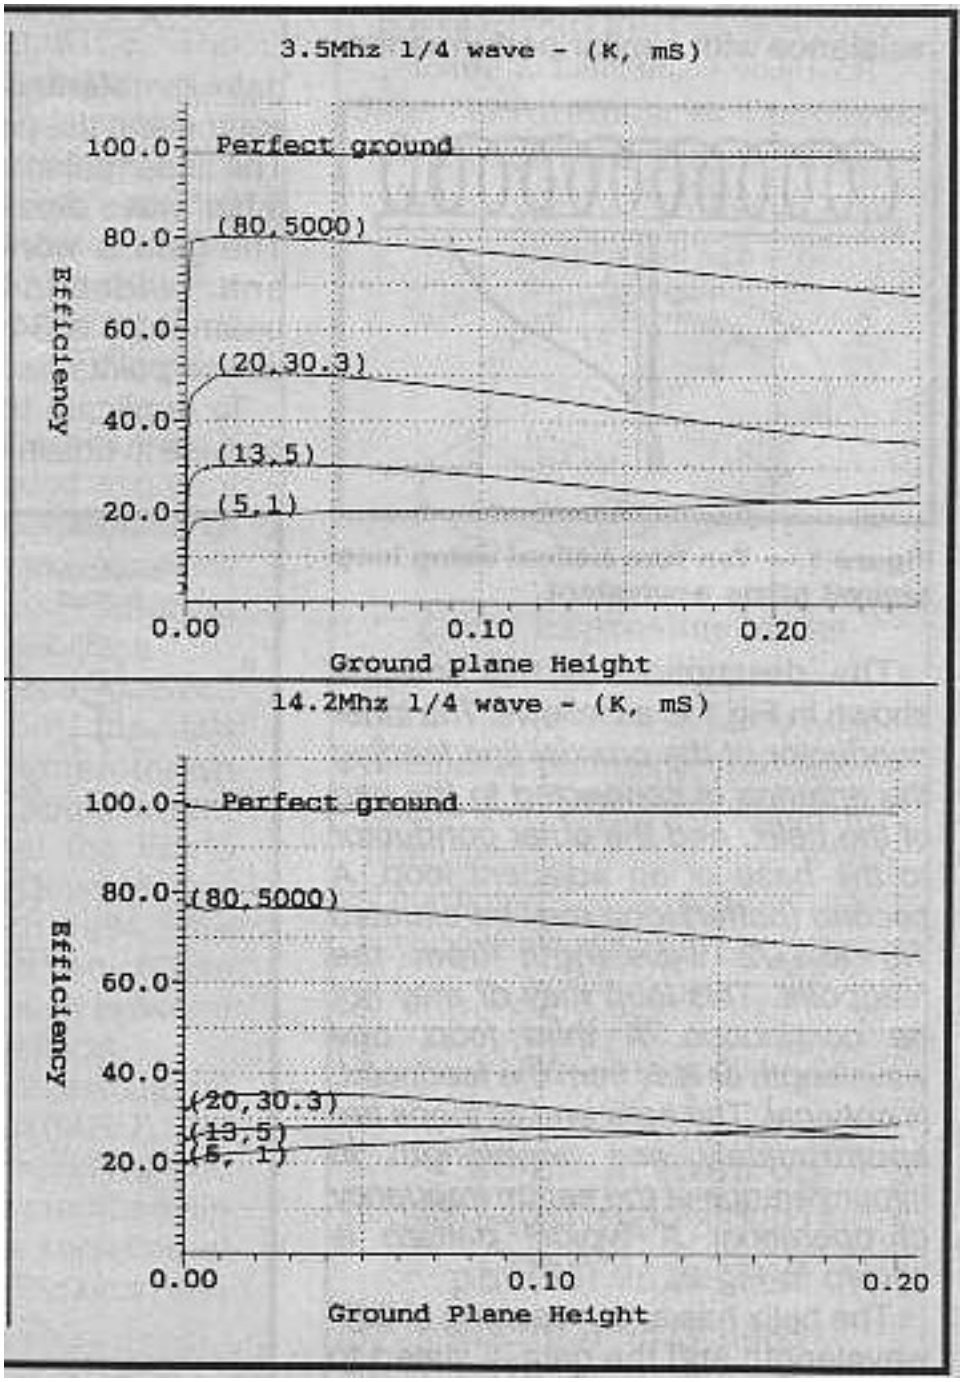

Fig 6B - The effects of changing frequency.

Each curve is labelled by its ground parameters. The curves could be named from top-to-bottom as: Perfect, Sea water, Good, Average, and Poor respectively. Recall that the Average curve, labelled (13,5) is indicative of the dry clay soils.

Notice that the curves peak between 0.002 and 0.05 wavelengths displacement. A more difficult observation, due to the scale of the graphs, is that the curves point steeply towards zero efficiency at zero height (you can obtain a better indication from Figure 2).

Conclusions

From the Figures it is obvious that the simulated antenna efficiency declines dramatically when the groundplane displacement approaches zero.

With three or more radials the radial length is more important to the overall efficiency than the number or radials, with a few exceptions. An interesting side-effect I noticed is that under certain conditions a vertical antenna with one radial was substantially more efficient than an antenna with any other number of radials; such an hybrid antenna has been studied before and been applied in marine and land-based systems. (I would like to present the analysis of this and horizontal antennas at a later stage.)

Points to remember:

1. Short radiators have a low base resistance and a relatively low radiation resistance and consequently you can expect lower efficiency. However, short radiators can still be quite efficient; the shorter radiators require shorter groundplanes and are more optimum at lower groundplane displacements - don't write-off a short radiator! Do take into account the lower feedpoint resistance and consequential difficulties with feeder and element losses, some form of atu at the base is the best. Also note that a short radiator has a very high base impedance, caused by its capacitive reactance, and that the rf voltages at the base are very high!
2. There is an optimal height for an elevated groundplane, that height is not at ground zero, and is typically around 0.05 wavelength. (The statement the higher-the-better is not always true for such systems.) Do not place your ground system on or in the ground unless you have space, time and materials for about 120 radials, unless you are fortunate to have excellent ground, or the desire to hide your ground system. (You may be able to see from Figure 4 that there is a lot to be gained from watering an inadequate ground system - so don't write-off that folk lore!)
3. The efficiency curves are forgiving and somewhat broad; displacements as little as 0.005 wavelengths can be tolerated; some curves actually peak around 0.01 wavelengths.
4. Large numbers of radials are not required for elevated groundplane systems. Three or four radials are sufficient, doubling the number does not double the efficiency.
5. The elevated groundplane system is more efficient at lower frequencies.
6. A lot can be gained by placing your antenna near swamps, lakes and in close proximity to the sea; you should expect substantial improvement, often more than 3db in these cases.

7. Lastly, these results are only as good as the simulation program. However, this program is good at modelling linear antennas close to lossy ground. NEC-2 has been validated numerous times; even so care must be taken because inappropriate use has caused the model to fail.

I have also performed simulations for elevated groundplanes with an underlying secondary ground screen placed on the ground. It is detrimental to connect the elevated groundplane to this form of lower ground system. Note the recommended commercial practice to terminate radial systems with a ground stake - I would highly recommend against such practice; the situation is made even worse if the ground stake is under the feedpoint rather than at the ends of the screen.

I originally thought that this grounding anomaly was an artefact of NEC-2, but I have subsequently read the preliminary publication ***'Recent Advances to NEC: Applications and Validation'*** >by G. J. Burke, 1989, which investigated these effects and others; he used the new improved and classified NEC-4 to model situations for several typical broadcast antennas and antennas below the ground. Burke found, to my surprise, and others, that the recommended grounding practices are detrimental. Burke's findings were based on the relative communication efficiency (RCE) of the antenna measured in terms of field strength at some distance outside the near field, a more appropriate value, rather than the efficiency figure I employed.

Bibliography

The MINI-NEC and NEC programs are based on the Method-of-Moments (MoM); you can find a description of this method in ***" Antennas, Second Edition"***, by John D. Kraus, McGraw Hill 1988.

Another book, which describes the foundation of the technique, is *" **Field Computation by Moment Methods"***, by R.F.Harrington, McGraw Hill 1961. Post publication note: This classic has been reprinted by the IEEE and is available at a discont if you are a member.

The hybrid vertical - horizontal marine dipole, developed by VK3AM, is described in "***Hf Antennas for All Locations***", by L.A. Moxon, G6XN, on page 154.

The *"**ARRL Antenna Compendium***", Volumes One and Two, (now Three, Four and Five) are also interesting reading for antenna construction and modelling.

The book review *"**Computational Electromagnetics: Frequency Domain Method of***

Moments" by Edmund K. Miller, Louis Medgyesi-Mitschang, and Edward H. Newman was extracted and printed in an ACES newsletter. The extract stated that the review contains 528 pages and recommends several books.

One book of recent publication is: "***Generalised Moment Methods in Electromagnetics***", by J.H. Wang, John Wiley and Sons, NY, 1991. I believe this would be for the serious MoM enthusiast.

Ray Jurgens

(Up-Dated 2/25/2000)

Quickie Vertical (October 1998)

Hear I am sitting in front of the rig listening to everyone working CQ World Wide, and I don't really have time for this, but I hear a few interesting stations on 20 meters and try to call them. Trying to bust the pile up with 100 watts and my hustler dipole is going to be difficult on this band, so I tune up on 15 meters and there is action, and I have a good wire beam, so I tune up and down the band and can't find a clear frequency. Then I hear some one say that 10 meters is open. So I tune up there, and there is a world of DX coming in. I choose a few interesting ones to call, but can't be heard. I should have expected that, as my antenna for this band leaves much to be desired. It is a vertical above my Hustler dipole, but it has no effective ground plane and SWR no better than 3:1 at its best frequency. With no time to assemble a Quad, I start thinking about a better vertical. Suppose I take the parts for the quad and make a good ground plane and put the mobile whip above it. That won't take long. So I quickly assemble a short 4' mast with a center hub and add four 8' long 1/2" diameter fiber glass spreaders and set in on my test stand in the center of the back yard. I dig into my portable antenna box and find an extra mirror mount (Radio Shack variety) and mount it at the top of the mast. Oh, the bolts are too short for the 1" mast, so I am off to the hardware for 2" bolts. I remembered that I had cut eight #16 solid copper wires for a ground mounted vertical about a year ago, so I unroll 4 of them and attache them to the lower bolts on the mirror mount and tape the other ends to the tips of the spreaders. I then tighten the wires by dropping the hub 30" below the mirror mount which pulls the spreaders into the horizontal position and allows the radials to drop at about 17 degrees. Quickly, I mount the Hustler 10-meter whip, connect the coax, and check the SWR. The SWR is great, 1.1:1, but at 29.6 MHz. So I add two more inches to the stinger and recheck. That gave 28.6 MHz for best SWR which is now 1.2:1. Not bad, a total of a half hour has passed, and the same stations are still holding the frequencies. So I start down the list that didn't answer earlier. To my amazement I work each one within a minute. So there I sat wishing I had time to work the contest.

To complete the story, the radials are 101" inches long. The spreaders were at an elevation of 4 feet above the ground. Later, I raised this to a height of 8 feet, and nothing much changed. I also tried resonators for 12, 15, 17, 20, 30, 40 and 75 meters with equally good impedance matches, but I didn't raise them up. The table below gives the measured SWR and bandwidth for each band. A photo of this antenna is shown below the table. As I really didn't design this antenna, we have to call this one just plane luck. By the way, if you want more radials, it is possible to use two hubs with one rotated 45 degrees to the other. Add four more spreaders to get 8 radials. This might reduce the stinger lengths a little, as mine are fully extended on a few of the bands. The 20 meter Ham Stick wasn't long enough to get down into the CW portion of the band, so I added four alligator clips to the tip of the stinger. This worked about the same as the Hustler, So here is an antenna that can be set up in as little as 15 minutes once you have the parts together. If you paint all the parts black, it is nearly invisible at night and not objectionable by day. Note that this antenna works fairly well on 75 meters, but does not work well on 30 and 40 meters. I'll tell you why some time later after I figure it out.

Band (meters)	**SWR**	2.0:1 **SWR Bandwidth**	**Stinger Length (inches)**
10	1.20:1	1.53 MHz	7 1/4"
12	1.05:1	1.00 MHz	11 3/8"
15	1.00:1	1.44 MHz	9"
17	1.00:1	0.52 MHz	20 5/8"
20	1.25:1	293 KHz	15 3/4"
30	5.00:1	--	15 1/4"
40	2.60:1	--	26 1/4"
75	1.00:1	33 KHz	28"

Table 1

SWR, Bandwidth, and Stinger Length for Quickie Vertical, Using Hustler Whips as a Function of Band

Note, the bandwidth is the SWR bandwidth for 2.0:1, and the stinger length is measured from the top of the compression nut. All configurations use the Hustler MO-3 mast part, and all resonators are the low power versions. It is interesting to note the excellent match on 75 meters. Normally, this whip gives a much lower impedance when set on a good ground plane, so this probably means that at least half of the power is going into the ground, even more is lost in the loading coil, but it still works pretty well.

Quickie Vertical Antenna

Fiberglass spreaders stretch out the ground radials. Central hub is PVC. A Radio Shack Mirror Mount supports
a 10 meter Hustler Whip all of which is supported by a Radio Shack tripod mount for testing.

Item Quantity Description

Item	Quantity	Description
1.	1	8' 1" OD fiberglass tube for mast (MGS)
2.	4	8' 1/2" OD fiberglass tube for spreaders (MGS)
3.	1	Hustler MO-3 Mast section and resonator for desired band (HRO) (AES) etc., Ham Sticks also work.
4.	1	Antenna Mirror Mount, (Radio Shack) (HRO) (AES) etc.
5.	4	2" by 1/4" bolts (to replace those in item 4. (Hardware)
6.	1	Versi-Hub (RFJ)
6.	4	1/2" Hose Clamps (Hardware)
7,	4	Terminal Lugs with holes large enough to pass the 1/4" bolts
8.	34'	#16 AWG solid copper wire (Hardware, Electrical)

Genealogy of "Karlquist" family

The name "Karlquist" is not very common.
From time to time, I receive inquiries from others with the same name wondering if we are related.
The suffix "quist" means "branch" or "twig" in Swedish.
Unlike "Karlquist", most names ending in "quist" start with the name of a tree
E.g., "Alderquist" (Alder), "Lindquist" (Linden)
I have listed some genealogical info in case you are named Karlquist and are curious.
I know I have some distant cousins in Sweden who go by the name "Carlqvist."

10 Meter Vertical Dipole

I was in need of an antenna for my 10 meter beacon, so I decided to build a design I remembered seeing in an issue of QST several years ago. A friend of mine built one at the time and it worked great. It is a simple rigid dipole made from two lengths of 1/2" electrical conduit that are separated by a 5/8" wooden dowel that is inserted into the ends of the conduit and held together with hose clamps. It is necessary to cut two 2" or so long slits in the end of the conduit that the dowel rod is inserted into. This allows the hose clamps to compress the conduit onto the dowel rod to hold it all together. The dowel rod I used is four feet long, so I had about 2 feet in each leg of the dipole for rigid support.

The dipole can be fed directly with coax, or a balun can be used. It can also be fed with twinlead or ladder line. It is important to seal the insulating dowel with epoxy to keep it from rotting. I used the hose clamps to attach the coax to the antenna.

Caps should be placed on each end of the antenna to keep out moisture. I found that the threaded 1/2" PVC caps work well on 1/2" conduit. They can be just placed on the ends but I fixed them on with epoxy. Make sure that this is done after shortening the antenna for best VSWR match.

The length for each leg of the dipole is found using the formula L=234/F, where L=length in inches and F=frequency antenna is to be used on. If the antenna is too short, it can be lengthened by increasing the space between them on the insulator

and lengthening each side of the coax or ladder line feed on the dowel.

This antenna must be mounted so that it is insulated from ground. Mine is mounted on a 4X4 and attached to a 2X4 that is buried two feet into the ground. I used U bolts to secure the antenna to the 2X4. This antenna could also be mounted horizontally off the side of a tower.

This antenna could also be built for the 12 meter band, and possibly even for the 15 meter band. However, most conduit you find in hardware stores is sold in 10-foot lengths, and a 15 meter antenna will need to be around 11 feet long. Some method If lengthening the antenna will be needed. It could be done by attaching another foot of conduit to each end by using connector pieces for conduit.

No. 26: When Should I Use a Vertical on 10?

L. B. Cebik, W4RNL

Most of the antenna we have discussed in this column have been horizontally polarized. There are some good reasons for this fact. First, 10-meter horizontal antennas are fairly compact, with a half wavelength being about 16-17' long. Second, the shortness of a wavelength on 10 meters (35') generally simplifies the process of supporting a horizontal 10-meter antenna at a good height (at least 1/2 wavelength, with over 1 wavelength preferred for best performance). Third, even 3-element 10-meter Yagis are fairly light-weight, for easy support, even in field or hilltop operations.

Nevertheless, there are some good reasons for using a vertically polarized antenna on 10. Although the gain of such antennas may not usually compete with a well-installed horizontal antenna of the same size, this factor is rarely a problem when the band is open. So let's look at the question of when to use a vertical.

1. **Mobile in Motion**: The standard these days for mobile-in-motion operation is the short, center-loaded, magnetic mount vertical set on the car roof. Although the least efficient of almost any antenna used on 10, these antennas acquit themselves well. Full size 1/4 wavelength whips have gone out of vogue, especially with the increased use of plastics in autos. When auto bodies themselves become universally plastic or fiberglass, we may have to rethink the center-loaded mag-mount vertical for mobile operation.

2. **Lunch-Time Operation**: With small rigs, short antennas, and an open band around noon, 10-meter lunchers are more numerous than we imagine. Since the lunch hour (or half-hour) is all too brief, operators want a system that wastes no time in set-up and take-down. The vertical--again, usually a mag-mount antenna in the parking lot--fills the bill.

3. **Local Convention**: In some towns and cities, most of the locals may use vertical antennas. Sometimes, this represents a lot of mobile work; sometimes it represents former citizen's band operators who have joined the amateur ranks and cut down their old antennas to resonate on the higher frequencies. Since local work is mostly point-to-point, as in VHF operation, cross- polarized antennas result in major losses in signal strength. So if the local group is mostly vertical, then it will pay you to have a vertical at home

(as well as on the car) to join the fun full strength.

Since the path through the ionosphere generally skews signal polarization, distant stations will not suffer from being cross polarized relative to your antenna.

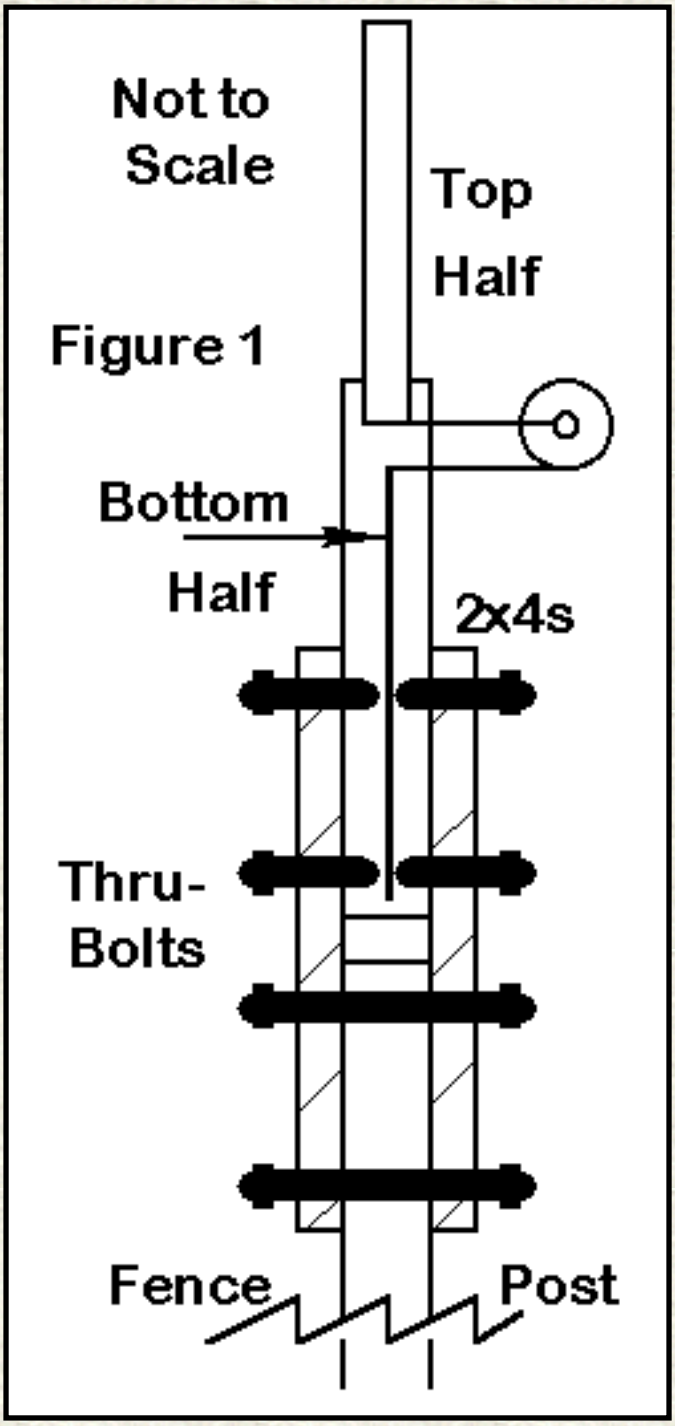
4. **Lack of Space**: Many hams live in homes without large yard. So space for antennas must compete for space with play equipment, patio furniture, and flower gardens. A vertical may be the only antenna type the home owner can erect.

The question here is not whether to use a vertical, but what kind of vertical to use. There are a number of multi-band verticals now on the market that will open many of the ham bands. They come in two major types.

If the roof top is the mounting area of choice, then one of the 1/4 wavelength trap verticals may be best. The heaviest part of the antenna is mounted near the roof top or chimney mounting system for maximum support. The necessary radials, installed according to the antenna makers instructions, can run along the roof top. If the antenna is at the end of the house, radials in the open direction can be run to trees or fence post, well out of reach of children or adults.

Where space is too restricted for an elevated radial system, one of the half-wavelength verticals may be more fitting. Some demand an elevated mounting point and may rest well on top of a fence post, short flag pole, or even a mast attached to a deck post. Other models call for ground mounting and can be placed in the most clear usable place in the yard with buried coax.

In all such installations, safety to children, family members, visitors, and neighbors is a top requirement. These antennas are rarely large enough to cause damage to neighboring property if they fall. Of course, they should be well clear of any utility lines crossing the yard. Finally, they should be isolated so that no one can get an RF burn by touching the antenna while in use. For some models, we achieve this last safety measure by elevating the antenna above reach, even by fence-climbers. Ground-mounted models require some extra thought. Setting up a flower bed and small fence around the antenna can keep most folks away. Sheathing the lower portion of the antenna in large-diameter black plastic down-spout drainage pipe for about 8' up is quite effective in preventing children from touching the antenna and has been found not to adversely affect performance. The protective sheathe can be attractively painted (with non-metallic paint) to call attention away from the antenna. Whatever the safety measures we take, we should also insure that they meet FCC requirements regarding RF exposure to other people.



Even hams with room for a host of horizontally polarized antennas may wish to consider installing one of these multiband verticals. They make good (even if not great) low-band antennas, provide back-up service in case the main beams collapse in high winds or ice, and allow the operator to match the polarization of locals using mobile whips or other vertical antennas. so even if you can afford the highest, the biggest, and the best, one of these simpler antennas makes good sense as part of the antenna farm.

5. **Home Brewers**: Some of us like to build antennas. Some of us have to build antennas to save the cost of commercial versions. Whatever the reason, a vertical dipole for mounting at least 20 to 25 feet up at the center on a non-conducting mast is a good starter project. I suggest a vertical dipole, since it saves a lot of grief over where to run the radials for a quarter- wavelength ground-plane model. The vertical dipole also takes less space than a horizontal dipole and requires no turning for maximum signal.

You can construct a vertical dipole from hardware store materials: aluminum rod or tubing (a little over 8'), PVC, and wood are the main ingredients. **Figure 1** shows in bare outline a vertical dipole I once used to capture Worked All Continents in about an hour at the height of a long-ago sunspot cycle. The 4x4 fencepost was the main support, with underground bracing from bagged concrete. The side rail 10' 2x4s supported a good quality 2x4 mast, with the 4" side running between the rails. Two long galvanized bolts braced the mast. Removing the lower bolt permitted tilt-over operation.

The antenna itself began with an 8' length of aluminum tubing for the top extension. The lower part of the antenna consisted of insulated #12 house wire, purposely cut long. I tuned the antenna to frequency by trimming the lower wire for minimum SWR. Many local hams seemed initially horrified by the idea of a dipole made from unequal diameter elements and trimming only one end. They thought that terrible things would happen to performance, since the antenna was obviously as unbalanced as its builder.

Actually, virtually nothing happens except for a bit of building and adjusting convenience. Half-wavelength antennas lose nothing in performance by being fed slightly (or even radically) off-center. The feedpoint impedance does not begin to change noticeably until the feedpoint is well off center. The only

precaution was for safety: the dipole end is a high-voltage point on the antenna, so it had to be inaccessible to human touch when in operation.

There you have it: some good reasons for using vertical antennas on 10 meters, whether they are commercial multi-band antennas or home brew specials. There are other reasons of a specialized nature that we could add. For example, if you live by the seaside, expect an exceptional increase in performance over the same antenna placed on a rocky hillside in the Smoky Mountains. Verticals have proven to be more than good enough in some island contesting locations. Some operators even prefer the wider beamwidth of a vertically oriented Yagi to one that is horizontal. Whatever the reasons, vertical have and will always have an important place in 10-meter operation, even if we never mention FM and repeaters at all (which I just did).

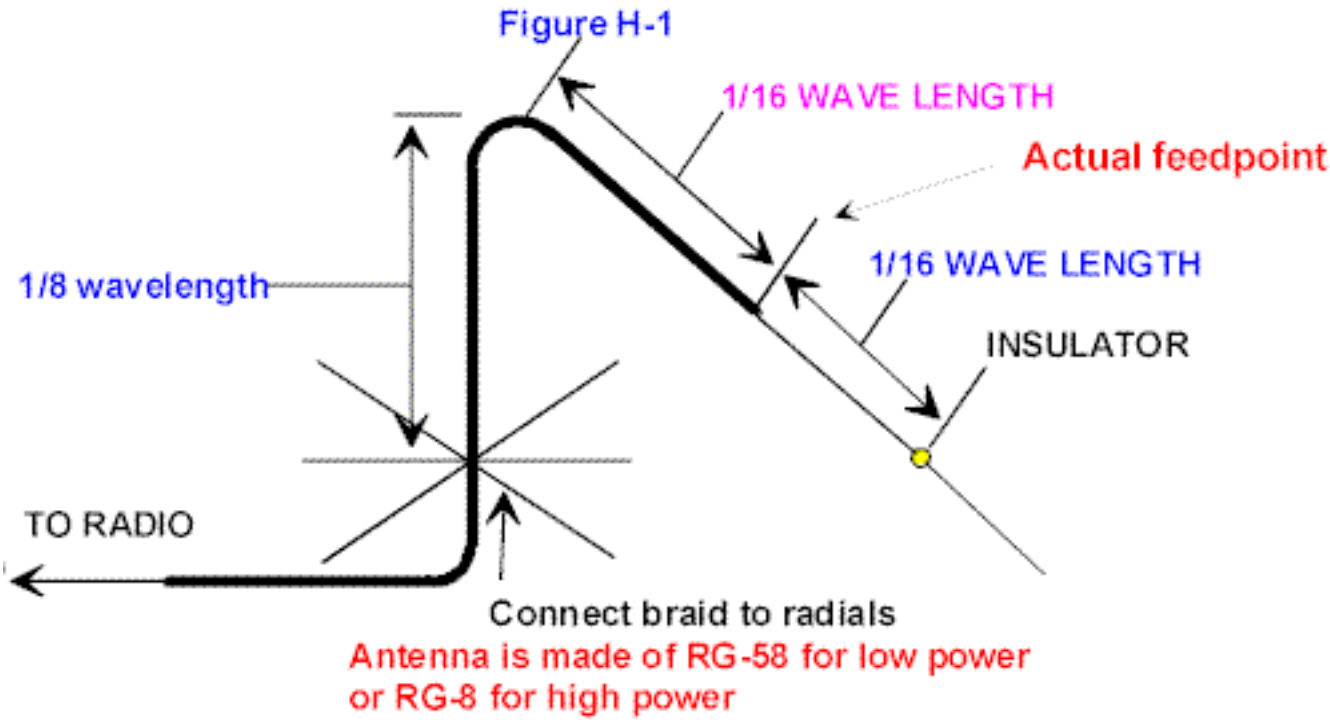
The W5QJR Antenna Revisited

By Richard Morrow, K5CNF



Back in October 1989, the entire paper magazine issue of ***antenneX*** was dedicated to a new antenna concept that engineer/inventor, Ted Hart, W5QJR had come up with in the course of trying to develop a good feed method for his tower on 160 meters. In the process he came up with the antenna that is depicted in Figure H-1. This rather odd looking antenna is a very interesting antenna in that it worked when it was taped to the leg of his existing tower. If it was tuned up there or if it was strung up with an insulating support, it worked just as well. But, an existing tower isn't essential—a tree or similar support will do fine. Here's how Ted's article introduction describes the concept:

"A short wire can be added to an existing tower (or hung from a tree) to form an excellent low band antenna. This antenna ***combines*** the features of a horizontal and a vertical antenna to provide constant signal level to all stations from ***near-in to more than 1,000 miles.*** It is the optimum antenna for rag chewing and net operation on 40, 80 and 160 meters. It is also an excellent DX antenna."

RUNS LOW POWER

So I put one up for 75 meters that was only 32 ft. (9.75 meters) tall. To say it worked is mild. I was only running about 15 watts out and got some reports that were far better than I would have imagined. No one believed I was running so little power. A report of 20 over 9 from Los Angles was the first one I got—then a 30 over from Atlanta, followed by a 25 over from Cuba was enough to convince me that this antenna worked. No only did I get these good reports, I could hear Ted, who lived in Melbourne, Florida, which is about 1,100 miles due east from me across the Gulf of Mexico. He was working into Europe

and making contacts in just about every country east of Moscow. Ted had only a TS-440 on the air, running 100 watts and he was getting good reports. Also, I could hear the stations he was talking to, but could not break into the pileups due to my low power. Moreover, I had a rather large amount of power lines, telephone cables and other utility lines surrounding my antenna. These lines were to the East of my antenna and also very close to the antenna. I am sure that these multiple conductors had a definite effect on my signal in that direction.

SIMPLE CONSTRUCTION

The interesting thing about this is that the antenna was hung from a 35 ft. (10.67 meters) pole held up by a 20 foot (6.10 meter) redwood pole. There was no problem tuning up the antenna, and it worked as long as I had it up. The construction of the antenna is simple and well described in the October, 1989 issue, which is in the Library archives. This antenna is well qualified to be a disguised antenna, since it is so short for the lower frequencies—32 ft.(9.75 meters) for 75 meters, 16 ft (4.87 meters) for 40 meters, and the size goes down from there. An interesting feature is that the folded-over portion of the antenna can be straightened out and extended straight up after going up in frequency past 20 meters. The folded part of the antenna adds a horizontal component to the radiated signal, which enables you to make more reliable contacts in closer than a pure vertical antenna would. This is due to the horizontal and vertical mixture of radiated energy giving higher angle radiation to the signal, yet enough vertical radiation for DX work.

REALLY DISGUISED

This is a very unusual antenna, indeed. It can be put up easily and tuning is not that difficult either. It does work and work well. I have no explanations other than it is another of these antennas that came into being by accident. A very pleasant accident as well, I might add. One thing that is also interesting is that it does not look like an antenna, which adds to the disguisability of the antenna.

Another experimenter who put one of these antennas up was G6RJ, Rob. He had very good results working into the Far East with excellent reports via long path on 18 MHz. For those who are interested, there is several ways to make these antennas directional and if enough interest is expressed, we will put more about this in a future issue.

For now, if you are interested in this antenna, go to the Library under Past Articles and look at the article "The W5QJR Antenna-Revolutionary Concept!" and all of the basics and tuning information will be there and get you on your way to putting up one of these antennas. Many folks have reported finding this to be a very interesting concept and solves some unique problems. **-30-**

802.11b Homebrew WiFi Antenna Shootout - 2/14/2

Update 11/2/2003
Added notice at bottom

Update 2/16/2:
I've been Slashdotted!
Some grammatical/spelling errors corrected

Update 2/21/2
How To finshed, linked.

- Introduction
- What the huh?
- The Shootout
- Performance Summary
- The How To

Greg's obsession de' jour

In my efforts to add the words "wireless savvy" to my network admin resume, I've been reading books and web pages on radio propagation, antenna theory and design, and building wireless networks with 802.11 (WiFi). One of the first things that got me excited was the Pringles Can Antenna. Published on the internet and in a fine book by Rob Flickenger, the net admin for O'Reilly, this design for a do-it-yourself, VERY inexpensive antenna made from a recycled junkfood container is as cool as the other side of the pillow. It seems that everyone is building and using these. The various community wireless network groups all talk about them and folks are reporting that they do the job.

A friend of mine built his before me and looking at his finished antenna got me excited to understand the theory of how it works. Reviewing his plan, I came up with different spacing that he Rob did. To see if I could improve upon the design, I built mine with corrected spacing. While waiting for some wireless equipment to come in, I started looking for my next antenna project. Oddly, the more I studied, the less I understood. There seems to be quite a bit of confusion on how the Pringles antenna works and what design category it falls under. The inner lining of a Pringles can looks metallic, but my tests show it not to be. The Pringles Antenna design, and some designs that pre-date it, seem to treat it as though it were metallic. While folks are calling it a Yagi-Uda style antenna, the design of the driven element in the Pringles can antenna looks like a Waveguide style design.

Waveguide antennas don't use the director assembly (the washery bits), and therefore are much simpler to build. An old tin can of the right size, about $5 in parts and 10 minutes of time are all that are needed. The math for computing correct sizing of the components in a waveguideWiFi antenna is simple. Formulas in hand, I started searching my cupboards for tin cans that fit the spec. I found myself staring at the products on the canned food aisle at the grocery store. I even went so far as going grocery shopping with a tape measure. "No no, this spaghetti sauce looks much better. It's about three quarters of a wavelength in diameter, hon!"

What the huh?

On Feb 11th, Rob, posted an article on his newest homebrew WiFi antenna - a tin can waveguide! Rob used a large, 39oz. coffee can and placed a quarter wavelength driven element a quarter wavelength from the back of the can. He reported good results - even better than the Pringles can design used by so many. For the antennas I was building, I was using different measurements based on the antenna design material I had been reading. Now I'm a late entry into this wireless stuff and the experts are going a different way than me. It's time to benchmark.

The Shootout

My plan was to get relative performance measurements for various designs (including mine) of homebrew antennas for 802.11b (WiFi) wireless networks. To do this, I setup a wireless link and changed only the antenna- recording each antennas' performance under identical conditions. I didn't compare them to a commercial directional antenna as my only one has a male connector and I don't have

the right cable to hook it up yet. The contestants were (click on each for design specifications).

- A commercial Lucent "range extender" omni directional
- A buddy's Flickenger-design Pringles can Yagi
- My modified design Pringles can
- A Flickenger design coffee can waveguide
- A coffee can waveguide with corrected radiator placement
- A Hunts 26.5oz. pasta sauce can waveguide that fell in the optimum size range
- A Nalley 40oz. "Big Chunk" beef stew can Waveguide

Performance numbers and methodology

The Performance Summary

The results surprised me! In our test, the Flickenger Pringles can did a little better than my modified Pringles design. Both did no better than the Lucent omnidirectional. Now this is just on raw signal strength, noise rejection due to directivity still makes a directional antenna a better choice for some uses even if there is no gain benefit. The waveguides all soundly trounced the Pringles can designs. I mean they stomped them into the ground on signal strength - as much as 9 dBm better. Every three dB is a doubling in power - that's three doublings (8x increase)!

Of the waveguides, the Nalley's "Big Chunk" took top marks. It was followed by the Hunts Pasta Sauce, my modified coffee can, and the Flickenger coffee can in that order. My three waveguide designs, which utilized the correct theoretical spacing, out performed the Flickenger Yuban coffee can handily. It seems that the design formulas for the waveguide design made a sizeable difference in performance. In the yagis, it didn't matter much. This could be because neither Rob's nor my designs are anywhere near right for optimum performance for a Yagi. I've decided that Yagi design is not for the timid or non-radio-expert.

With these results, I'm convinced that the waveguide design is the way to go for cheap wireless networking. The performance is good, the cost is very low and the skill required is minimal. If you can eat a big can of stew, you can make a high performance antenna.

The How To

Build your own Tin Can Waveguide WiFi Antenna (Cantenna). It's the easiest antenna design I know of.

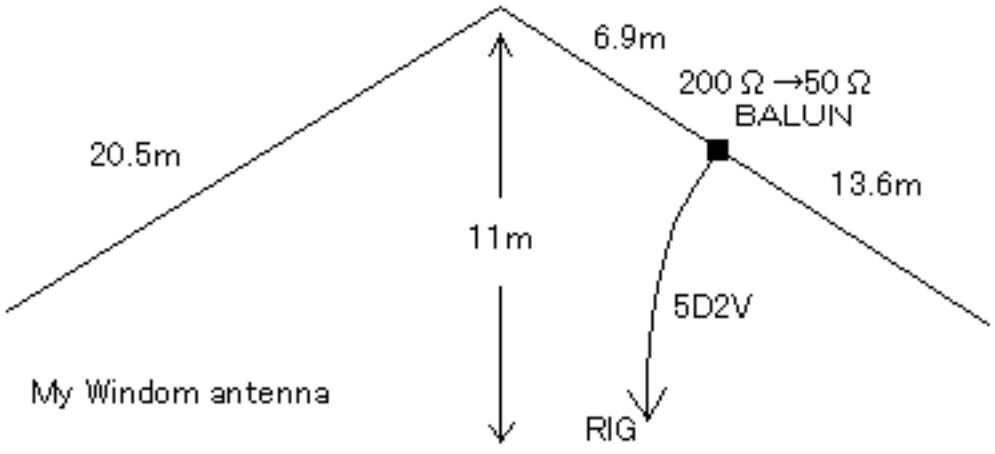
WINDOM ANTENNA

I'm using homebrew Windom-Antenna recently.
In the total length of this antenna is 41m, height is about 11m, and diameter of element is 2mm.
However, it is up only about 4m height from a metallic roof.
I modified this antenna originally used as Inverted-V type of 80m band Dipole a little.
The feeding point of this antenna is located 13.6m from the edge of Element. Yes, it is **Off-Centered**.
BALUN of making which uses two cores, converts impedance into 1/4. The core is the one of about 4cm in the diameter. so there's no problem in the input power 100W at all. Because two cores are used, I think as much as 500W safe in power.
The diameter of the wire rolled in the core is about 1mm.
The VSWR to frequency is shown as follows.

Freq.	VSWR	Freq.	VSWR	Freq.	VSWR	Freq.	VSWR
3.525	1.1	14.050	1.8	18.070	3	28.150	2.5
3.570	1.4	14.100	1.7	18.160	3	28.500	2.0
3.795	1.6	14.150	1.6	21.050	>3	29.000	1.3
7.030	1.4	14.200	1.3	21.449	>3	29.300	1.1
7.060	1.3	14.349	1.2	-	-	29.600	1.2
7.099	1.2	-	-	-	-	29.699	1.3



In 21MHz, VSWR exceeds 3. However it is likely to QSO with the domestic area, if Antenna-Tuner is used. I did not obtain good results though I measured its VSWR with 10MHz and 24MHz besides <showing up>.
I think this easy structural wire antenna is Very FB. Because I can QRV on multi BANDs without switching some antennas.

By the way, I had one question. This antenna might be a name of "Windom" why?...

I thought it might designer's name or name of a place of development ground.

The answer's as following e-mails via radio-amateur's FWD-Net.

> Dear friend, i have a self building Windom; it is a dipole of 80 meter with the connection at 1/3 of the lenght: in this point the impedance is 300 ohm, and with a balun 1:3 i obtain 50 ohm; for the band of the 21 Mhz i put a second dipole only for this band, connected ad the same mode of the other; the lenght of this is 2.3 + 4.6 meters.
> In a test with a vertical groun plane 5 band, the windom result better in 14 7 3.5 Mhz; using a good antenna adapter, it can be used in 1.8 Mhz.
> This antenna is named Windom because was bilded from Laurent Windom (W4DZZ ?) around the 1930.
> It' s not a long time that i use this antenna and i have some thing to understand about it; in any way i'm really satisfate from this antenna.
> I wish to you to have big satisfation using them.
> Best 73 an good DX. Ciao de **Franco. IK1OWB**@IK1JNS.IPIE.ITA.EU

> Hello Tada !
> The "Windom Antenna" was described by Loren G. Windom (QST, Sep 1929, pp 19-22, 84) so this kind of antenna was named after its inventor.
> 73 / **Peter, DJ2ZS**@db0gv.#hes.dl.eu

> The windom is called after its inventor.
> Here I use a windom antenna on 80 - 10 m. the ntenna is 41 meter long.
> 13% off center I feed it with 300-ohm open air-spaced feeder. I use an antenna tuner with the balun coin connected to the antenna tuner. The antenna hangs in zig-zag between some trees. I am very pleased with it, it works quite well locally and on DX. Thought this might be of interest to you..
> Good luck!
> 73 de **Egil. LA8HF**@LA4O.OSL.A.NOR.EU

Thanks to Franco, Peter and Egil. Best regards to you.
And thanks for more infos via the Internet. Those are ...

> I just read an interesting article in Czech ham radio magazine "AMA".
> The article itself was about history of the bobtail curtain antenna, but there was an interesting note: Loren Windom first described this antenna, but he himself said that it was invented by someone else as a modification of Hertz antenna.

I found some people to call the coax fed antenna with a balun "FD4" - but some other people call FD4 the modification mentioned by Franco IK1OWB (but the measures are doubled: 9.4+4.7 meters).
73 **Jindra OK1FOU**

Regarding the Windom, I have a long time experience with such an antenna. I designed mine in 1978. It is different from the "normal" ones because I use a different type of balun and this, from my point of view, is superior to the toroid one because the core does not saturate with high power or reactive loads.
From my point of view, this type of antenna is not rightly called "Windom", it should be called, probably, Long wire off center fed antenna.
The reason is very simple; the Windom antenna was referenced to ground as the feed point was between an off-center side point and ground.
The modern type of "Windom" Antennas are off center fed but not referred to ground. The validity of calling them Windom is due to the idea of "off-center feed".
73 **Gian I7SWX**

The windom antenna should never be configurated as an Interted Vee but should be Flat Top as it was originately.
Matching network such as the Johnson Viking Matchbox is highly recommended
if fed all the way with 300 ohms line.

This antenna is suitable for all traditionnal ham bands.
73 from **Cam. VE2SO**

O-kay, Definitely maybe, it should not be called "Windom" that is not single-wire fed or flat-top.
But I will call the antenna for multiband "**Windom**" in high regard.

Well, that is as same as a relation between **H-Hentenna** and Hentenna. You know Hentenna, don't you? Hentenna is a kind of Loop antenna, but H-Hentenna is not loop.
Anyway, **H-Hentenna, that is one of variation of single-wire fed Windom (or 8JK).** It was developed by **JR1FTE** and expanded by **JA7KPI** in 1982. For more infos, **see the LINKs below**.

My Favorite Multi-Band Antenna

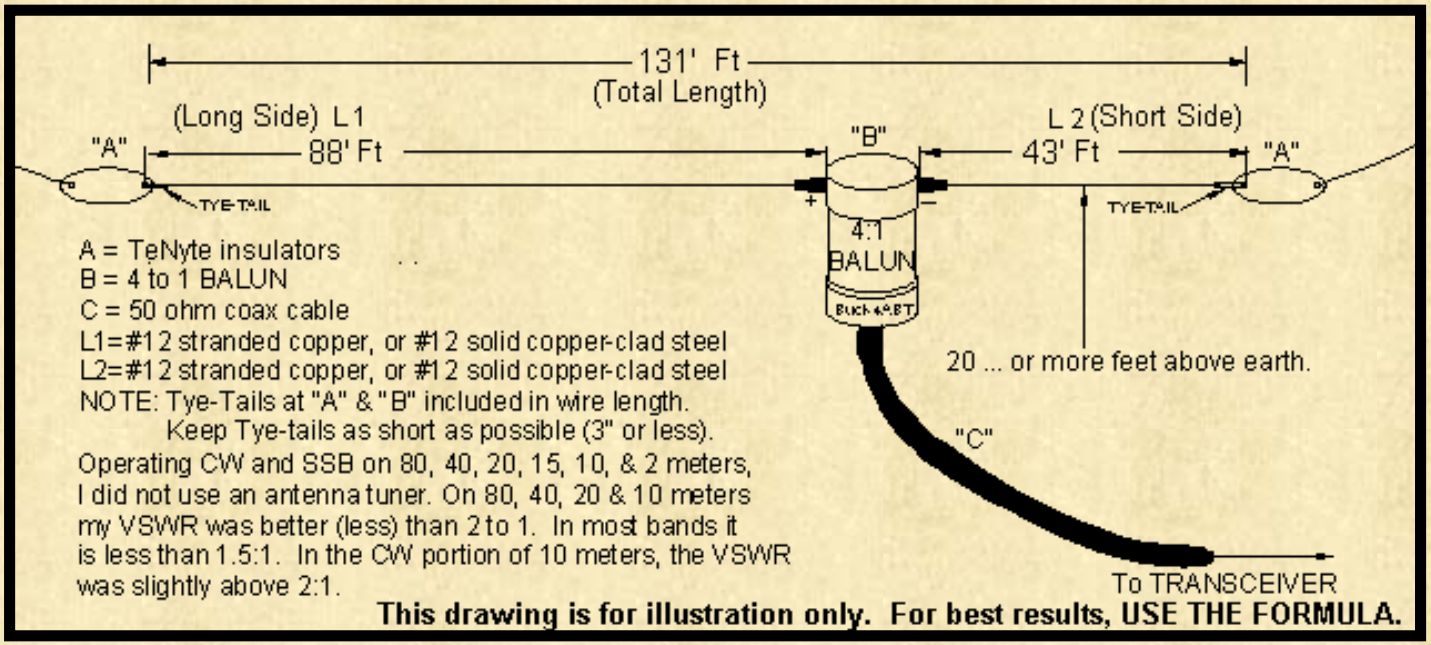
The "WINDOM"

By G. E. "Buck" Rogers Sr; K4ABT

In September of 1949, I was tired of climbing poles and trees to move, remove, add, or change my single-band HF antenna's. In those younger years of my HAM radio hobby, I had used single band dipoles and doublets for almost every HF Amateur band. I had tried long-wires, doublets, dipoles, and Zepps, but again, operation was restricted to single band operation, maybe two bands at most.

I had heard of the "Windom" and read a few articles about the Windom, but most of my thoughts were ... ho-hum.. just another dipole fed a bit off-center. Then one evening at a meeting of the GARC in the old "Sea Scouts" club house near the Coosa River in Gadsden, Alabama; I heard some of my "elmers" Gilbert Watson (SK) W4PAC, Gale Caudle (then W4CFB), Jack Kennamer (SK) W4YPC, Bob Bynum W4USM, Austin (Vic) Vickery, Walter Damkohler (SK) W4EBO, W4CWF, Ed Elkins (SK) W4CDI, Homer Dupree (SK) W4OZK, Jim Runyan, Homer O'Dell, Robert Martin, ... and others discussing the Windom *all-band HF antenna*. It was when Jack (W4YPC), mentioned ***using one (Windom) antenna, on the all HF bands*** *that my ears went directional!*

That last phrase caught my undivided attention. "most all HF bands, ...etc"
What ! *A multi-band HF antenna ?* Surely I had been blessed.



To think that I could put up a Windom, and no longer have to climb the poles and trees to hang another (single band) HF antenna was great news to me. To be able to use it without an antenna tuner was icing-on-the-cake. For a kid without extra funds, an antenna tuner was a luxury that I could *not* afford. Even my transmitter was a single 807 rig I homebrewed on an old *Atwater-Kent* radio chassis, my grand-father had given me.

In those days, a BALUN was unheard of. My Elmer's described, a means of connecting the coax to the off-center fed antenna using a nine (9) turn coil of the coax feed-line at the feed point. This coil of feedline coax formed a "de-coupling" loop. The de-coupling loop provided a crude means of matching the feed coax to the antenna, and at the same time, it would reduce the "re-radiation" (RF currents) along the outside (shield) of the feeder coax.

Today we have toroid cores and BALUN devices that provide a more efficient means of coupling RF energy to the antenna (reducing the VSWR, "standing-waves"), while performing better impedance matching. In the drawing shown above, I've drawn the exact dimensions of the Windom I built in 1949. The only differences in my Windom of 1949 and today are:

1) the material the insulators are made of, and
2) I've substituted a 4 to 1 BALUN for the 9 turn, 8 inch diameter, decoupling loop.

AN UPDATE:

Since writing this article a few decades ago for a major HAM radio magazine, I've received tons of mail (and eMail) asking for more information, especially with regards to a 160 meter version; Here then is "the rest of the story."

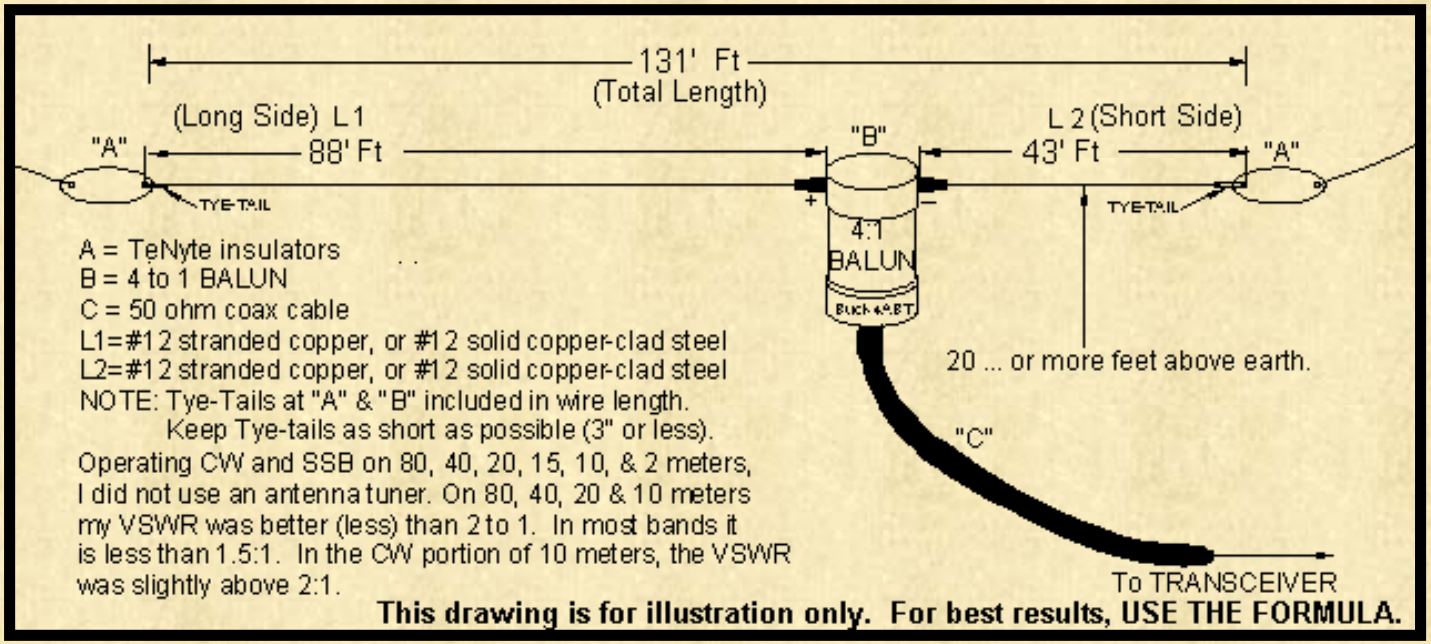
First of all, we'll address the formula, and how to determine the length(s) of each section, using the same old formula that I used in 1949.

Long side.... = 468, divided by the frequency, then multiply by **.**64 (= Feet)

Short side.... = 468, divided by the frequency, then multiply by **.**36 (= Feet)

THUS; for 160 thru 10 Mtrs.....
Long Section; 468/1.8 MHz = 260 x .64 = 166.4 feet.
Short Section; 468/1.8 MHz = 260 x .36 = 93.6 feet.

For 75 thru 10 meters do similar math to arrive at/near the dimensions shown in the drawing below, but for best results, use the formula.

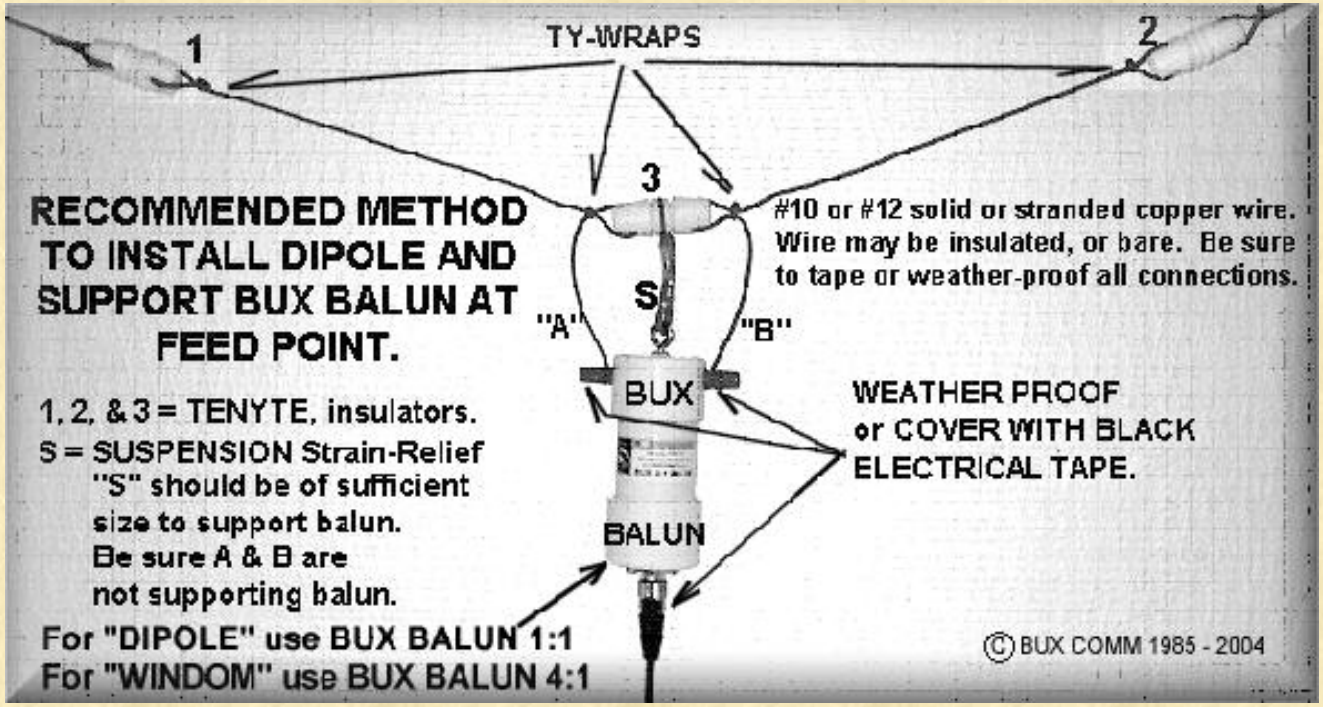


The Windom can be installed as an inverted VEE, or as a sloper, ***but in no case,*** should the angle be less than 90 degrees against itself. *To use an angle that folds against the pattern of the opposite end of the Windom, would change the impedance of the feed-point, change the multi-band features, and most important, destroy the radiation characteristics of the antenna.*

In other words, install the Windom as you would any other dipole, while using a common sense approach. The fact that we are feeding
this Windom using *coax,* and a single balun, gives us the ability to construct it as an inverted VEE or at a "real estate saving (angle)" without destroying the features and performance of the Windom.

This is *not* true with those antennas fed with ladder-lines and those that have several impedance transitions built into the feeders

of the "*basic" Windom..... There's more to come, so read on!*



ANTENNA INSULATORS

Weatherproof, (TENYTE) insulators. Perfect for your DIPOLE or Windom antenna.

For the apartment dweller, you can now hang the 20 meter doublet in the attic. I've QSO'd with stations all over the world with the 33 ft dipole in my garage attic. One insulator at the center, and one each end.

It's great for other HF WINDOM and single-band dipole antennas. Dielectric strength is comparable to the old ceramic insulators, without susceptibility to cracking or breakage under impact or extreme temperature changes.

Package of 3, $2.99 ANTINSL3 Order Now

Package of 10, TeNyte Insulators $8.99, ANTINSLX10 Order Now

Now it's time for me to P O the wire and cable vendors, and the proponents of Windom's with too many feed-line transitions. Twin Lead, Ladder-line, Window Line..... etc.. is an over-kill.. The trade-off is not...; I repeat; NOT... worth the pain and upkeep to replace it every year or two.

And trust me... It is NOT a problem of the ladder-line insulation quality or properties that I'm speaking of. I speak from experience; Wind will destroy ladder/twin-lead line. Even the robust type will succumb to the wind element in time.

IF; you decide to use ladder line, make one turn (twist) to each 20 to 24 inches of line to decrease the wind resistance presented by the "flat" line..... even if it is "window-slotted" type ladder-line. By adding the one twist per 20 inches, it may last longer than three years.

COAX does NOT present a high degree of wind resistance, and it'll last much longer.

Having *been there, done that*, and heard similar horror stories from others; another question arises regarding parallel line currents that come with the use of so-called balanced (twin-lead) feed-lines. To add injury to the ladder-line proposition, the balanced line may also assume the properties of a *single wire feeder (yuk)*.

Some purveyors of the Windom that use ladder-line transitions, must use two impedance matchers (or BALUNS) with their (knock-off) Windom. One is to transition the coax outside the HAM shack *(heaven forbid, we use ladder-line inside the shack... RF "feedback" in everything)*, to the ladder line, then another at the Windom (antenna) feed-point to choke off parallel current from the ladder-line.

Since the feed point of this antenna has been found to be near 220 to 260 ohms, *the use of a 4:1 BALUN to join our coax to the antenna,* emerges as a compromising solution.

Let's not lose sight of the most important advantage of using this antenna; and that is: It provides us with a powerful, multi-band antenna, and a minimum of feedline components.

Now for the "perfectionists" among us, if you want to smooth out the hills and valleys on some of the bands, add your antenna tuner to the system, and the Windom becomes very flat across the bands. When I say "flat," we are talking about reducing the VSWR to a minimum, to produce a good forward power, transfer of RF energy to the Windom.

We're having fun already... with the Real WINDOM antenna

The "Windom Antenna" was described by Loren G. Windom in QST magazine, September 1929. Pages 19 through 22. It is named after its inventor/designer.

Loren Windom, W8GZ, was first to reveal the antenna to the radio amateur community by describing the antenna in the September 1929 issue of QST. It was by Windom's name that the antenna became known. The Windom antenna is an off-center fed dipole with an unbalanced coax feedline.

In 1937, the Windom was first described as a compromise multiband antenna. The antenna can be employed on 80, 40, 20 and 10m with considerable, though acceptable levels of VSWR. What became perhaps the most popular multiband Windom design of all, was the German-made Fritzel FD4 antenna, described by the late Dr. Fritz Spillner1, DJ2KY, in 1971. It had the same dimensions as the multiband Windom antenna, but fitted with a 200Ω (4:1) balun in its feedpoint and fed with coax.

Today, many radio amateurs are using multiband Windom antennas with more than satisfactory results. It would not be without reason that Windom antennas are being employed during IARU HF World Championships! and most of all, by "high-stake-contests." ***Perhaps many young hams ignore the multiband Windom antenna because of its sheer simplicity and may be thinking it is too good to be true.*** *The complexity of feeding other dipoles and doublets, the losses in dipoles with traps and the esoteric marketing of some other antennas seem to appeal to them more.*

CLICK HERE: and read more about the evolution of the WINDOM, to ZEPP, to VHF J-POLE.

BUX BALUNs should be installed at the antenna feed point, or where the coax or feed-line attaches to the above ground antenna. BUX BALUNs are used to connect balanced antennas to unbalanced transmission lines, such as coax cable. Their primary purpose is to prevent antenna (RF) currents from flowing down the outside of the cable. Another function of the BUX BALUN41 is to match the impedance of an unbalanced coax to the balanced feed point of a balanced input antenna(s). BUX BALUNS may also be used as “line isolators” anywhere along the cable to prevent the destructive influence of induced RF currents (VSWR).

BUX 1:1 BALUNs are current BALUNs. They consist of several large, number 73, ferrite type 44 cores. ***BUX BALUN11*** operate from 3.5 to 72 MHz and allow use of RF power to the rated capacity of the BALUN.

BUX 4:1 BALUNs are voltage BALUNs. They consist of a large, number 41, ferrite dough-nut bobbin. ***BUX BALUN41*** operate from 3.5 to 55 MHz and allow use of RF power to the rated capacity of the BALUN.

During this month, when you purchase either of our BUX BALUNs, we will include 3 (Tenyte™), insulators FREE. A $2.99 value. *Be sure too mention this offer in*

the "Comments" space on the order form check-out page!

At BUX COMM, *We don't cut corners!

The components used in the manufacture of our BALUNs are from top quality components, beginning with the Silver Plate SO239 connectors and center insulator is made of teflon™(E.I Dupont). The wire we use to wind the ferrite donut is heavy-duty, silver flashed wire, with teflon™ insulation that will handle RF voltages above 5000 volts, and temperatures above 2000 degrees. The binding posts are heavy-duty, tempered brass, with end holes and side-thru holes to accommodate either type loop-thru connection. A double-shoulder brass capture nut is used to add a secure bite and improve antenna wire electrical connections. With our BUX UN UN (ONION), the coax is Belden™ and the PL259 connectors are Amphenol™.

4:1 Balun, BUXBALUN 41 $19.95 Order Now

o 50 ohm, SO-239 unbalanced input
o Balanced output
o 1.6 to 50 MHz
o Toroid (Voltage) design
o Heavy Duty, Lightweight construction
o Sealed against moisture

1:1 Balun, BUXBALUN 11 $19.95 Order Now

o 50 ohm, SO-239 unbalanced input
o Balanced output
o 1.6 to 50 MHz
o Toroid (Current) design
o Heavy Duty, Lightweight construction
o Sealed against moisture

BUX UN UN *De-Coupling transformer, similar to above,* but has *SO-239 (female) input* connector and *output connector is 1 ft Mini 8 cable with PL-259 (male).*

BUX ONION $19.95 Order Now

4:1, *1.5kw* Balun, BUX BALUN 41HD $27.95 Add To Cart

Toroid design, wound with teflon covered, silver plated wire.* Heavy-Duty, construction.

1:1, *1.5kw* Balun, BUX BALUN 11HD $27.95 Add To Cart

Toroid design, wound with teflon covered, silver plated wire.* Heavy-Duty, construction.

BUX ONION Decoupling Transformer

BUX UN UN De-Coupling transformer, has SO-239 (female)input connector and output connector is 1 ft Mini 8 cable with PL-259 (male).

BUX ONION is and UNbalanced to UNbalance (UN-UN) *decoupling transformer* designed to be used specifically with **the DBLSPCL antenna.**

High RF currents traveling along the coax feed-line shield can cause high VSWR. This decoupling transformer prevents RF currents from traveling down the outer shield of the coax.

The input connector is an SO239 (female) and the output connector is a PL259 (male), which mates the connector of the "DBLSPCL" RV/Apartment dweller antenna shown above.

BUX ONION $19.95 Order Now

WHY USE A 4:1 BALUN

Krusty Olde Kurt is now going to repeat himself. Why? Because the same question keeps coming up over and over. And he wants everyone to get it right.

"I'm feeding my dipole with 600-ohm line. At the station end I need a balun to convert to 50-ohm coax. I need a 12:1 balun, right?"
Wrong! *A **4:1 balun** would be better.*

Why is that? If your dipole is up, let's say, 35 feet then on 80 meters it will probably have a resistance at resonance of about 40 ohms. The actual resistance depends on the height above ground in wavelengths.

If the dipole is 40 Ohms then what do you see at the transmitter end of your 600 ohm line? If the line is a half-wave long (120 ft on 80 Meters) you'll see 40 ohms. Remember, a half-wave line repeats what it sees at the other end. But if it is a quarter-wave long you'll see 8500 Ohms! At other line lengths you'll see impedances somewhere between these two extremes.

So you are not going to see 600 ohms at the end of your 600-ohm line. That only happens if you have a 600-ohm antenna hooked onto it. With such a variation in impedance at the trans-mitter end of the line there is no one balun transformer that will match it. Most of the time the impedance will be above the 50 Ohms of your coax so a high impedance balun would be desirable. Unfortunately high imped-ance baluns don't work well when not matched.

Experience has shown that ***4:1 baluns work best*** in this service. They are more rugged and will take bad mismatches especially if they are wound on an iron powder core. So stop searching for that 12:1 balun. **Use a 4:l BALUN and your system will work just fine.**

You can read Kurt N. Sterba "AERIALS" column in **World Radio Magazine.**

BUX MOBALUN

When you hear those strong HF mobile signals, here's one reason they stand out from the rest.
By installing the BUX MoBalun near the input to your antenna, you deliver more RF energy to the antenna. At the same time, the BUX MoBalun prevents RF from traveling back along the shield (high SWR) of your coax. High power rating, Low-permeability toroid, with Internal composition fiber-glass to prevent vibration during mobile operation. For input and output connectors, we use only the best Silver plated, Teflon insulated, SO239 connectors. 700 watts PEP. *Our **MoBALUN** is also ideal for marine antenna installations*.

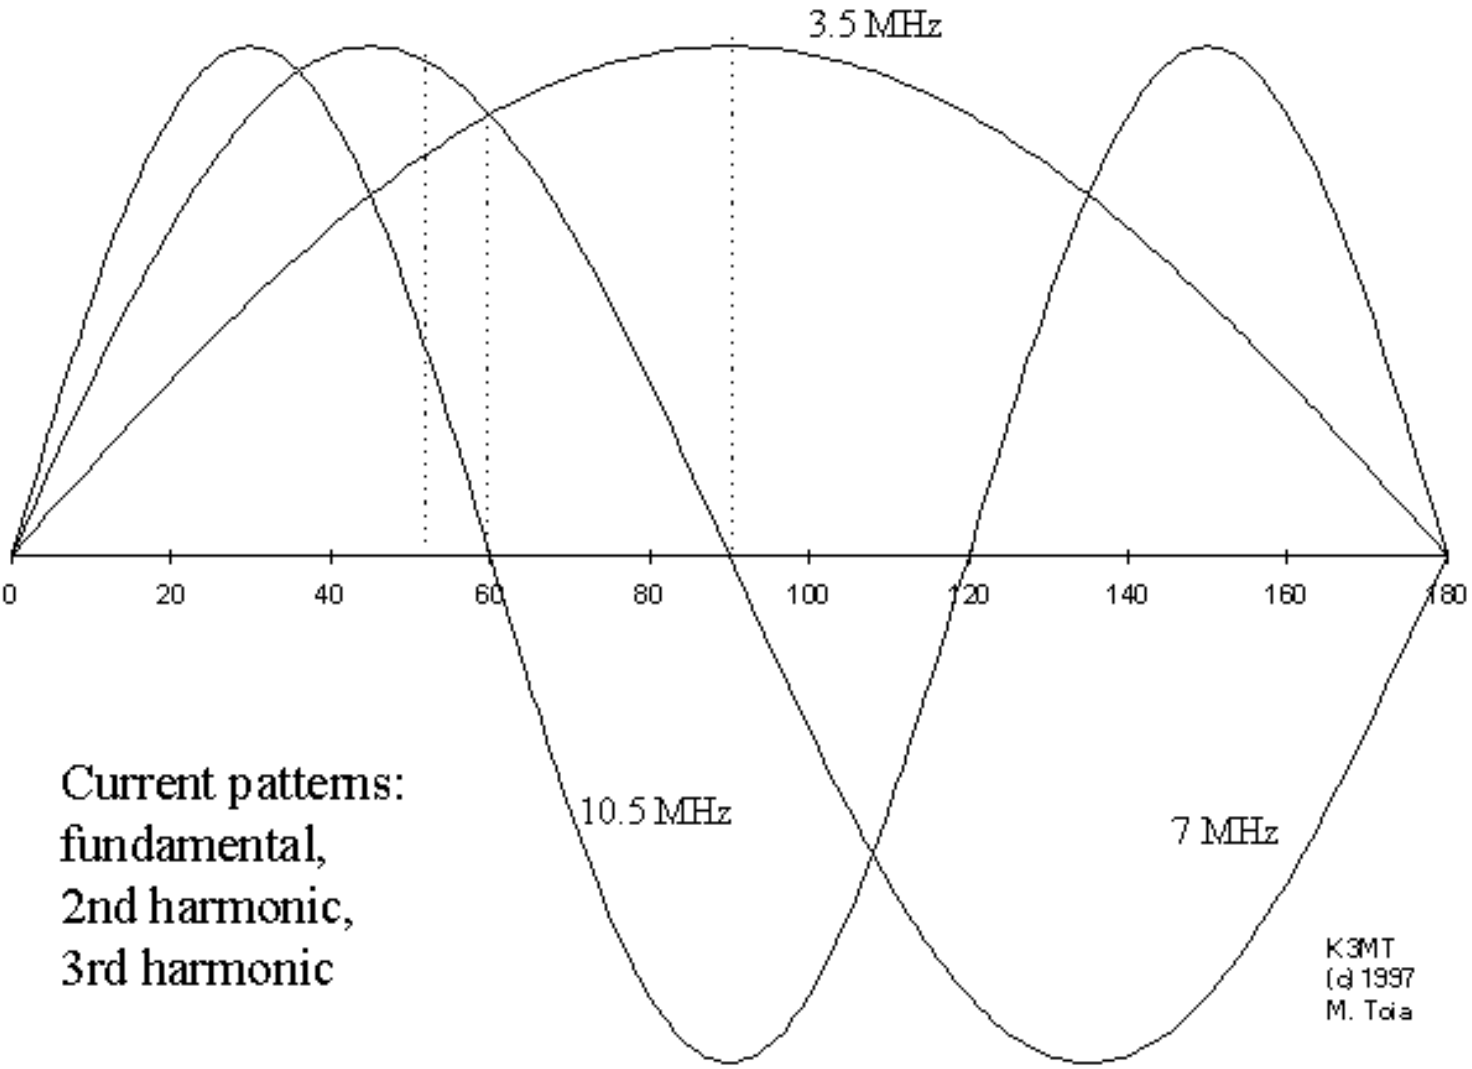
A six-band, HF Windom antenna

April, 1997
Corrected September, 2000

This Windom antenna was marketed in the late 70's and early 80's as *Smithe's Windom.*
It was designed to cover 80, 40, 20 15, and 10 meters. By serendipity, it also covers the 17
and 2 meter bands.

(Authors' note - we now market a revised version of this antenna that covers all HF bands except
30 meters, and covers 30 meters with use of an antenna tuner. e-mail us for details.)

Now, how was a Windom antenna developed? It began with a center-fed, half-wave dipole.
This antenna also works fairly well on all *odd* harmonics, because the center of the
antenna has a current maximum, just as a half-wave antenna has. But on *even*
harmonics, the center of the antenna has a current *minimum.* It is a high-impedance,
center-fed Zepp antenna on even harmonics. This figure shows the current standing wave on a
3.5 MHz half-wave dipole, and the currents on the second and third harmonics (7 and 10.5 MHz.)



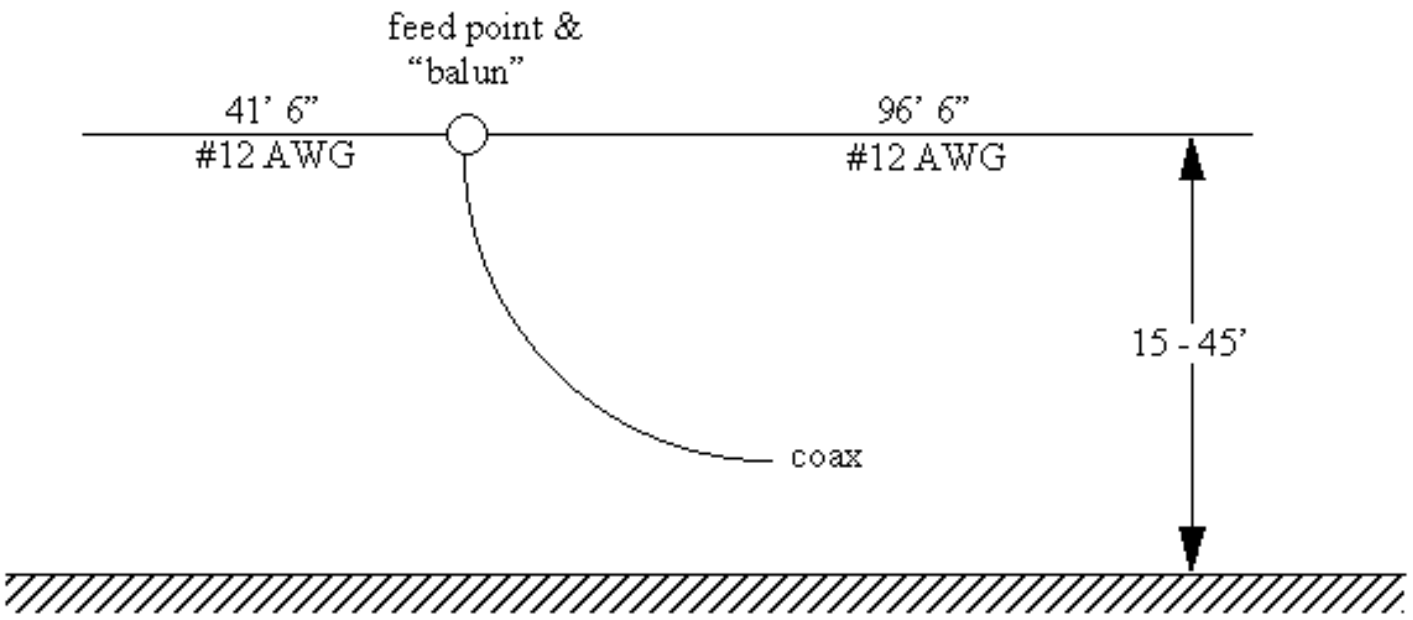
When fed at the center - 90 degrees from one side - a good match to coax occurs on 3.5 MHz.
But the match at 7 MHz is bad: the current is a minimum, so the impedance is very high.
So try feeding it 60 degrees from the left end. Since the current at 3.5 MHz is lower than at
the center (and the voltage is higher) the feed impedance is higher - over 100 ohms. But the
antenna is still resonant, so the *reactance* is low! What you have done is to
increase its feed resistance.

Look now at the action on 7 MHz. The feed point is no longer at a current

**minimum. Therefore,
the second harmonic feed impedance is quite a bit lower than it had been earlier, and is in the
range of a few hundred ohms. Since the antenna is resonant here, too, it has low reactance.**

**But now the feed impedance at 10.5 MHz is poor, because the 3rd harmonic current standing wave
is now a minimum. So try feeding it at about 52 degrees from the left end. Here the match at
3.5, 7, and 10.5 MHz is fairly good. The impedance at all three is now somewhere around 200
to 400 ohms.**

Now you can play these games all day, and if you build this antenna,

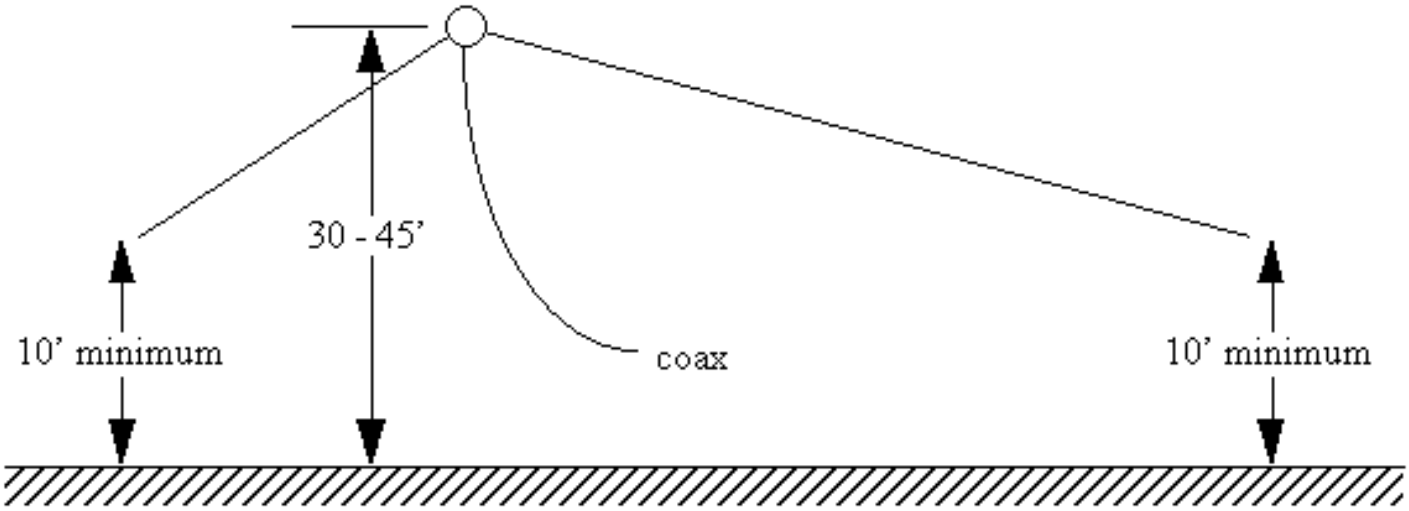


Off-center fed Windom
mounted horizontally

K3MT
(c) 1997
M. Tola

you will find it works well on 80, 40, 20, 17, 15, 12, and 10 meters - plus 2 meters as well,
provided **you pay attention to the balun! To boot, the balun matches 50 ohm coax**
without an antenna tuner. I admit, that this is a compromise design, and a tuner helps on the
low end of 80 meters a bit, and on the high end of ten. But without a tuner, and with a fussy
rig - my Drake TR-7 - a lot of DX has been worked on all bands, from 80 through 10 meters.

I put my windom up a bit differently, as shown here:



Mounting the Windom
as an inverted vee

K3MT
(c) 1997
M. Tola

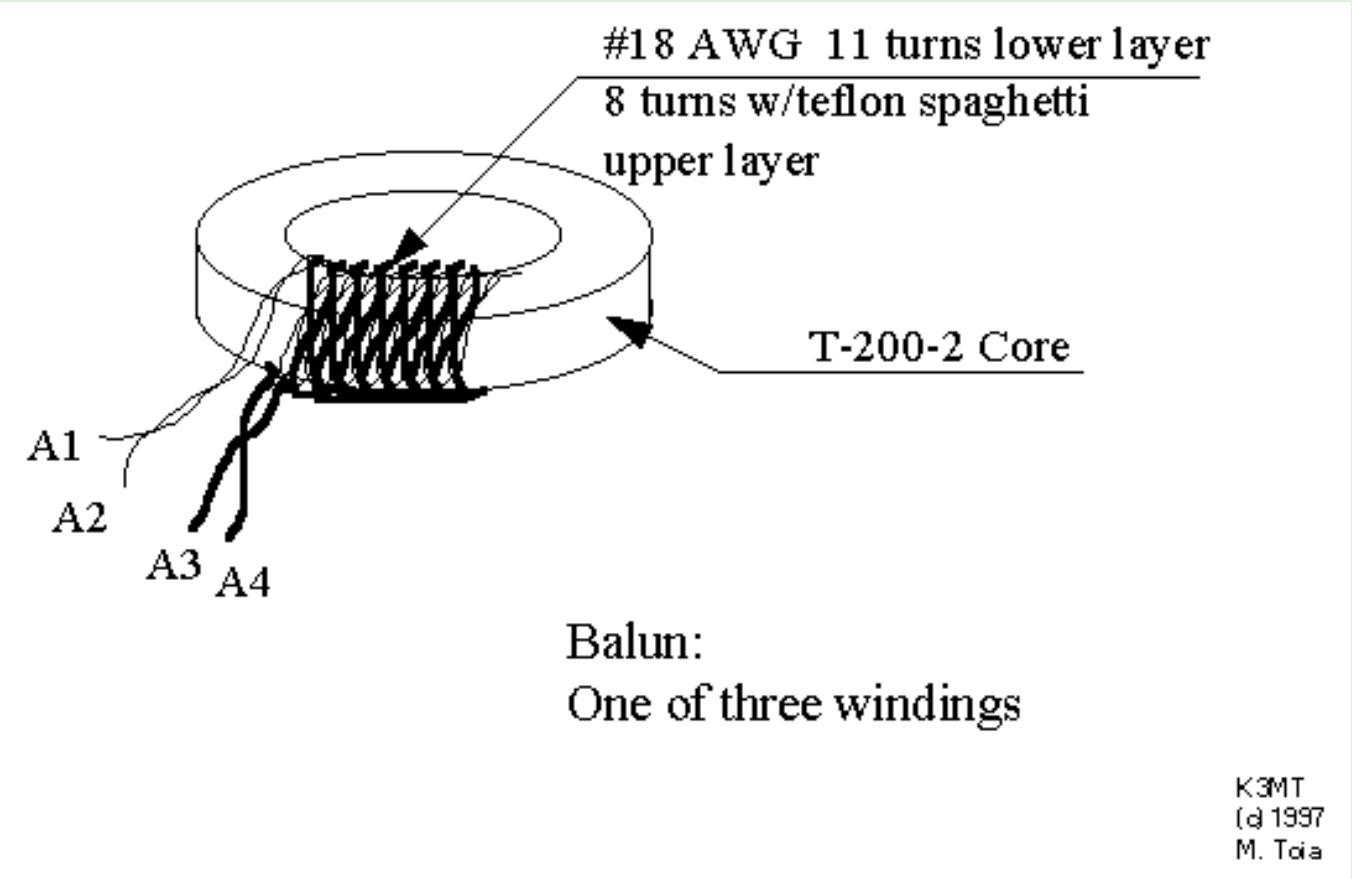
Balun Details

What about the balun? The original unit sold with the Smithe Windoms is a Guanella-type (as opposed to a Ruthroff-Sevick design) parallel transmission line balun. Since the design impedance was measured to be between 300 and 600 ohms, a 9:1 down-converting balun with three 150 ohm lines was designed and built.

To build one, obtain an Amidon T-200-2 core, tape it with two layers of black poly electrical tape, and obtain some #18 AWG magnet wire with a bit of #17 AWG teflon spaghetti. Twist the magnet wire to make three twisted pairs - about one twist per inch. Wind 11 turns of one pair on the core, and slip the teflon spaghetti over *each* lead of the remainder (untwist it a bit to do this.) Then wind 8 more turns back overtop the 11 turn winding. Do this with the other two twisted pair lines as well. Space them on the core so no two lines overlap.

(Apologies and thanks to readers who noted that the original web article called the core a "T-250-2." The correct core is a T-200-2.)

This image shows a single winding on the core - make two more windings like it.

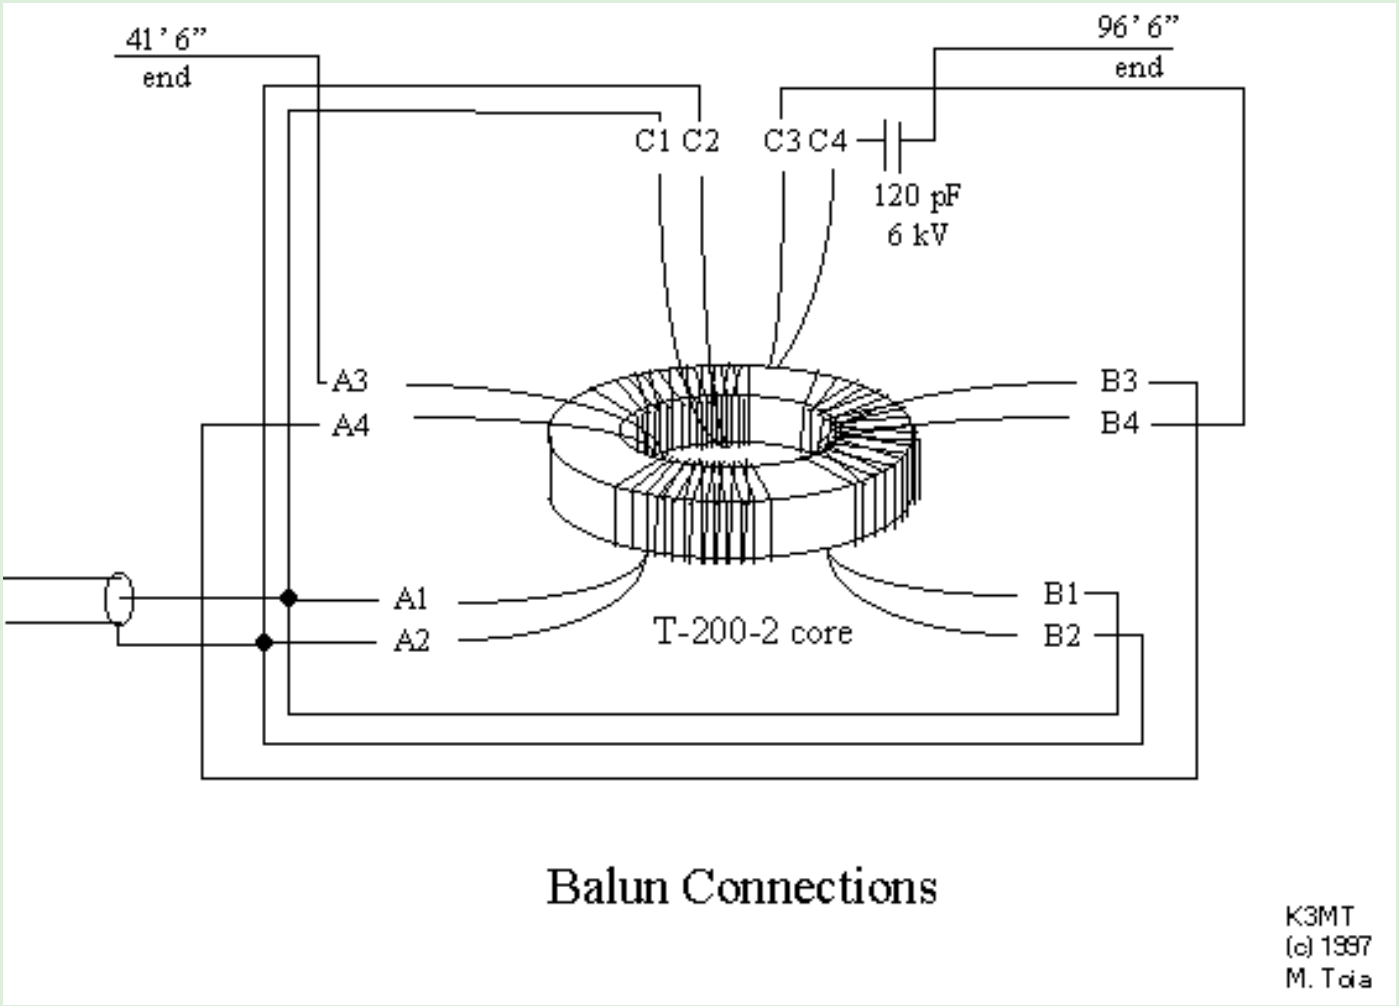


Get an ohmmeter to check continuity. Label the lines A, B, and C, and their ends 1 & 2 where
the uninsulated wire starts onto the core, and 3 & 4 where the wire (insulated with the spaghetti)
leaves the winding. Pay attention to the wiring detail that follows, and use your ohmmeter to
check your work. Label the wires so there is continuity from:

- **A1 to A3**
- **A2 to A4**
- **B1 to B3**
- **B2 to B4**
- **C1 to C3**
- **C2 to C4**

Refer to the next image to guide the balun connections, and wire the balun as follows:

- **Connect A1, B1, and C1 together. These will connect to the center conductor of the coax.**
- **Connect A2, B2, and C2 together. These must connect to the coax braid.**
- **Connect A3 to the *short* end of the windom. *This is important!***
- **Connect A4 to B3, and B4 to C3.**
- **Connect C4 to a 110 pF, 6 kV capacitor.**
- **Connect the other end of this capacitor to the *long* end of the windom.**



NOTE: if you think the balun is too complicated to build, e-mail us. We can

provide one.
Ask for pricing. In fact, we will be glad to provide an entire windom, according to this
design, if you wish.

You are now ready to install and enjoy your windom. If you have the same luck that K3MT and
daughter KF4LGR have, it will have been worth all the trouble!

X-Beams

KQ6RH

(C) 1998, 1999, 2000

Ray Jurgens

(Up-Dated 2/25/2000)

X-Beams

The X-Beam has been described in QST and the ARRL Antenna Compendium # 1 in enough detail that it should not be difficult to assemble this antenna and obtain the specifications indicated here, though the specifications claimed by the author may be a little over-stated (see reference 1). The claim is that the antenna has 6.0 dBd and 18 dB F/B ratio. The figures below indicate the reality of the situation based on the E&M modeling program. I present both the free space patterns and the ground mounted pattern for 20' height.

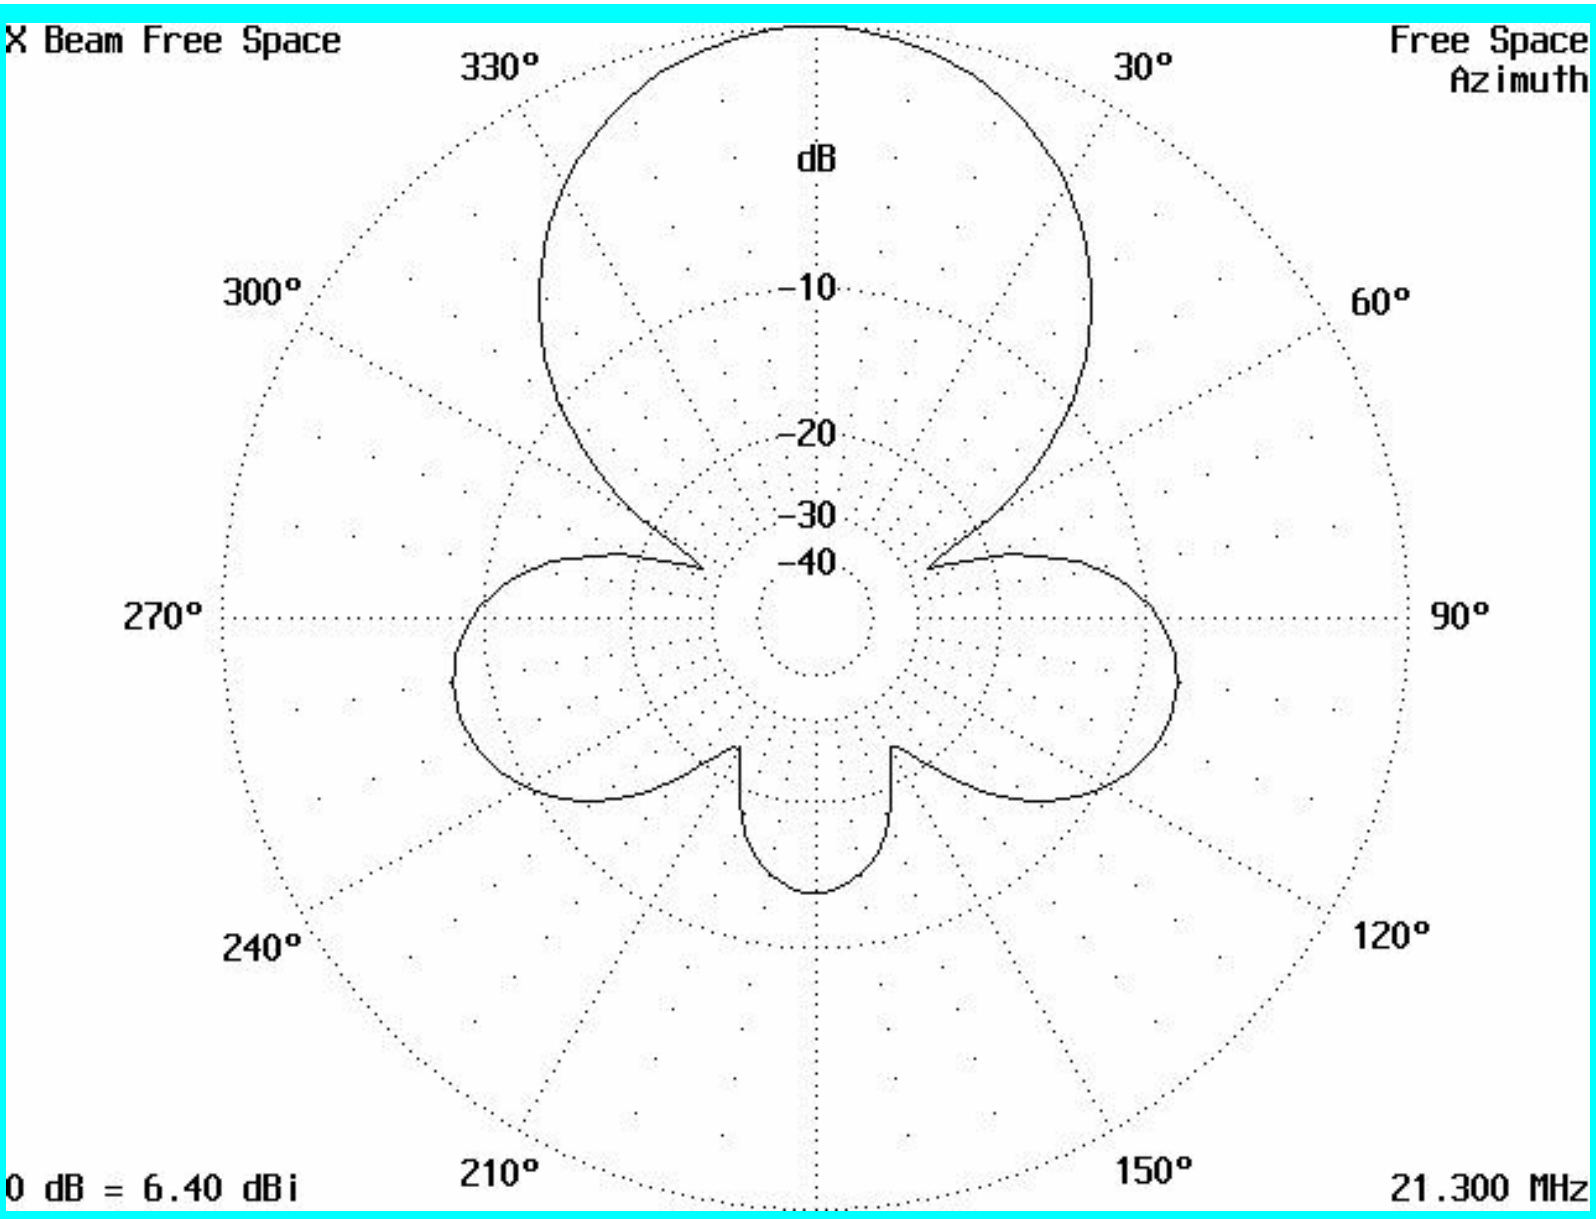

Figure 1

Azimuth Pattern for X-Beam in Free Space

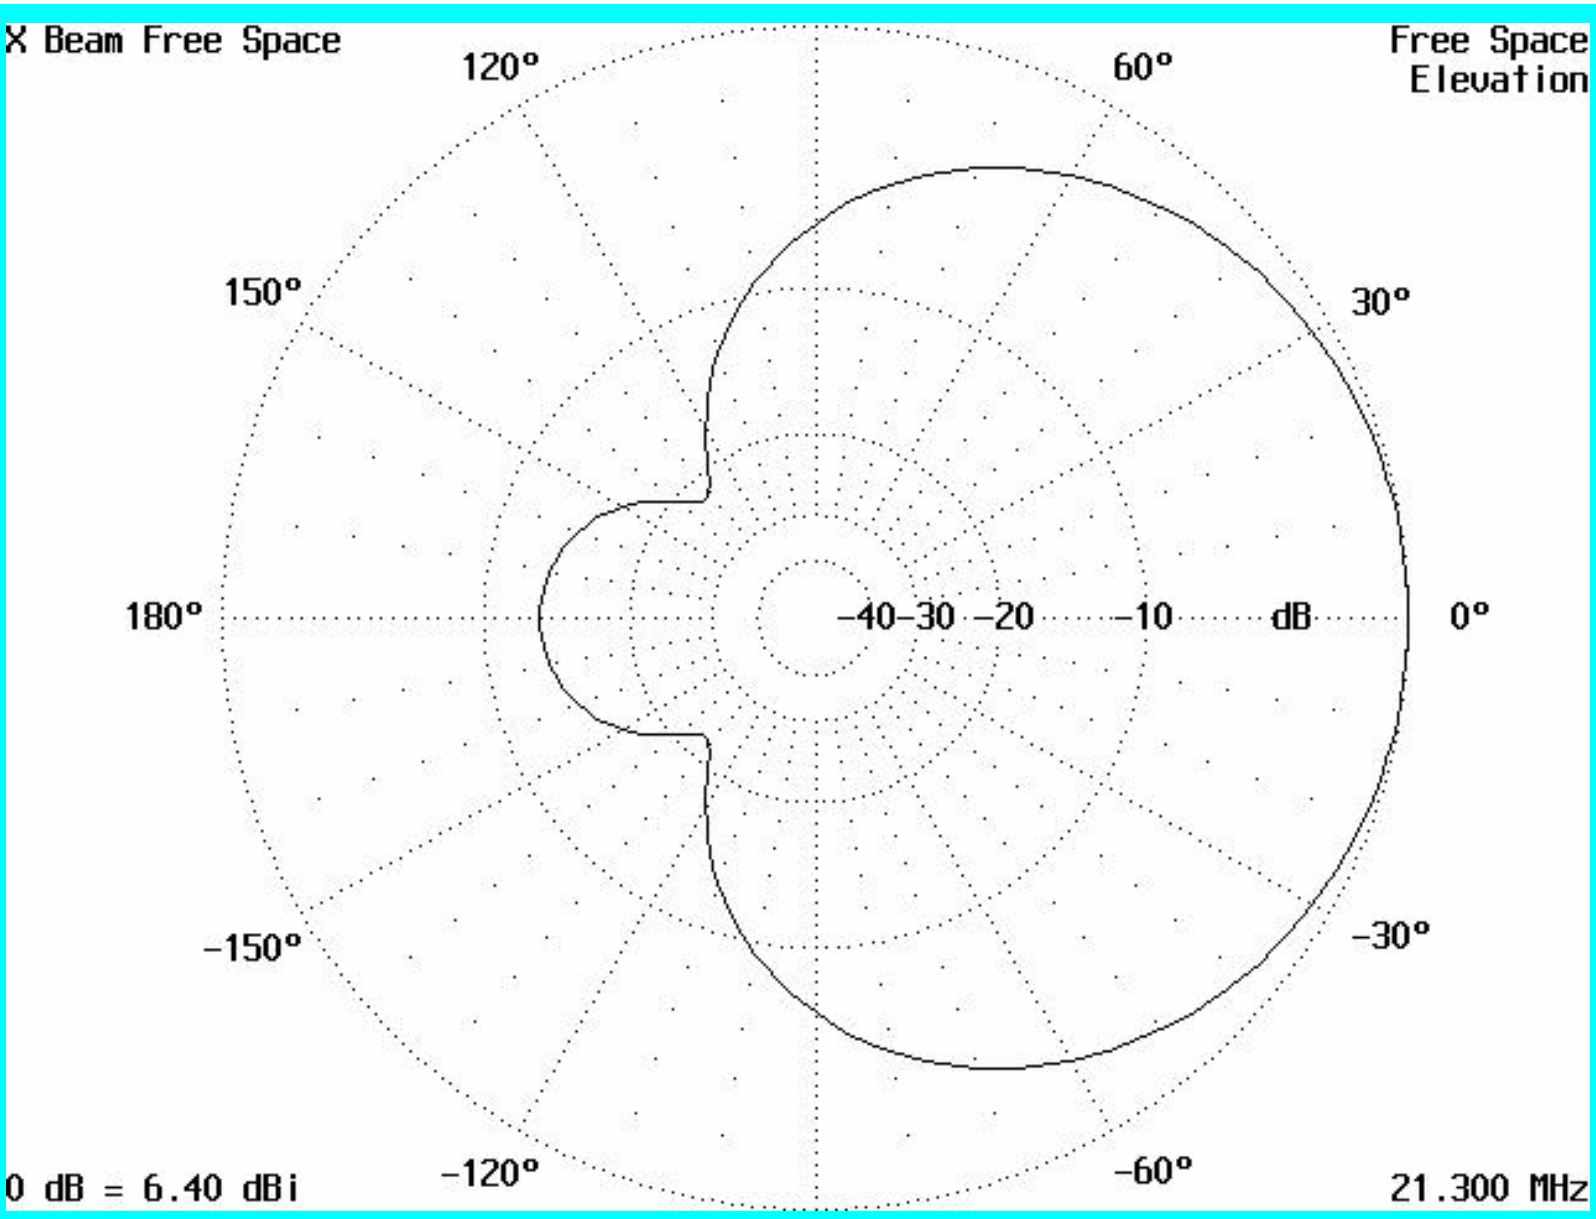

Figure 2
Elevation Pattern for X-Beam in Free Space

Note that the total gain is 6.4 dBi, not 6.0 dBd, and although the F/B ratio is about 13 dB, the side lobes are much worse (about 8 dB). The performance of the antenna looks a bit better when placed about 20 feet above the ground as indicated by the following two figures.

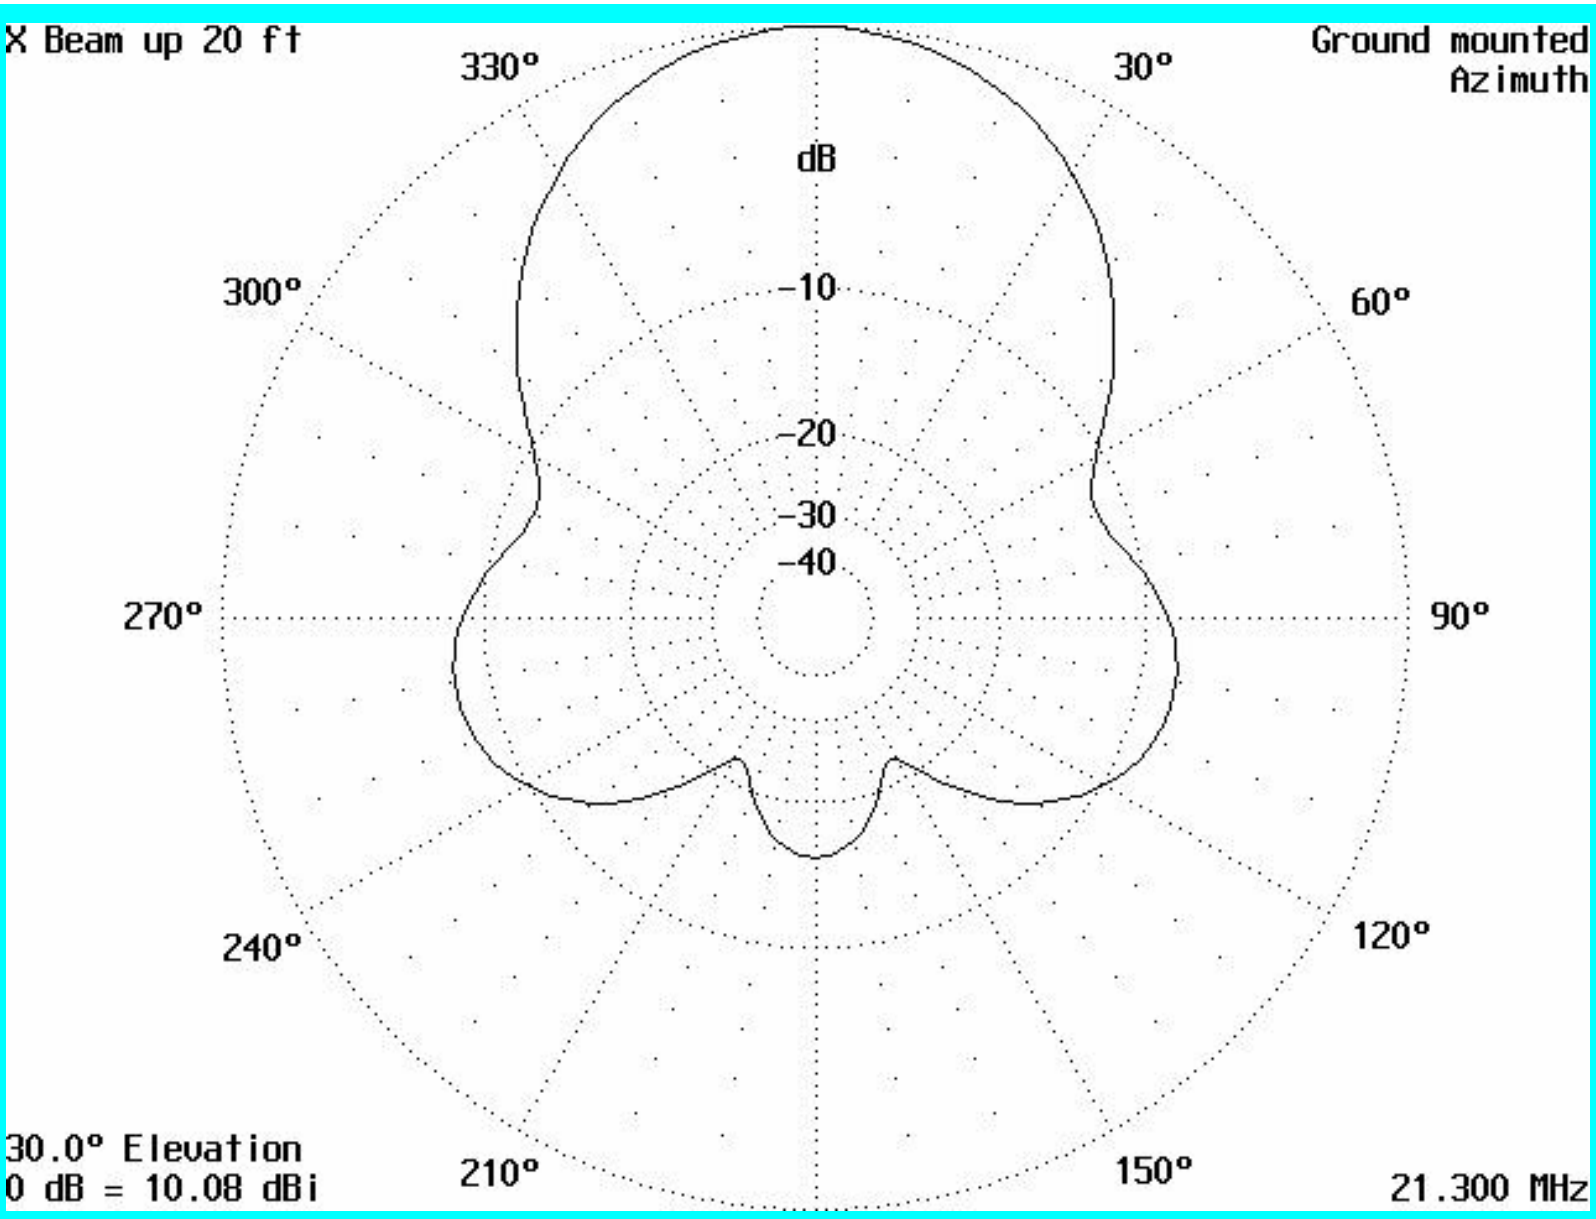

Figure 3

Azimuth Pattern of X-Beam Elevated 20 Feet Above Ground

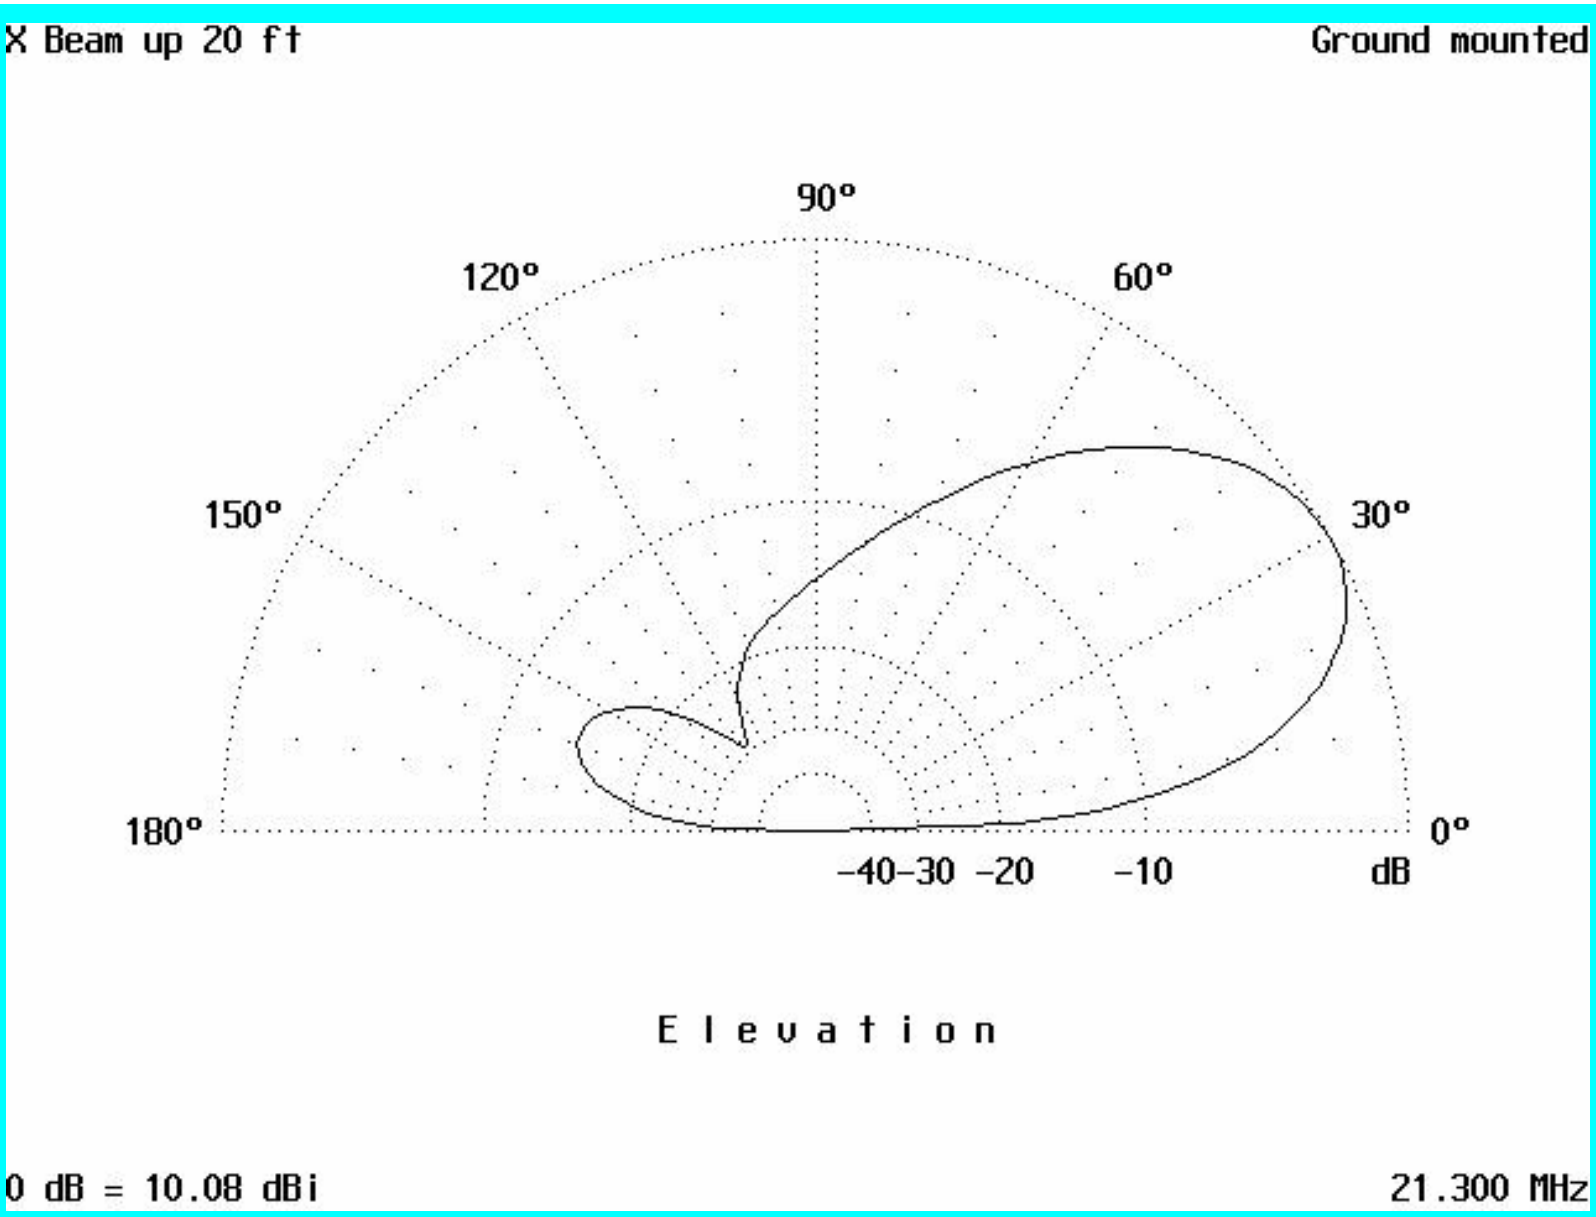

Figure 4
Elevation Pattern of X-Beam Elevated 20 Feet

Note that the gain peaks at a 30 degree launch angle with a peak gain of about 10 dBi or 8 dBd. So this is a fairly good antenna, but not quite as good as the Author indicates. The poor side-lobe level is perhaps the greatest deficiency of the X-Beam, however, it is relatively easy to construct, and portable versions based on telescoping sections of aluminum tubing are easy to transport and erect.

In this case, I'll only consider the design of a 15 meter version, because the 20 meter version requires aluminum spreaders 13' 9" long, and this length is larger than I can construct in my back yard, and the tubing size required is considerably larger than what can be considered as light weight and portable. The spreader (arm) length for 15 meters is only 9' 3" . The director tails are 4' 2", and driven-element tails are 4' 10". The sum of the tails is 9', and

the distance between the tips is sqrt(2) * 9' 3" = 13' 1", which leaves 4' 1" to be spanned by nylon line or cord. You will also need 13' 1" lengths of Nylon cord to span the tips in the front and rear to prevent them from pulling apart when the tails are added. The spreaders (arms) can be assembled from three standard sizes of aluminum tubing beginning with 1/2" OD #22 which has an ID of 0.444 inches. This 1/2" will accommodate 7/16" OD #18 tubing which has an ID of 0.339 inches. The 7/16" tubing will then accommodate 5/16" #20 tubing. I used 4' of 1/2", 4' of 7/16" and 2' of 5/16" tubing for each spreader arm with the first two overlapped by 6" and the outer one overlapped by 4". The hub adds an extra inch from the center of the mast giving a total distance to the tip of exactly 9' 3". The author never states wire size for the tails in the ST article, but in the Antenna Compendium article, he indicates #19 vinyl-covered wire was used. We used #20 vinyl-covered lamp cord by splitting it apart. Various light weight speaker cables work equally well. The directions for tuning this antenna are given in the pair of articles and should be followed in order to get best results. My experience with this antenna mounted about 18' above the ground is that the driving impedance is roughly 25 Ohms when properly tuned. The author indicates a good match with 50 Ohm coax, which probably means that some compromise in performance was accepted to get the good match. The driving impedance does vary with height above the ground.

Parts Required

Discussed above.

The Optimized Wideband Antenna

Yagis for 20m - 10m

by Nathan A. Miller
NW3Z
Penn State University

Hello again to every one that read the article I had posted here previously. I have updated all of the previous designs and have added some new ones that you may find interesting. In addition to the 48' boom yagi antennas, I have included a 36' boom 15m antenna as well as a 24' boom 10m antenna that work almost as good as their big brothers. Finally I have posted some pictures of these antennas; both at the K3CR and WP3R contest stations.

Notes regarding stacked installations of antennas:

There were originally two separate versions of the 48' boom 20m antenna: one was designed in free-space and worked well as a stand-alone antenna while the other was designed to operate stacked on a 175' tower. The reason for re-optimization in the stack was that the F/B of the original design was degraded when it was placed into the 6/6/6 stack. To improve the stacked F/B, I unfortunately had to sacrifice the excellent VSWR characteristics of the original antenna. In addition, the F/B of the individual stack-optimized antenna is not as good when it is used independently. The only reason the F/B was degraded is that there is a back-lobe generated at the same elevation angle as the main beam: for the 175' tower this is at 7 degrees. Other than this single lobe, the rear suppression of the stack is quite good. In short, I have been thinking that the small increase in stack performance is not worth the compromises in individual antenna performance.

For this reason, I show only the optimum stand-alone design in this article. I should note that any time antennas are stacked, there is the potential for serious effects on both the F/B and VSWR of the antennas. In general practice, yagis are never stacked closer than .7l. At the K3CR station, the 20m antennas are seperated by .85l which would allow the stand-alone designs to perform relatively well. The 15m antennas are seperated by 1.3l : there will eventually be 3 of the 15m antennas on the 185' tower. While a fourth antenna could have been added without problem, modeling showed that the increase in performance would have been undetectable. For the 10m installation, there will be 4 antennas on the 175' tower with a spacing of by 1.25l. Again, additional antennas could have been added but the performance increase was negligible.

This brings up another question. In the earlier article I posted to WWW.CONTESTING.COM, I mentioned the F/B problems encountered when stacking 6 four element antennas on a large tower. This method will produce a large forward gain but the side-lobe and back suppression will always be limited by the short boom antennas. While there are many advantages to installations such as this, such as the ready availability and low cost of short boom antennas, I still think a smaller number of high performance antennas will produce superior results with less mechanical complexity.

But no matter how good your antennas are, the key to a successful station lies in one simple thing…. RELIABILITY! In stacked installations, the importance of reliable switching and impedance matching systems cannot be over stressed.

Modeling 6 Long-Boom Yagis

L. B. Cebik, W4RNL

Over the last year or so, I accumulated designs for 5 different 20- meter Yagis with boom between 45 and 55 feet long and having either 5 or 6 elements. After the appearance of a preliminary version of these notes, a 6th was donated. All display an average free space gain from 14.0 to 14.35 MHz of over 10 dBi, with good front-to-back ratios averaging well over 20 dB across the band. It seemed to be an interesting project to model all 6 on the same versions of NEC (in this case, NEC-2 with Leeson corrections and NEC-4, using EZNEC Pro) and do some comparative assessment.

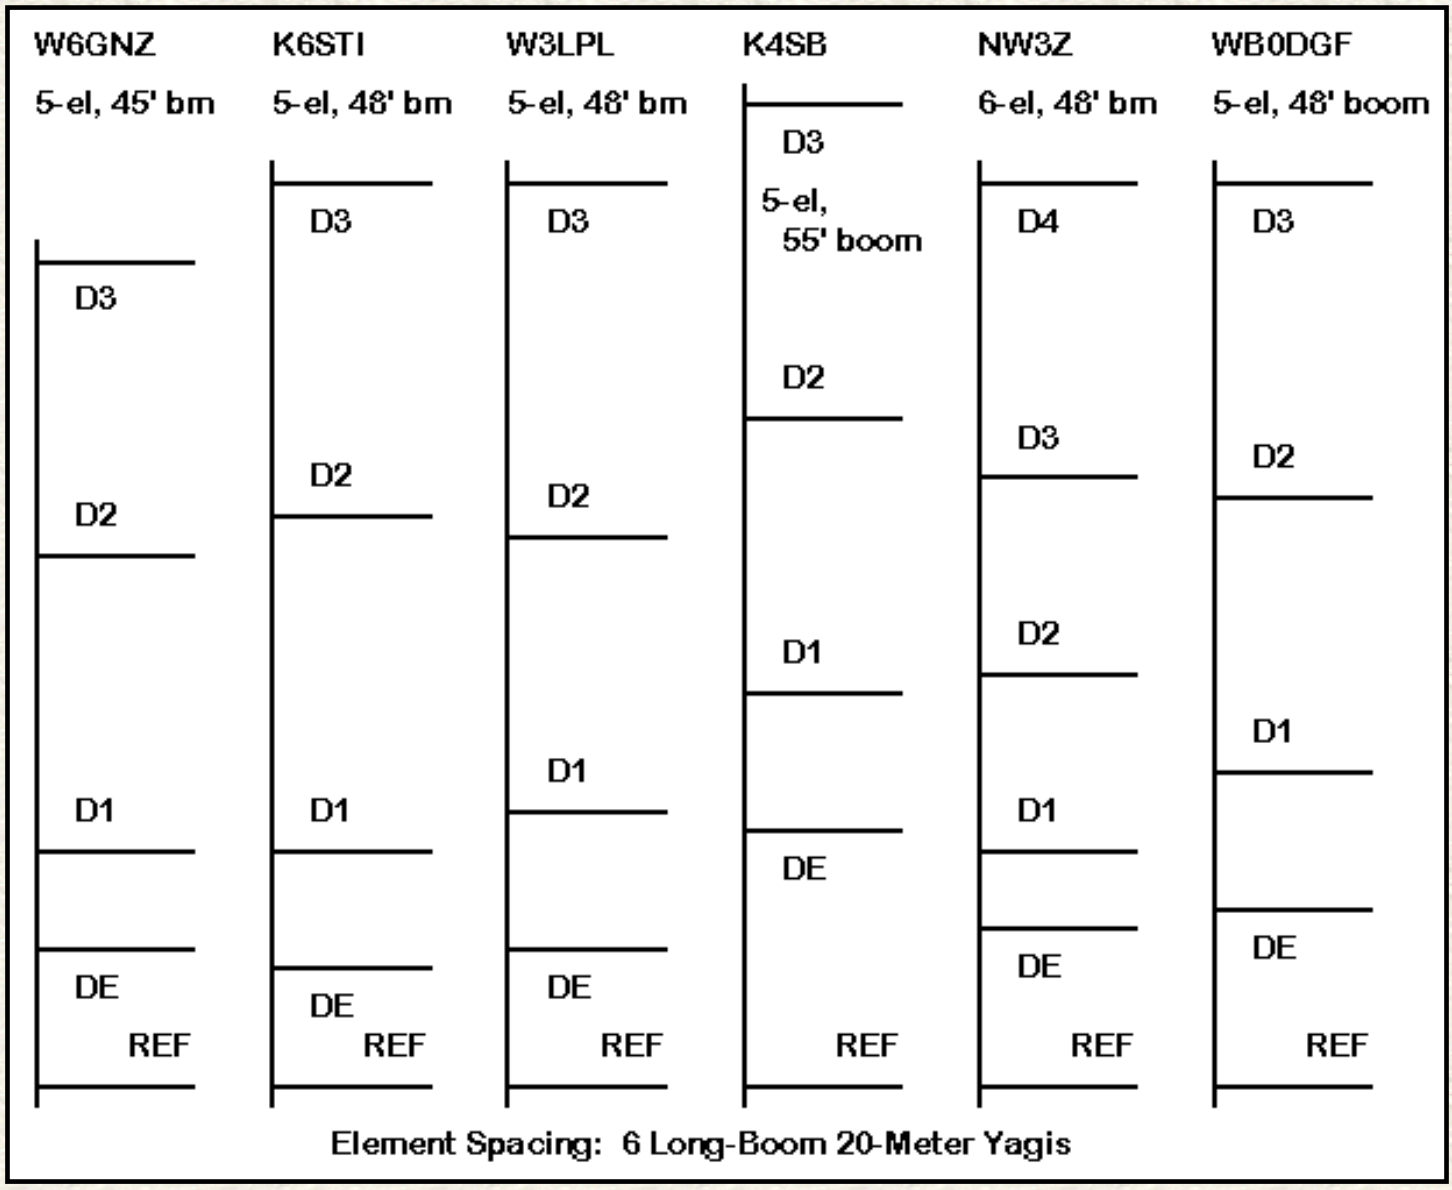
What actually emerged is a lesson in some of the difficulties in making such assessments. Some of those difficulties arise from limitations of the programs (and every version of NEC/MININEC has limitations). Others emerge from differences among models and specification sheets that cannot be resolved without additional data not at hand. Hasty modeling and simplistic conclusions can yield fog where clarity is desired.

The Six Beams

The six beams are the following:

- 1. A 5-element, 45' boom design by W6NGZ, published in *CQ* for October, 1996, p. 22.
- 2. A 5-element, 48' boom design by K6STI, published among the beams in YA, which accompanies the *ARRL Antenna Book*--this is a medium strength model.
- 3. A 5-element, 48' boom design by W3LPL, published on the World Wide Web.
- 4. A 5-element, 55' boom design by K4SB, originally developed in monotaper for 10 meters, modified for this study by me for a somewhat arbitrary element taper (used by permission).
- 5. A 6-element, 48' boom design by NW3Z, published on the World Wide Web.
- 4. A 5-element, 48' sent to me by WB0DGF and once published on the Hy-Gain web site as HG205XLB.

The beams are interesting for their differing design features, not the least of which is the choice in element spacing, as shown in the figure below.



Element Spacing: 6 Long-Boom 20-Meter Yagis

The K6STI has the lowest design feedpoint impedance, which is indicated in the reflector-driver spacing. The W6NGZ design aims for a higher feedpoint impedance and uses a correspondingly wider reflector-driver spacing. The W3LPL design has a comparable feedpoint impedance and hence a similar reflector-driver spacing to the W6NGZ design, despite the differences in boom length. These three designs are similar beyond the driver in that the directors are proportionally spaced, relative to each other. However, do not ignore the ability of D2 to affect feedpoint impedance. The WB0DGF design demonstrates how a different taper schedule may influence the required spacing for a design, since its reflector-drive spacing is greater than the K6STI antenna, but the DGF version has only a moderately higher feedpoint impedance.

The longest model (K4SB) tries for a direct 50-Ohm feed and uses the widest reflector-driver spacing. D1 is not especially different in spacing from the driver relative to the first three models. The truly different design is the NW3Z 6-element Yagi, which uses a moderately wide spacing between the reflector and driver combined with the closely spaced D1 to set the basic parameters of the antenna. However, D2 also plays a crucial role in setting the feedpoint impedance: at correct spacing, the feedpoint impedance is a good coax match; with D2 40" closer to D1, the feedpoint impedance drops to the 25-Ohm neighborhood without seriously affecting the gain and front-to-back characteristics of the antenna.

These notes are not designed to recommend one design over another, either overtly or tacitly. That would require a detailed construction analysis plus the resolution to some modeling questions which I intend to leave open.

Some Modeling Preliminaries

Unfortunately, modeling Yagis within the amateur community has become somewhat of a casual process, without the care and attention to detail used by serious designers, such as the author's of the designs shown here. Whatever the source of the design--YO, Yagi-Max, or simply manual design on AO or EZNEC--evaluation of a design requires good modeling practice.

NEC-2 without a correction factor cannot accurately model a linear element using a tapered-diameter schedule. For that reason, some implementations of NEC-2 include Leeson or similar corrections, which substitute a carefully calculated mono-tapered element for each tapered-diameter element in an array. However, it is possible to disturb the substitute element by paying too little attention to segment length equality. Especially at current nodes (the center of near-1/2 wl elements), segment length needs to be equalized along a linear element element (whether it is a single dipole or a part of a larger array). Since the Leeson corrections modify the length and diameter of a wire but not its segmentation, segment lengths should be equalized in advance. This factor plays an especially important role where the designer may place a very-large diameter short segment at the element center to simulate boom-to-element mounting plates and hardware. Often--as with the K6STI and WB0DGF models--the length of this segment sets the approximatele length of segments in the adjoining sections of the element.

Therefore, for the models at hand, segmentation was increased to yield segment lengths between 8" and 12", depending upon the model. The K6STI and WB0DGF models use the shorter lengths due to their center "lumps." (Note that the WB0DGF model omits the center "lump" on the driven element, while the K6STI model preserves it.) The W6NGZ model uses 12" segments, because they came out most even with the element sections in the design.

Other beams used 8" (W3LPL) or 10" (K4SB, NW3Z) per segment for similar reasons: the chosen segment length turned out to be the best way to achieve roughly equal length segments on the most elements. Despite best efforts, some variations inevitably result. Designers will always have, for any segment length chosen, a section that comes out to be n.5 segments long. Some will choose center sections that for any reasonable segment length seem to require an even number of segments. Adding extra segment is necessary for the driver--and hence, for the other elements in order to keep segment junctions as well aligned as possible.

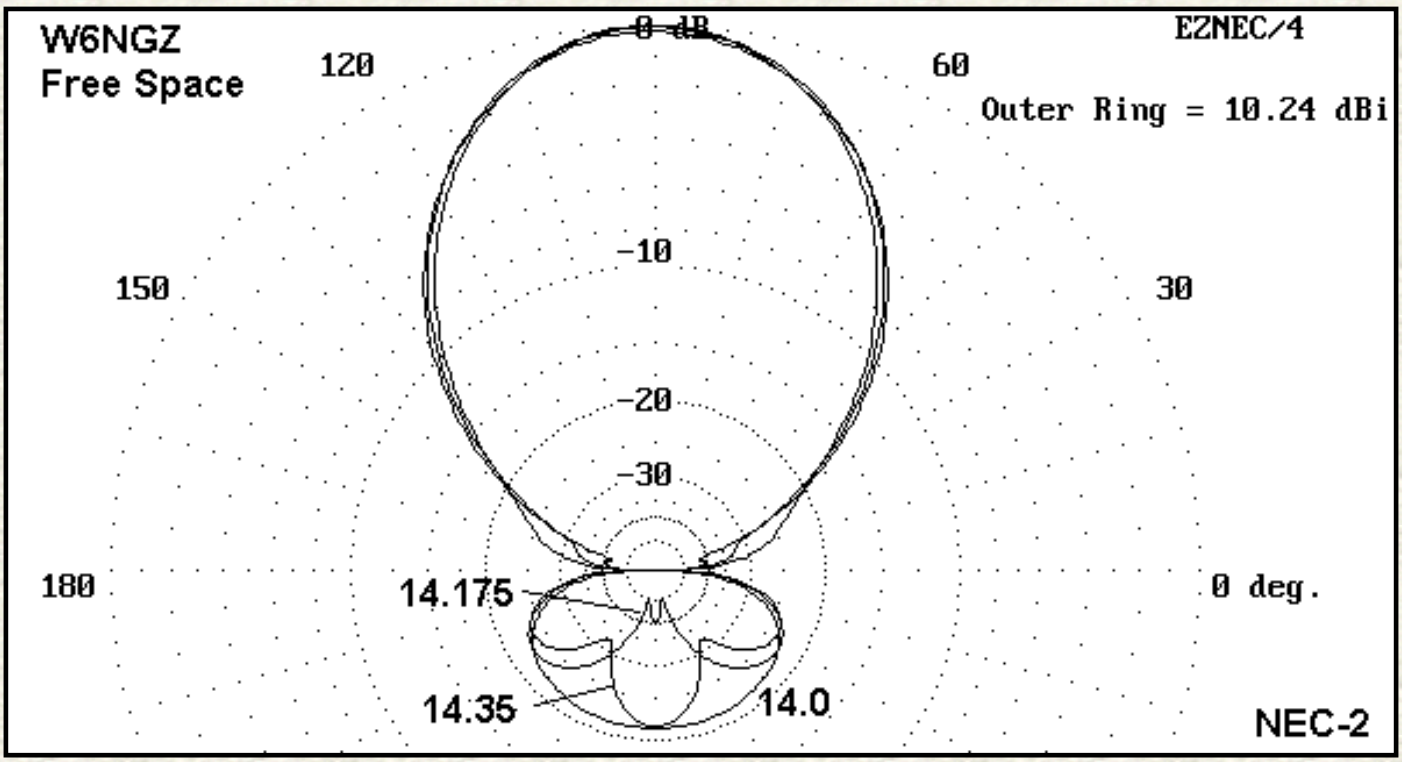
NEC-4, by its initial reports, overcomes the NEC-2 weakness with tapered-diameter elements. Unfortunately, the initial reports have proven overly optimistic. Although NEC-4 is a vast improvement over uncorrected NEC-2, it falls short of the standard set by NEC-2-corrected, which also correlates with MININEC results. (MININEC does not have a tapered-diameter element problem, although it has other limitations.)

The NEC-4 limitation is somewhat minor for general purpose modeling, unless the element shows too large a diameter change between wires in the element, especially close to the current node, with the driven element the most crucial. This condition exists with the K6STI model.

In order to show the modeling differences between NEC-2-corrected and NEC-4, I have modeled all 6 beams in both programs via EZNEC Pro. (I could have applied the Leeson equations to the NEC-4 runs, but that would have produced the same results as the NEC-2 runs.) I graphed data comparatively for NEC-2-corrected and for NEC-4, to include free space gain in dBi, 180-degree front-to-back ratio, feedpoint resistance, and feedpoint reactance. SWR data is also shown wherever the source impedance is close enough to 50-Ohms to make such data relevant. All graphs run from 13.8 to 14.4 MHz in order to show downward slides of NEC-4 curves.

Let's look at the designs individually.

The W6NGZ 5-element, 45' boom model



The W6NGZ model is the shortest of the five, but it sustains a free space gain of over 10 dBi across the band, with better than 20 dB front-to-back ratio everywhere on 20. The element taper is from the *CQ* article, and it contains no compensation for element mounting plates at the element center. Within these constraints, NEC-4 and NEC-2-corrected tell very similar graphical stories about the beam. Differentials are marginal at best, although a wee bit of excess gain estimation and a slide of the curves downward in frequency are both evident.

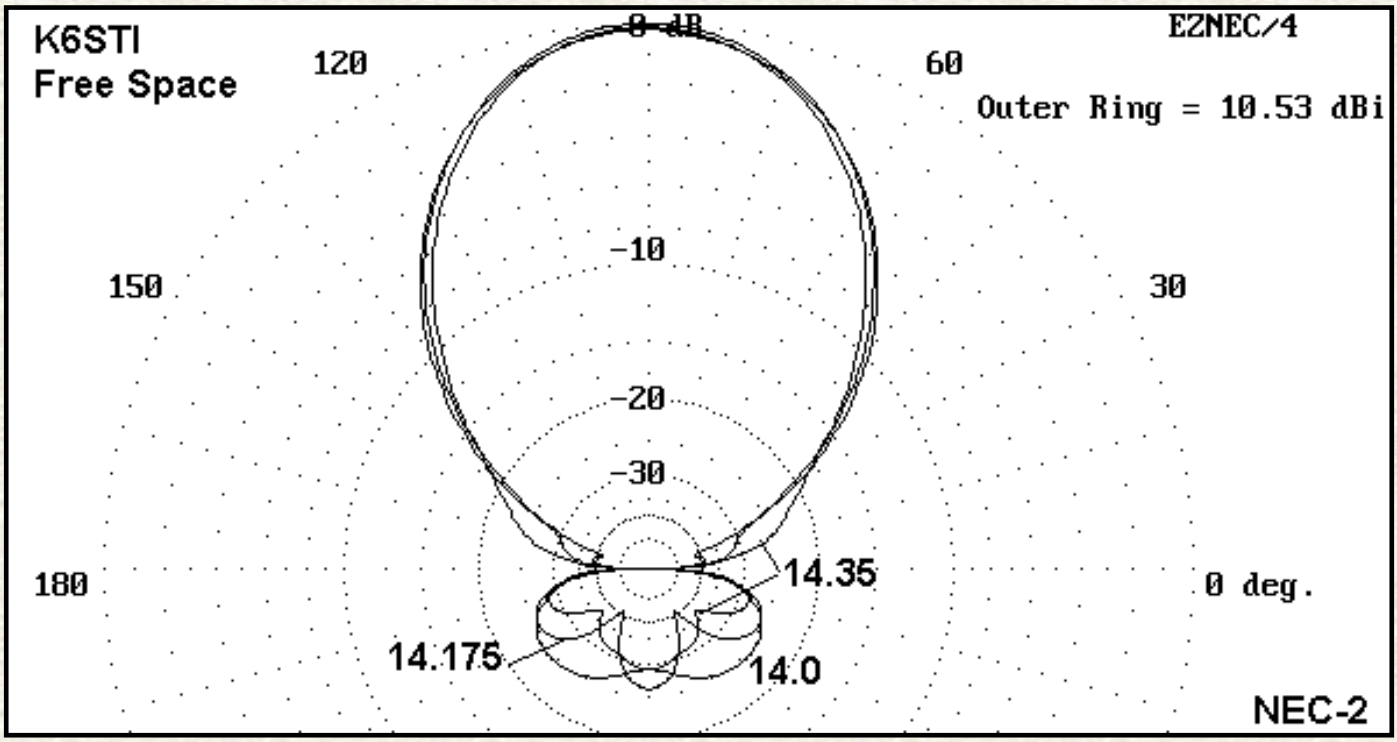
As the graphics make plain, the antenna close being a very good match for 50-ohm cable.

The K6STI 5-element, 48' boom model



The K6STI design, with its center "bulge" in place, models quite well in NEC-2-corrected. It also displays very well the weakness of NEC-4 in dealing with the large change of diameter so close to the source or highest current point on the elements, despite extensive efforts to equalize segment lengths. NEC-4 gain data is almost a full dB higher than the more reasonable NEC-2 data, with a curve displacement lower in frequency, which also shows up on the front-to-back graph. The source resistance and reactance graphs show a similar slide, with the resistance values low in the NEC-4 run. Since current, impedance, and far field strength are related, the coincidence of these value differences from those in the NEC-2 run are not unexpected.

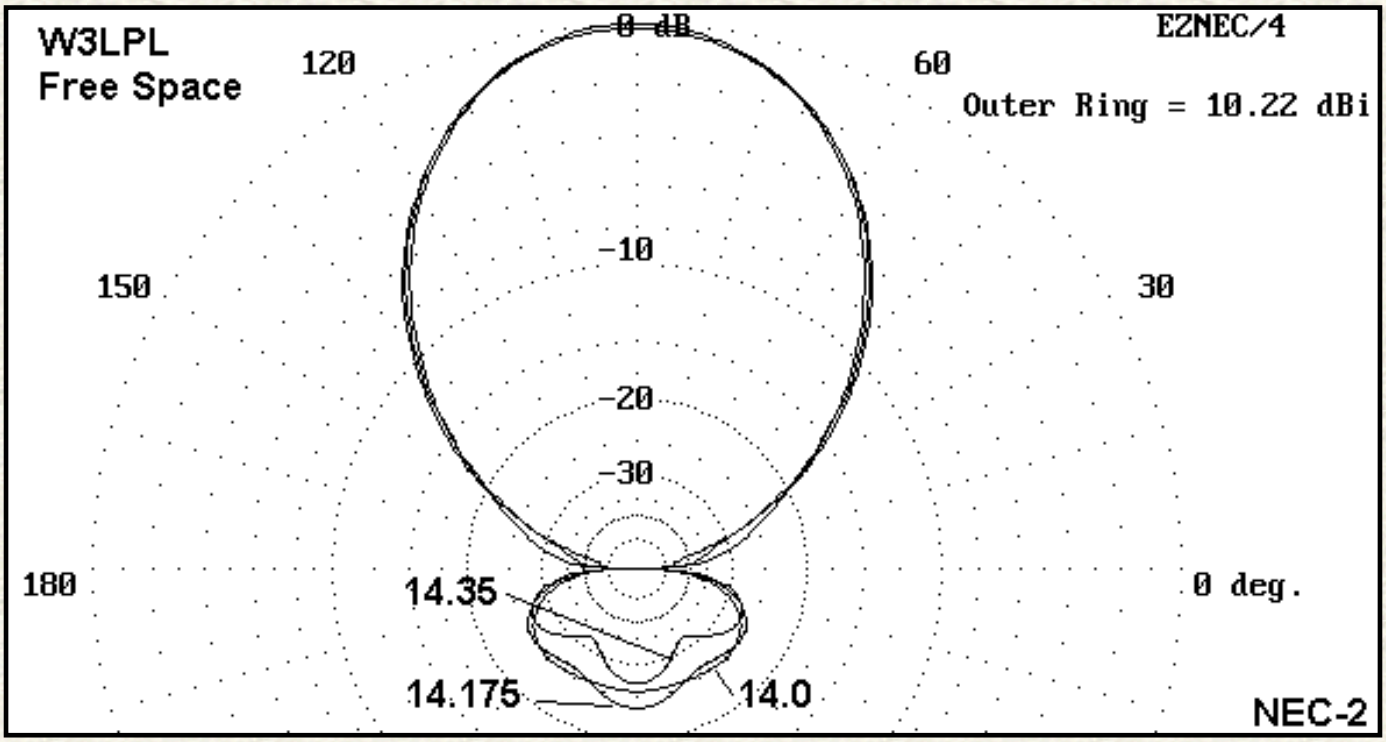
No SWR curve is shown, since the antenna is designed for a matching system such as a beta/hairpin match.

The W3LPL 5-element, 48' boom model



The W3LPL beam was designed for use with a Tee match, which neither NEC-2 nor NEC-4 can physically model accurately. Interestingly, W3LPL designed the antenna with non-conductive boom-to-element mounting plates in mind. Nonetheless, the curves--plus a look at the antenna characteristics just below 14 MHz--suggests that there is an approximate 50 kHz offset in frequency, with the elements in the model again playing short in the NEC-4 run, relative to the NEC-2-corrected run. Gain is still a little high in NEC-4. Given the W6NGZ model runs, this much difference is somewhat unexpected. The chief difference in the modeled data is that the W3LPL antenna shows considerable and constant inductive reactance, due to its intended use with a Tee-matching system.

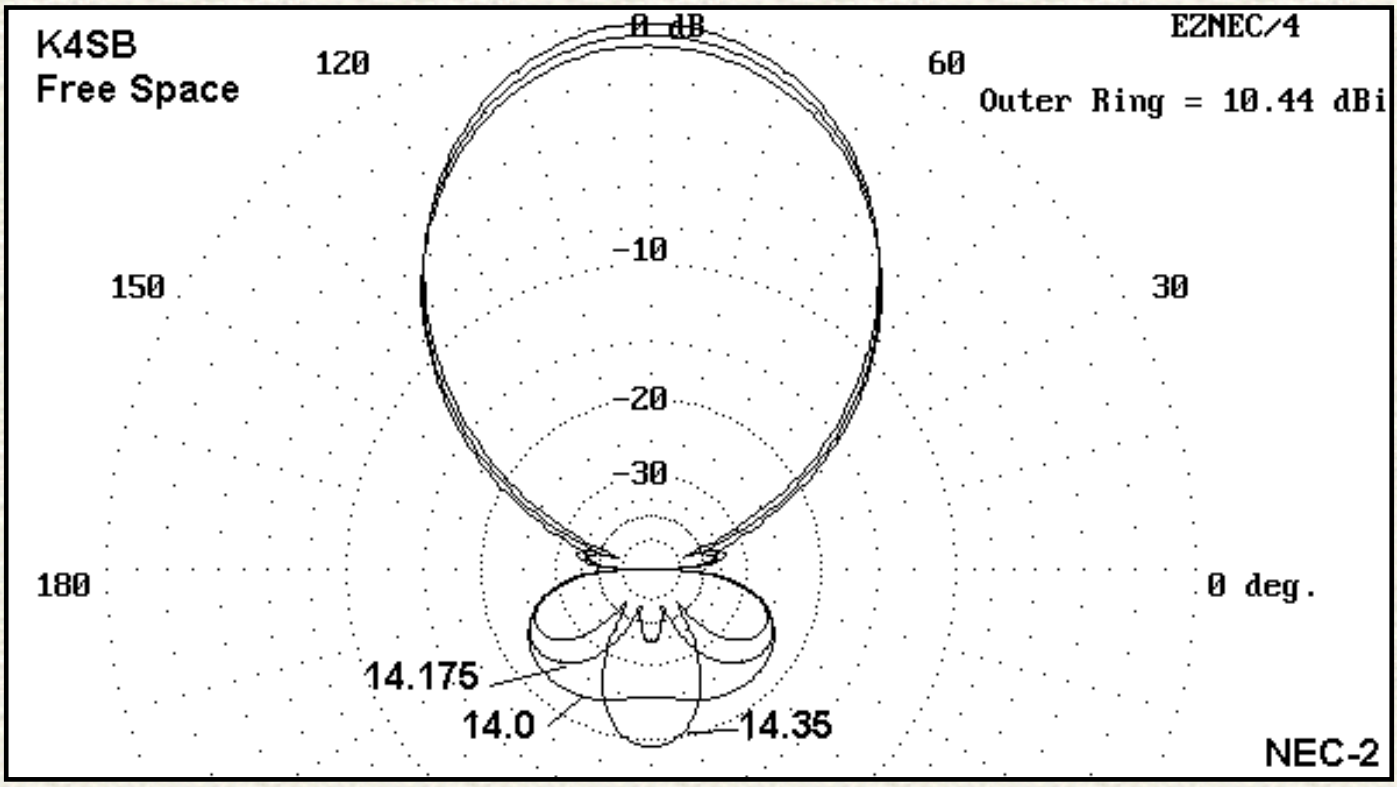
I have included the 50-Ohm SWR curve for the W3LPL antenna because it makes a good contrast with that of the W6GNZ antenna, even though the antenna designer specifically introduced the inductive reactance in the driver to set up conditions for a no-capacitor Tee match system for a 200-Ohm feed impedance. Shortening the driver to resonance in an attempt to reduce the SWR will result in a decrease in the resistive component so that no great improvement actually occurs. However, those wishing a direct 50-Ohm feed without a Tee match may wish to consider a beta match using a shunt capacitor, instead of the usual shunt inductor which is applied when the driver element is capacitively reactive. A capacitor value of about 90 Ohms reactance (about 125 pF) with sufficient voltage and current handling capabilities would come close to serving the need.

The K4SB 5-element, 55' boom model



I received this model from K4SB (with whose permission it is used here) in simplified form, using monotapered elements on 10-meters. I frequency-scaled it to 20-meters and then assigned it an element taper schedule, readjusting the element lengths until it closely approximated the monotaper performance. The antenna shows the greatest gain and front-to-back differential across the band of all the models, and this exhibits the effects of using wide reflector spacing alone to raise the feedpoint impedance of the beam.

This beam is for me simply a modeling exercise and does not take into account any variations in building technique. It does not compensate for the effects of boom-to-element hardware. Considerable model tweaking would likely be required before construction.

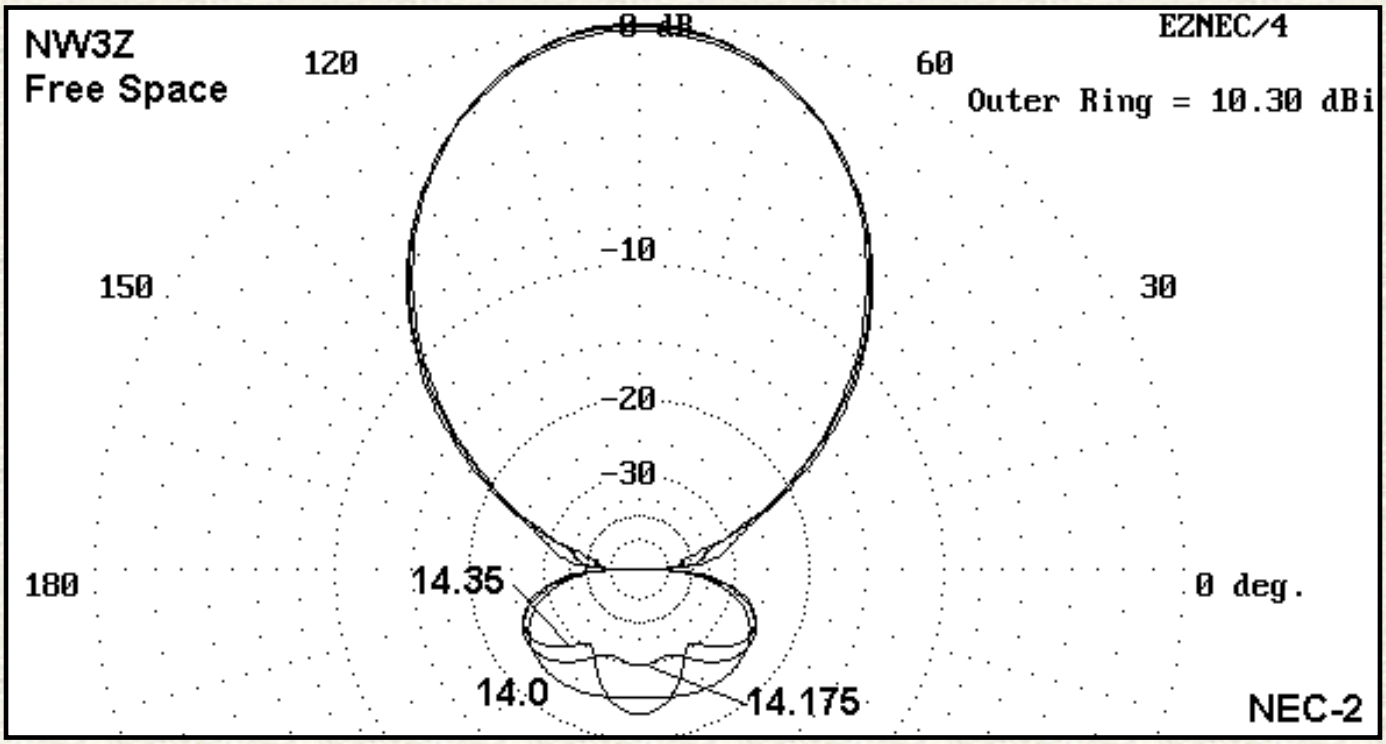
The SWR curve is quite good. There is a significant variation in reactance across the band, to go along with the variations in gain and front-to-back ratio, although the beam demonstrates close to the optimum of what may be achieved using refelctor spacing alone to determine a 50-Ohm feedpoint match.

The NW3Z 6-element, 48' boom model



The NW3Z design adds a director close to the driven element. Along with the spacing of director D2 for impedance control and the spacing of the remaining directors for performance characteristics, this design provides a very tight near-50-Ohm feedpoint impedance with very little variation in other antenna performance characteristics across 20 meters. Indeed, everything remains stable for a little ways below the lower end of 20 meters.

As with all other designs, NEC-4 tends to overestimate gain and move the performance characteristics lower in frequency relative to NEC-2 curves. Since this model uses a 96" constant diameter center section in each element, the effect is not too extreme, but still greater than for the W6NGZ design.

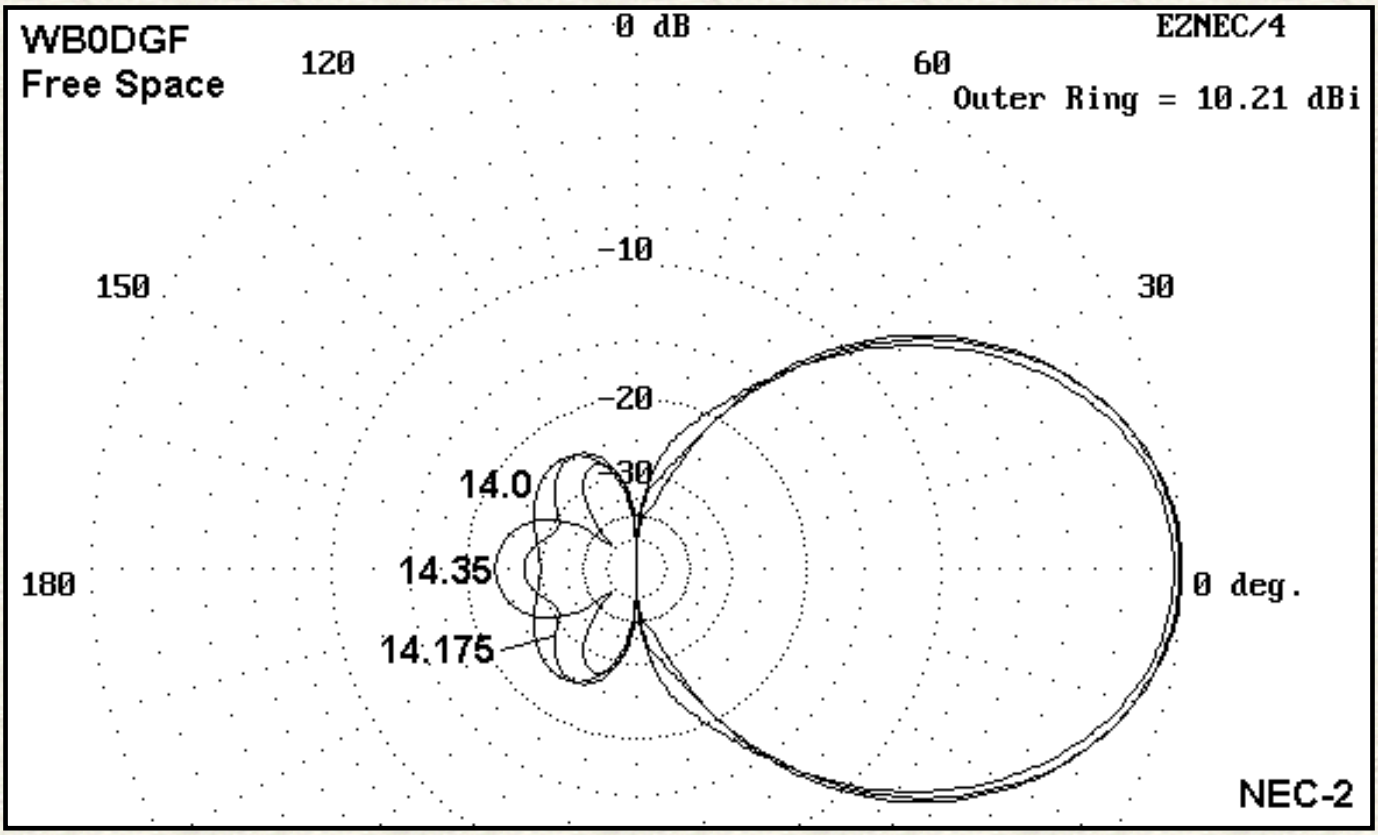
Beware of misreading the steep SWR curves: first read the axis values. Only then can you compare the numbers with those appearing in the other beam graphs.

The WB0DGF 5-element, 48' boom model



The WB0DGF design, provides an interesting contrast to both the K6STI and the NW3Z designs with respect to modeled properties. It contains center "bulge" sections that limit segment length to 8". However, these occur on only the parasitical elements. Moreover, the design uses a wider reflector spacing than some of the other designs. The result is a far less extreme overestimation of gain, but a significant shift in the NEC-4 curves lower in frequency than the NEC-2 curves. These phenomena are clear on all four of the graphs.

Since this antenna design was set up for potential use with a beta match system, no SWR curve is shown.

Conclusions

Because of the open questions left along the way, no evaluative assessment is warranted by this exercise alone. However, two reminders are in order.

1. The beams do reveal something of the broader aspects of large Yagi behavior in the means we use to design specific feedpoint impedances while retaining the highest levels of gain and front-to-back performance. Study of the spacing sketch alone (made more precise by the EZNEC Pro file descriptions appended to this note) may give some insight into future Yagi design directions. Yagi design innovations are far from exhausted.

2. Modeling comparisons are not to be undertaken lightly or hastily. Analyzing the foundations of received models as well as those inherent in one's own creations is a necessary step if models are to be compared against some set of design or analysis goals. It would have been very easy to see two of the designs above as simply inadequate to cover the entirety of 20 meters by looking solely at NEC-4 curves, when what is more likely at work is a frequency offset. Add to this the limitations of each core used to model the structures unambiguously, and the simple conjunction of models would become a disservice to understanding the antennas involved.

Within these handicaps, the comparison of some of the best of extant long- boom 20-meter Yagi design provides an interesting and potentially productive exercise. It can assist us in understanding both antenna design and antenna modeling just a little bit better.

TEARA - The Triangle East ARA

3509 Rolesville Road; Wendell, NC 27591-9135

WAIT!! **If you came to this page directly from a search engine or link, and don't see a menu to the left and top of this page, you're missing out on hundreds of pages of amateur related info on our server. CLICK HERE, or click the large NC State Logo at the top, to move to the top of our site (which automatically loads this page). From there, you can select hundreds of pages of information on our server, complete with all of our site navigation tools. Enjoy your visit with TEARA!**

The TEARA Email Reflector

An Email Group for Triangle area Amateurs!

The TEARA email list is primarily for TEARA (Triangle East Amateur Radio Association) members, and those interested in membership in central NC. It is specific to this local amateur radio club for the purpose of distributing club bulletins and promoting communication within the club membership.

The list can be subscribed to as a normal list, or as a digest. Here is the subscription info:

- **To subscribe to the list through email, send an email to: teara-subscribe@yahoogroups.com**
- **To unsubscribe to the list through email, send an email to: teara-unsubscribe@yahoogroups.com**
- **To switch your subscription to normal, send an email to: teara-normal@yahoogroups.com**
- **To switch your subscription to digest, send an email to: teara-digest@yahoogroups.com**

Once you're subscribed, send your messages to: teara@onelist.com and everyone who is subscribed will see them.

[Digest Version]

Now, having said that, I wonder how many of you are aware that this list is available in "DIGEST" format? The DIGEST format takes every day's email, rolls it into a single email, and sent it to you at once, rather than a bunch of individual emails. Personally, I prefer individual emails so I can easily see the subject and reply to them that way, but lots of people like the digest version for it's compactness. If you want to be set up on the digest version, drop me a note and I can make the change. You can also change to either normal or digest versions yourself by doing this:

- **To switch your subscription to digest, send a blank email (with nothing in the subject or message body, and no signature) to: teara-digest@yahoogroups.com**
- **To switch your subscription back to the normal delivery, send a**

blank email (with nothing in the subject or message body, and no signature) to:
teara-normal@yahoogroups.com

[TIPS for using the Digest Version]

- **1)- When replying to a digest message, be sure to take a look at the subject line. It'll usually state the digest # it's replying to, rather than the individual message within the digest. Change the subject to reflect what ever topic you're replying to, so folks will know what the message is about.**

- **2)- When you click "reply" to a Digest message, everything in the digest will be captioned or quoted as part of reply. Be sure to highlight and delete the rest of the digest that doesn't pertain to your specific reply, so the email (if you're clicking "reply") won't contain a bunch of other messages. That'll also help keep the email as small as practical.**

[ARCHIVES]

The TEARA list has mail archives of all the traffic on the list. These can be accessed with a web browser like Netscape or Internet Explorer. This could be helpful if you're looking for a missed note, or maybe at another terminal somewhere (public library, work, friend's house, etc) and want to check in to see what's going on. There is also an archive storing every digest of every message ever sent on the ncvulcan list.

- **To get to todays messages, click --> HERE<-- !**

I hope these tips improve or supplement your enjoyment of the TEARA list!

Welcome to VE7CA's Antennas Page

Since becoming an amateur radio operator I have built a lot of antennas. I have had several articles published where I described antennas that have served me well. The above menu bar will take you to the articles.

December, 2003

One hour before the 2003 CQWW CW Contest, I decided to raise the telescoping tower that supports my modified Telerana LPDA, 30/40 meter dipole and 6 meter yagi. Just before it reached max height the tower collapsed into its self and came down with lightning speed. With the rapid deceleration and then sudden stop, the outer ends of the booms and fiberglass spider supports kept moving downward and broke a couple of the poles. The damage is evident in the photo below. This is a reminder to those who own crank up towers, check the cable, cable fasterners and winch brakes regularly!

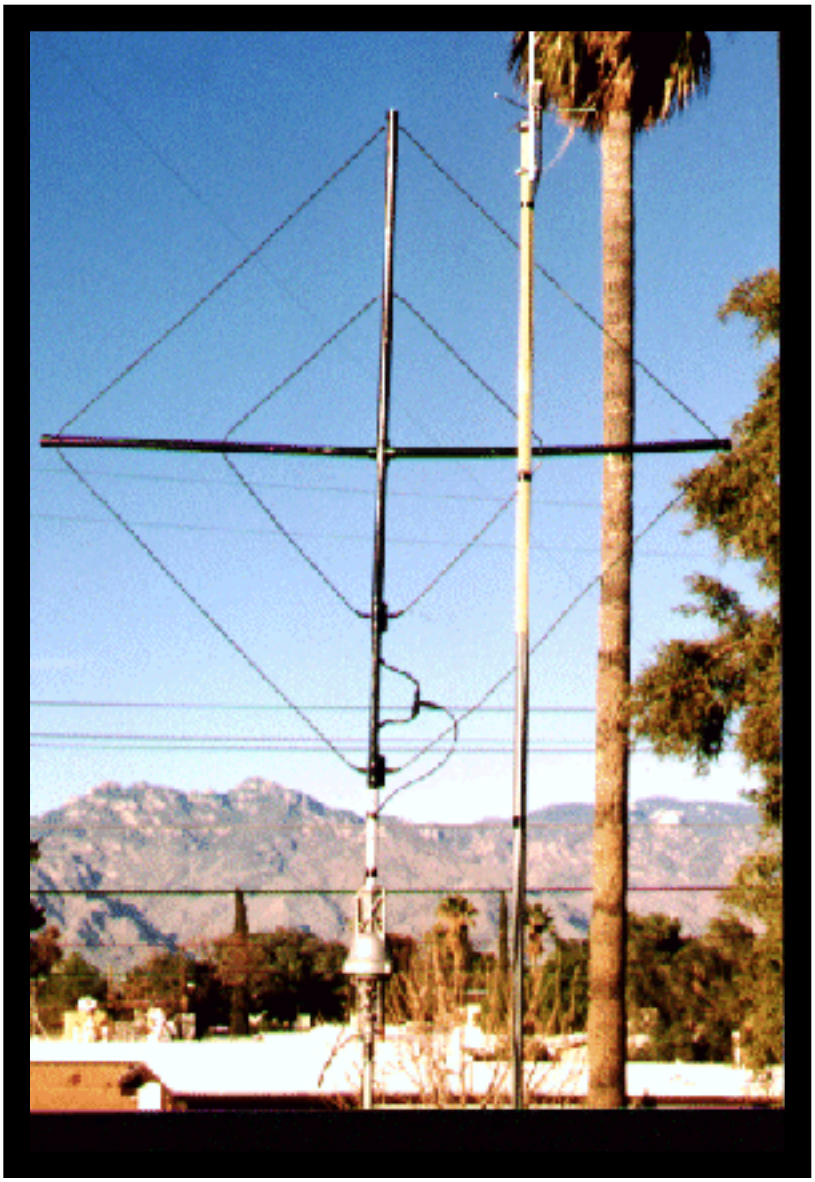
Fortunatly, no damage to VE7CA or the skylight through which I was watching the tower as I operated the switch that controls the electric winch.

August 23, 2004

After lowering the tower to determine why the tower collapsed, I found that the raising cable broke where it entered the electric winch. Why it broke I have no idea. There was also damage to the bottom ends of the each section where the winch cables are attached. I am in the process of repairing the damage and hope to have the tower up by the end of September 2004.

I am also in the process of designing a new antenna to replace the Modified Teleranna. Since I have been concentrating on QRP contesting of late, I have decided that I need an antenna with higher gain in the CW portions of 20, 15 and 10 meters. As well, gain on 40 meters would be much appreciated. I will keep you posted on my progress as I near a new design.

160/80m Coaxial Receiving Loops



NOTE: As of January 1, 2004 I must raise the price of my receive loops. As that my construction costs, have risen.

Several years ago a friend of mine (W7AE) and myself became interested in low band dxing. Lacking room for a beverage receiving antenna, we constructed several loop receiving antenna to see if we could find a suitable low /lower noise receiving antenna.

W7AE built the first loop for 160m following plans laid out in the ARRL Antenna Handbook. Encouraged by the results I built one for 80m. I found that with a proper pre-amp, such the Palomar series, or Ameco's PT-3 there was a significant lowering of noise, but the signals that I was unable to hear on my sloper now were quite workable using the receiving loop. For the past several years, we experimented with several different configurations , including a circular, and square loop. We found that the diamond configuration worked the best.The 80m version requires a pre-amp to bring the signal up to an acceptable quality. We've found that there is a one to two s unit difference (depending how high you set the gain on the preamp)in the lowering of noise. There have been several times that the loop has made the difference between working a DX station or not hearing him on my sloper.Though the antenna is not a beverage, we've found it to be a good alternative.

Click Here If you want me to construct one for you.

Click here If you wish to build one yourself.

Low Band Links (Presently under reconstruction.)

The latest news, is that now I can accept Paypal. Click on the link that says "If you want me to construct one for you" for more details.

Please note that there is a new e-mail address and price increase on the 160/80m loop. (Component prices seem to be going up.)

Super Linear - Loaded Inverted V

[Home] [Our Members] [Our Club] [Greater Buffalo Hamfest] [Ham Radio Information] [Ham Radio News] [Contact US]

[Standard Dipole Construction] [Super Loop Antenna] [J - Pole] [Pocket J - Pole] [Quickie Vertical]
[Super Linear - Loaded Inverted V]

The KGØZP Super Linear-Loaded Inverted V

How do you fit a full length 160 meter antenna into a 40 foot deep yard?
Install the KGØZP Super Linear-Loaded Inverted V, of course!

The Super Linear-Loaded Inverted V allows you to select your two favorite and most used frequencies as band centers, and offers excellent bandwidth as well.

The designers installation centerpoints are set at 1.840 the center of
the DX window or calling frequency and 1.875 at an SWR of 1.1-1
The bandspread at 1.5-1 is 20 kc at each center or
40 kc to an SWR of 2-1

The linear-loading section is mounted near enough to the ground that
you can easily install or remove precut pigtails using an alligator clip
to move the center point temporarily to make that sked, or you
can tune the whole 160 meter band with a simple antenna tuner.

The formula for construction is the same as for any dipole 468/fMhz
and the design will work equally well on 80 or 40 meters.

Reader Please Note: The photos on this page are greatly compressed to insure quick downloading.
The link accompanying each photo will cause the uncompressed full size photo to download.

It would be impossible to show an overall view of the whole antenna system in such a way that you could see the wires.

With that in mind, I have taken a couple of daylight pictures as well as flash night pictures which allowed me to highlight the wires against a black sky.

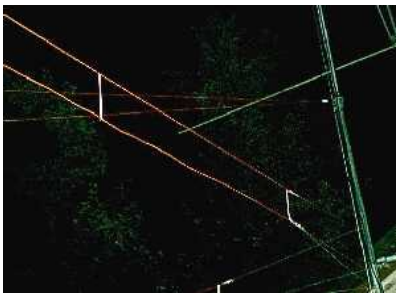
Lets take a thumbnail look at a daylight view of the Rohn 50 foot push-up pole utilized for this installation.

This is quite a busy photograph, so I will name the items in descending order to help pinpoint the areas relavent to the Super Linear-Loaded Inverted V.

The white stick at the top extending off the upper edge of the photo is a Diamond Tri-bander, model X3200A, fed with 9913 coax.
Directly below the tribander is the first guying ring. This is a dummy ring is used to ground and hold the upper wire of a Wermager type Broadband Sloper. In the full sized photo you can just barely see this wire extending left forward.
The highest of the three actual guying rings (second one down from the top) is at the 40 foot high point on the tower, a pulley is connected to this guying ring and through it is threaded a high quality flagpole rope. This rope can be used to raise and lower the balun for experimenting with different antenna designs, without changing the position of the push-pole.
The Super Linear-Loaded Inverted V, the topic of discussion is connected to this balun. The tension on the wires is so great that it holds the balun outward, the line descending from the bottom of the balun is Super Mini-8 coax. The pull of the Inverted V's two antenna wires is offset by two guywires on the other side of the guying ring. I have a wide yard and could keep the apex slightly wider than 90 degrees.
The next guy ring down is at the 30 foot height point and has nothing more three guy wires.
The lowest guy ring visible in the photograph is at the 20 foot level, and is the feedpoint for the Fan portion of a Wermager type Broadband Sloper originally used on 160 but now cut for 80 meters. I would like to mention again that the upper wire of the Wermager type Broadband Sloper is the wire grounded to the push-pole at the dummy guy ring at the very top. The other end of this wire is tied to the same location as the guy wire coming from the 30 foot guy ring, which places the metal guy wire directly between the driven Fan and the grounded sloper element of the Wermager type Broadband Dipole.

This photo is a view showing the East outbound leg of the Super Linear-Loaded Inverted V. In the upper left of the photo, you can see the single sloping wire descending from the balun. The two horizontal wires below comprise part of the Linear-Loading section.

The remaining photo's were taken at night using a flash, then enhanced to make the wires more prominent.



In this first photo, you can easily see that the Linear-Loading section is a good distance away from the push-pole. I used a distance of 5 feet in this installation, but you can reduce this distance to 3 feet if necessary. The vertical spacers are drinking straws, one nested inside the other for greater strength, a nylon tie line is fed through the center of the straws.
The upper tie off lines are located 1 foot above the standoff mounted to the eave. The lower tie off lines should also be located at or just above the standoff. Original twine used during initial setup is still visible and should have been removed before taking the photo.

The white insulator some 5 feet above the linear loading section is the feedpoint for the Fan portion of the Wermager type Broadband Sloper.

SPECIAL NOTATION: The upper wire and the lower wire of the linear-loading section are connected at this end only. This will be described in greater detail in the construction notes section.

These last two photos show the East and West outbound ends of the Super Linear-Loaded Inverted V.

If you look closely, you can see the pigtails wrapped around the lower nylon guys.

In the photo on the left of the East outbound end, the wire from the balun down to the insulator is not visible. The upper guy wire from the insulator is metal, the lower is nylon. An additional twisted wire above the insulator is used to lift the linear loading section slightly higher than the existing guy mount allows, I did this only because I had something above each outbound end to tie to.

The right photo shows slightly greater detail and the antenna wire from the balun is clearly visible. There are no electrical connections at the outbound end of the linear-loading section.
Again, if you look closely, you can see the pigtail extension wrapped around the lower nylon guy.

Construction Notes:

The construction of the Super Linear-Loaded Inverted V is quite simple and follows the same formula as for a standard dipole. 468/fMhz (FourHundredSixtyEight divided by the Frequency in Megahertz give you the total length in feet for a 1/2 wave dipole). In practice you will use two wires, each being 130 feet long. The antenna shown in the photos is made from 14 guage insulated copper wire. I ran out of insulators and am temporarily using loops made from 1/4 inch nylon cord at the push-pole end of the linear-loading section. If you start with two 130 foot long wires, you do not have to measure the turning or ending points, they will fall in place depending upon the height you install the horizontal portion of the antenna.

The height of the feedpoint can vary considerably, however, the higher the better. If you can only go up 30 or 35 feet, the antenna will still perform almost as well, but you will require a further horizontal distance to work in. With the feedpoint at 40 feet, the sloping elements are roughly 60 feet long at 40 feet away from the push-up pole. Any distance from 40 feet to 80 feet in length seems to make little difference in the performance of this antenna.

A balun is not an absolute necessity, however, if space constraints keep you from obtaining a spread between the sloping wires greater than 90 degrees, then a balun is strongly suggested.

For all practical purposes, installation is the same as for an inverted V, a feed type insulator or balun is assembled with the coax and both of the 130 foot long wires. Connection of the coax is the same as for a standard dipole. The center conductor goes to one wire and the shield to the other wire. The feed insulator or balun is now hoisted to it's permanent position on your push-pole, tower, gable or wherever you are mounting your antenna.

I will describe the finished setup first, then give some quick install tips immediately following.

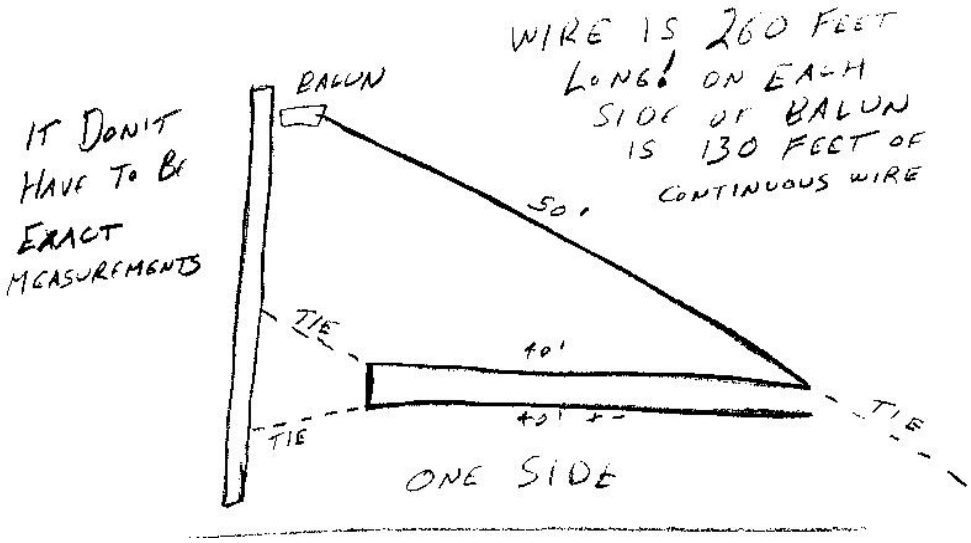
One side of the antenna is assembled first and will require a minimum of three insulators or you can use nylon mounts by giving the wire a twist to form a loop to connect the nylon rope to.
The antenna wire is brought out across the yard and the end of the wire is passed through an insulator at the outbound end of the antenna. The antenna wire is then brought back toward the push-pole and passed through the second insulator. The second insulator should be installed about 6 feet away from the push-pole temporarily. The wire then passes through a third insulator 6 to 8 inches below the second insulator, and then proceeds back out to the outbound end.

The ideal installation would have the feedpoint 50 feet above ground level and the linear-loading section 20 feet above ground level. In practice, the feedpoint can be as low as 30 feet above ground level and the linear-loading section as low as 10 feet from the ground without affecting performance to drastically. In any case, the linear-loading section should be maintained as close to horizontal as possible.

The idea is to determine at what height you wish to install the horizontal linear-loading section, and then adjust the insulators and distance between the push-pole and inside end of the linear-loading section so that the first insulator and end of the wire are on the same plane. And you'll really love this, give or take 2 or 3 feet on that tail, preferably give a few feet extra for trimming to resonance.

Any non-metal spacer can be used to maintain distance between the elements of the linear-loading section! No need to go overboard here, it's close enough to the ground you can replace the simple item I use in Quick Tips below.

Simple Sketch showing path of antenna wire on one side of balun.



Quick Tips:

Here is how to install this antenna system and have it up and running in well under an hour, exluding push-pole installation of course.

1. Install the wires to your balun and connect the coax, hoist it into position and secure firmly.
2. Pull one wire out taught to your guy mount and secure temporarily.
3. Take the loose end of this same wire and secure it to the push-pole temporarily at the desired final installation height. Note: This end of the wire will be at the other end of the yard when finished.
4. Go back to the outbound end of the antenna, using a stepladder if necessary, pull the wire so that it is taught from the push-pole and lift the wire until it is perfectly horizontal.
5. With a magic marker or piece of tape, mark the sloping wire at the point where the wire from the push-pole crosses the sloping wire. This is where the outbound insulator is to be installed.
6. Install the outbound insulator and tie off (guy) this portion of the antenna to permanent tension.
7. Disconnect the loose end of the wire from the push-pole, pass it through an insulator and bring the loose end out to the outbound end and temporarily connect it to the now secure insulator outbound insulator, leaving 2 to 3 feet of loose pigtail extending through this insulator.
8. Pull the wires from the insulator toward the push-pole until they are in balance at equal lengths from the outbound end, at this bend take the insulator and give it a twist, release the loose pigtail at the outbound end, then secure the push-pole end of the top linear-loading wire and it's insulator to the push-pole at it's permanent position.
9. Install your first spacer (see spacers below) by passing the loose end of the wire through it, bring it up snug to the insulator, install the second insulator and give it a twist to hold it secure. Tie this insulator off to the push-pole as well, trying to keep the spacer vertical.
10. Install additional spacers, one about every five feet, to maintain separation of the upper and lower linear-loading sections.
11. When you reach the outbound end, install your last spacer at the insulator, form a loop in the lower wire for attaching a nylon tie off rope. Pull the rope to tighten the lower linear-loading wire and tie off to the guy mount. Wrap the remaining 2 or 3 feet of pigtail around the nylon rope.
12. Duplicate the above instructions for the other leg of the antenna!

SPACERS:
I take simple drinking straws to use for spacers. But reinforce them to two thicknesses for all the spacers except the inbound spacer near the push pole, this one is three or four thicknesses.
To strengthen a soda straw, you merely slit another soda straw end to end and insert it inside of the whole unslit soda straw. You only need to pass the unslit whole soda straw over the wire for the inbound spacer, the other two or three slit straws can be added right over the wire and then slid into the whole unslit straw.

Joining the straws to the wires:
I take 24 inch long pieces of braided nylon, like mini-blind sash cord, fold it in half, hold it on one side of the top wire with the loop up and open, then I pass the loose ends of the rope over the wire and through the loop, pull it snug and let the ropes hang until I get all the ties (ropes) installed.
By taking a 12 inch long piece of 18 or 20 guage wire and bending a sharp turn at one end, you can use that to slip the ends of the ropes into and slide the soda straw over the wire pulling the rope down through the straw. Place the loose ends of the rope one on each side of the lower wire and tie a square knot, drawing the wire up tight against the soda straws. Don't worry if they are atilt right now, you can true them up later.
After the antenna is assembled, tied down nice and snug, and tuned. I will adjust the soda straws to vertical and place a dab of something like plasti-dip-your-grip or dumb gum over the tops of the straws to hid the nylon braid from UV and weather. I usually don't worry about the knot end or lower end of the straw.

Tune-Up:
If I have obstructions in the yard that interfere more with one leg than the other, I will make the shield side of the coax go to that side and the center conductor to the clearer of the legs. Now I tell you!
I normally tune both legs of the antenna first to 1.840 MHz, then I will continue to cut the clearer leg of the antenna all the way down to 1.950 MHz. I will then make a pigtail with an alligator clip on it and retune that leg of the antenna to 1.875 MHz. You can wrap the pigtail around the nylon guy and slide it down at least 6 inches away from the tuned pigtail end and it won't interfere with your upper band setting. In my case, I leave the pigtail connected as 1.875 MHz is one of my popular areas of the band for ragchewing. I may be over 50, but to really fit in up at 1.950, I need another 40 years under my belt, Hi Hi..... You may make other pigtails to center in other areas of the band also. It works on either leg of the antenna!

Half-Length 80-Meter Vertical Monopoles: the Best Method of Loading

L. B. Cebik, W4RNL

Summary

In the pursuit of obtaining the most compact and efficient 80- meter monopole antenna, numerous loading schemes have been proposed, including based lumped constant loading, base linear loading, top (capacity) hat loading, and a number of antenna element extension-and-fold-back systems. Modeling these systems is difficult due to the various limitations of existing modeling software, including MININEC, NEC-2, and NEC-4.

Preliminary work is best done in MININEC, because (with due caution) it is best capable of modeling nonlinear geometries employing wires of different diameters, a necessary condition of a compact 80-meter monopole. A monopole 37.5' long, corresponding to a common commercial height, is the constant main element used, with other parameters varied to achieve the following goals:

- a. Maximum gain within the limits of the antenna type;
- b. True vertically-polarized circular pattern;
- c. Highest feedpoint impedance for maximum efficiency;
- d. Flattest SWR curve between 3.5 and 3.7 MHz; and
- e. Most compact and mechanically practical assembly.

The range of models compared covered the following types of monopoles: full-length, 37.5' unloaded, lumped constant base- loaded, linear-base-loaded, "capacity" hat loaded; top linear loaded; zig-zag fold-back loaded, and helically loaded. Figures are provided on gain and feedpoint impedance at 3.6 MHz, as well as on feedpoint impedance and SWR at 0.05 MHz intervals from 3.5 to 3.7 MHz. Other data can be obtained from these models by rerunning them using the descriptions provided in an Appendix. Especially recommended is a study of current levels along the antenna wires.

No single model antenna achieves all of the goals listed above. However, the helical fold-back element extension model achieves goals a. through c., and perhaps holds promise of achieving e. The zig-zag fold-back element extension model excels in achievement of goals b, c. and d., with only slightly less gain

than the helix and with some promise of meeting goal e. The capacity hat model shows excellent gan, bandwidth, and feedpoint impedance, but may be mechanically problematical except in a Marconi configuration. All other models show lesser performance in one or more categories. Unless mechanical constraints preclude further work on them, the helical and the zig-zag foldback models appear to be the best candidates for further study and testing. However, before hats are discarded as too large or too fixed or too unwieldy, the spiral hat noted in the last segment (Part 5) should be examined. It was modeled in NEC-4 because the model was too large of standard MININEC.

1. Goals, and Methods of the Study

2. Baseline Data: Full-Size and Capacity-Hat Verticals

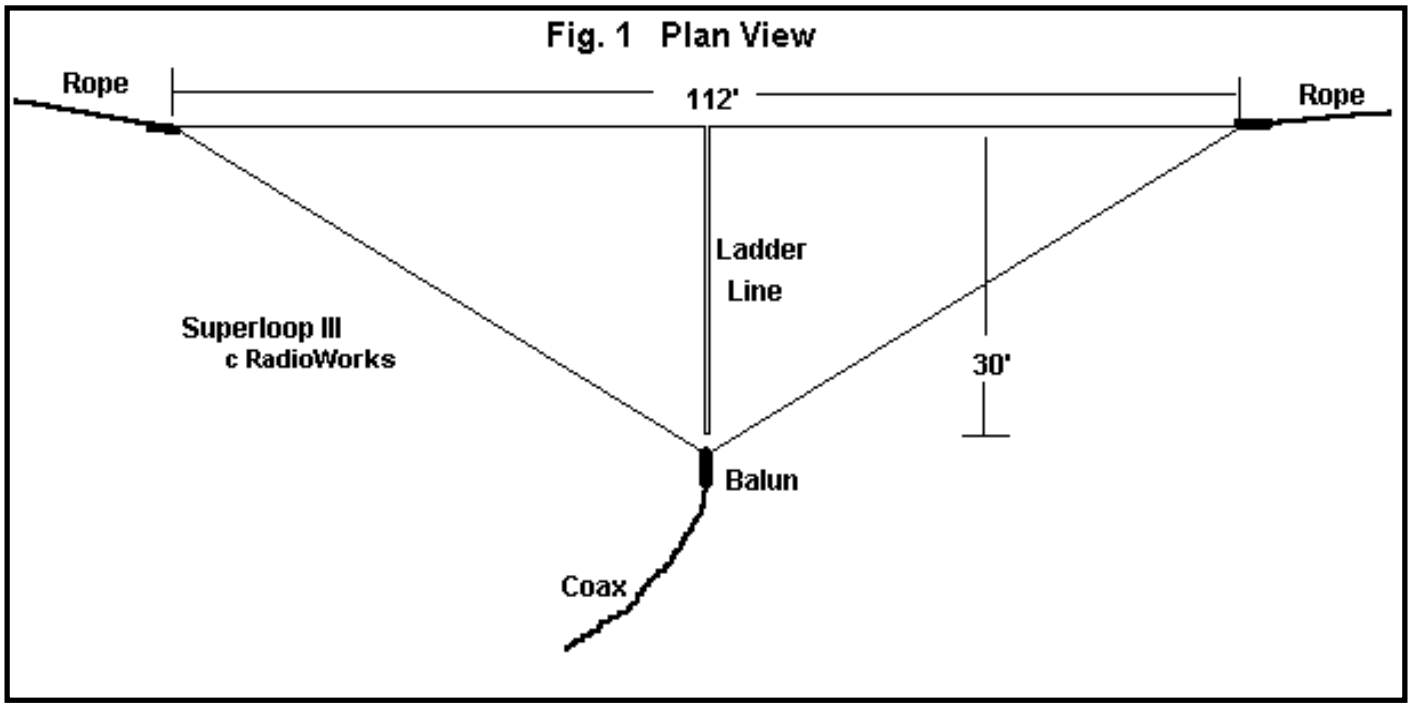
Super loop 80



G5RV verses Superloop 80

Many operators with small lots, a G5RV is what can fit for the 80 and 40 meter bands. The G5RV is 102 feet long and has a 34 foot
section of twinlead followed by coax into the shack, possibly with some sort of RF choke on the coax. The ends are typically supported by ropes up in
the trees. An 80 meter dipole would be about 134 feet long.

A tiny lot is limited in antenna potential and zoning laws prevent real towers.

RadioWorks "Superloop III" designed by Jim, W4FTU, and refined over the years, is a good alternative

PHYSICAL VARIATIONS

The standard arrangement is shown in Fig. 1. It looks like an inverted delta loop and is 112 feet across the top. It fit on the same ropes as my G5RV used and the coax even started at about the same point in space. The wire is heavy 14 gauge copper. If your space doesn't quite allow this, the top corner insulators can be moved to shorten the 112 foot dimension; also additional insulators can be added to the diagonal wires to make a rectangular

shape and raise the bottom balun up in the air more. I also added 6 feet of wire to move the resonant freq closer to the band bottoms for digital work.

The loop can also be mounted upside down and slanted if you only have a single support available. As with all loops, the area enclosed is important and so is the average height; the standard inverted delta shape is a very good compromise.

ELECTRICAL CHARACTERISTICS

The "trick" to the Superloop is the 30' length of ladder line hanging down from the center insulator. This length has been tuned so that appears to be a open-circuit stub on 40 meters; thus the antenna becomes two full-wave wires (at 40 meters) and is commonly referred to as the Bi-Square antenna. On 80 meters, it appears to be a short and the antenna becomes a single wave vertical loop. This happens automatically and no switching is involved.

A special balun is provided which gives a match between the 50 ohm coax lead-in and the higher resistance of the loop. For best matching, a 1/2 wavelength coax is recommended (e.g. 99' of RG-8X); however mine is about 70 feet into my diff-T tuner and the SWR < 2 points are 3495 to 3787 but the short coax gives a minimum on 40 of 2.05 at 7090 KHz. If you need to run without a tuner, close attention to the coax length will help. The balun is the typical ferrite rod in a PVC pipe with foaming urethane inside. This has the effect of heat insulating; mine works fine on 500 RTTY watts contesting, but real high power may be a problem on RTTY; but those guys all have beams, right?

OPERATING RESULTS

The diagonal wires make it partially a vertical antenna with a nice reduction in polarization QSB. You can possibly double contacts on 80/40 over the G5RV. RITTY can help on the reception. The Superloop tunes up fine on the 20,15,10 bands Antenna, ropes, and coax will run you about $US 135. RadioWorks advertises in CQ and QST and have an interesting catalog.

By Joe Everhart, N2CX

The NJQRP Squirt

This reduced-size 80-meter antenna is designed for small building lots and portable use. It's a fine companion for the Warbler PSK31 transceiver.

At one time, 80 meters was one of the more highly populated amateur bands. Lately, it has become significantly less popular because much DXing has moved to the higher frequencies and many suburban lot sizes are too small to accommodate a full 130-foot, λ/2 antenna for the band. That's unfortunate, because 80 meters has lots of potential as a local-communication band—even at QRP levels. The recently published Warbler PSK31 transceiver can serve as a great facilitator for close-in QRP communication without much effort.[1] What's really needed to complement the Warbler for this purpose is an effective antenna that fits on a small suburban plot. Because PSK31 (which the Warbler uses) is reasonably effective even with weak signals, we can trade off some antenna efficiency for practicality.

What's a Ham to Do?

I investigated a number of antenna possibilities to come up with a practical solution. One intriguing candidate is the magnetic loop. Plenty of design information for this antenna is presented in *The ARRL Antenna Book* and at a number of Web sites.[2, 3] To obtain high efficiency, however, the loop must be 10 feet or more in diameter and built from 1/2-inch or larger-diameter copper pipe. The loop needs a very low-loss tuning capacitor and a means of carefully tuning it because of its inherently narrow bandwidth. Another configuration, the DCTL, may be a solution, but it's likely not very efficient.[4]

An old standby antenna I considered is the random-length wire worked against ground. If it is at least λ/4 long (a Marconi antenna) or longer, it can be reasonably efficient. Shorter lengths are likely to be several S units down in performance and almost any length end-fed wire needs a significant ground system to be effective. Of course, you may not need much of a ground with a λ/2 end-fed wire, but it's as long as a center-fed dipole.

Vertical antennas don't occupy much ground space, but suffer the same low efficiency as the end-fed wire if they are practical in size.

Probably the easiest antenna to use with good, predictable performance is the horizontal center-fed dipole. Unfortunately, as mentioned earlier, the usual 80-meter λ/2 dipole is too large for many lots. But all is not lost! The dipole can be reduced to about a quarter wavelength without much sacrifice in operation (see the sidebar, "Trade-Offs"). Furthermore, if the dipole's center is elevated and the ends lowered—resulting in an inverted **V**—it takes up even less room. This article describes just such a dipole: the NJQRP Squirt.

V for Victory

You can think of the Squirt as a 40-meter, λ/2 inverted-**V** dipole being used on 80meters. Figure 1 is an overall sketch of the antenna; Figure 2 is a photograph of a completed Squirt prior to erection. The Squirt has two legs about 34 feet long separated by 90° with a feed line running from the center. When installed, the center of the Squirt should be at least 20feet high, with the dipole ends tied off no lower than seven feet above ground. This low antenna height emphasizes high-angle NVIS (Near Vertical-Incidence Skyware) propagation that's ideal for 80-meter contacts ranging from next door out to 150 or 200 miles. And

Figure 2—An assembled Squirt ready for installation.

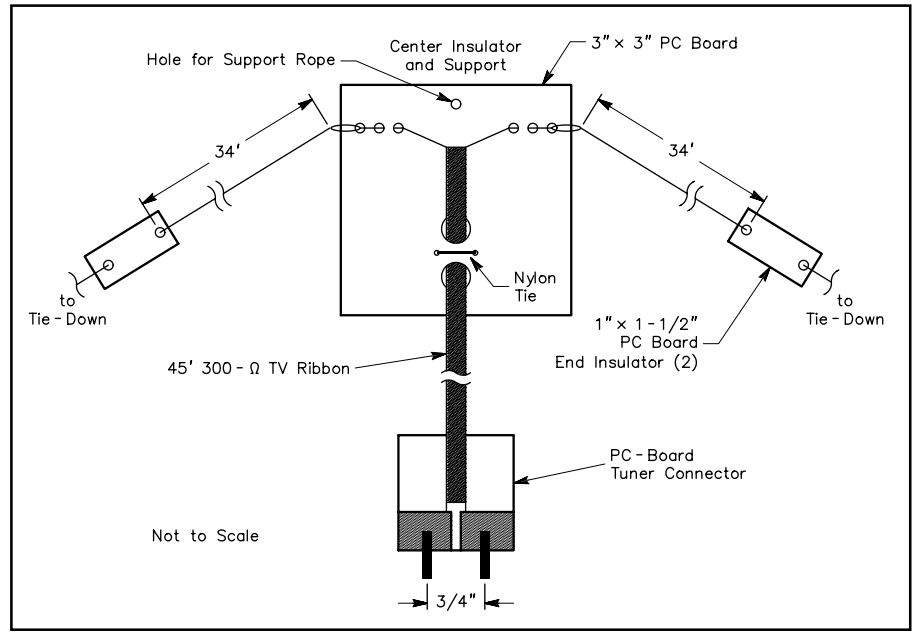

Figure 1—General construction of the 80-meter Squirt antenna.

[1]Notes appear on page 43.

From April 2001 QST © ARRL

that's where 80 meters shines! With the Squirt's center at 30 feet and its ends at seven feet, the antenna's ground footprint is only about 50 feet wide.

One nice feature of a λ/2 center-fed dipole is that its center impedance is a good match for 50- or 75-Ω coax cable (and purists usually use a balun). Ah! But the Squirt is only λ/4 long on 80 meters, so it *isn't* resonant! Its feedpoint impedance is resistively low and reactively high. This means that feeding the antenna with coax cable would create a high SWR causing significant feed-line loss. To circumvent this, we can feed the antenna with a low-loss feed line and use an antenna tuner in the shack to match the antenna system to common 50-Ω coax cable. I'll have more to say about the tuner later.

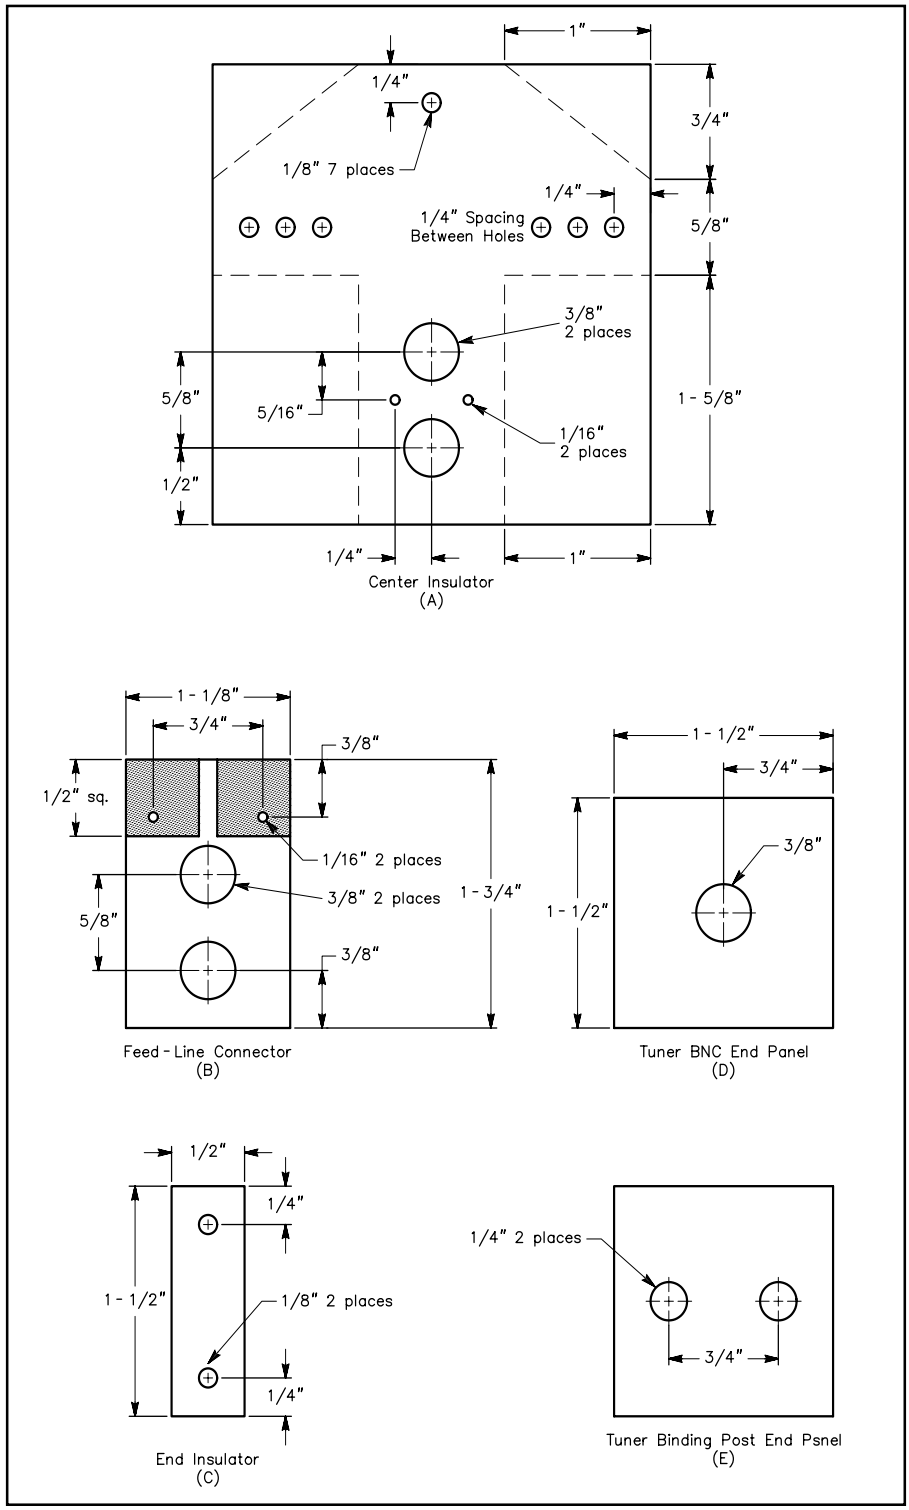

Figure 3—Hole sizes and locations for the various PC-board pieces. See Note 5.

I use 300-Ω TV flat ribbon line for the feed line. Although a better low-loss solution is to use open-wire line, that stuff is not as easy to bring into the house as is TV ribbon. Using TV ribbon sacrifices a little transmitted signal for increased convenience and availability. If you feel better using open-wire line, go for it!

Using Available Materials

It's always fun to see what you can do with junkbox stuff, and this antenna is one place to do it. See the "Parts List" for information on materials and sources.[5] For instance, the end and center insulators (see Figure 1) are made of 1/16-inch-thick scraps of glass-epoxy PC board. For the antenna elements, I use #20 or #22 insulated hookup wire. Although this wire size isn't recommended for use with fixed antennas, I find it entirely adequate for my Squirt. Because it's installed as an inverted **V** antenna, the center insulator supports most of the antenna's weight making the light-gauge wire all that's needed. The small-diameter wire has survived quite well for several years at N2CX. This is not to say, of course, that something stronger like #14 or #12 electrical house wire couldn't serve as well.

The 300-Ω TV ribbon can be purchased at many outlets including RadioShack and local hardware stores. Once again, if you want to use heavier-duty feed line, do so. The only proviso is that you may then have to trim the feeder length to be within tuning range of the Squirt's antenna tuner.

The End Insulators

I used 1/2×1 1/2-inch pieces of 1/16-inch PC board for the Squirt's two end insulators. As with everything else with the Squirt, these dimensions are not sacred; tailor them as you wish. If you use PC board for the end insulators, you have to remove the copper foil. This is easy to do once you've gotten the knack. Practice on some scraps before tackling the final product. The easiest way to remove the foil without etching it is to peel it off using a sharp hobby knife and needle-nose pliers. Carefully lift an edge of the foil at a corner of the board, grasp the foil with the pliers and slowly peel it off. You should become an expert at this in 10 or 15 minutes. Drill 1/8-inch-diameter holes at each end of each insulator for the element wires and tie-downs.

Tuner Feed-Line Connector

The tuner end of the feed line is terminated in a special connector. Because the TV-ribbon conductors aren't strong, they'll eventually suffer wear and tear.

From April 2001 QST © ARRL

Trade-Offs

One of the unfortunate consequences of shrinking an antenna's size is that its electrical efficiency is reduced as well. A full-size dipole is resonant with a feedpoint impedance that matches common low-impedance coax quite well. This means that most transmitter power reaches the antenna minus only 1 dB or so feed-line loss. However, when the antenna is shortened, it is no longer resonant. A *NEC-4* model for the Squirt shows that its center impedance on 80 meters is only about 10 Ω resistive, but also about 1 kΩ capacitive. This is a horrendous mismatch to 50-Ω cable, and feed-line loss increases dramatically with high SWR. The Squirt uses 300-Ω TV ribbon for the feed line with an inherently lower loss than coax. This loss is much less than if coax were used, but it's still appreciable. Calculated loss with 300-Ω transmitting feed line is about 7.7 dB (loss figures are hard to come up with for receiving TV ribbon) so the feed line used doubtless has more than that.

Although this sounds discouraging, it's *not fatal*. You have to balance losing an S unit or so of signal against not operating at all! Consider that the Squirt, even with its reduced efficiency, is still better than most mobile antennas on 40 and 80 meters. So for local communication (a low-dipole's forte), using PSK31 and the Squirt is quite practical.

If you don't already have an antenna, the Squirt's a good choice to get your feet wet when using PSK 31. Once you get hooked, you'll probably want a better antenna. If you have the room, put up a full-size dipole; you'll see the improvement right away. If you can't do that, use a lower-loss feeder on the Squirt, such as good-quality open wire.—*Joe Everhart, N2CX*

Figure 4—The pad side of the home-made feed-line-to-tuner connector.

Figure 5—Here the feed-line-to-tuner connector is shown attached to the binding posts of the Squirt antenna tuner.

This connector provides needed mechanical strength and a means of easily attaching the feed line to the tuner. In addition to some PC-board material, you'll need four or five inches of #18 to #12 solid, bare wire. Refer to Figure 3 and the accompanying photographs in Figures 4 and 5 for the following steps.

Take a $1\frac{1}{8}\times1\frac{3}{4}$-inch piece of single-sided PC board and score the foil about $\frac{1}{2}$inch from one end; remove the $1\frac{1}{4}$-inch piece of foil. Now score the remaining foil so you can remove a $\frac{1}{8}$-inch-wide strip at the center of the board, leaving two rectangular pads as shown in Figures 3B and 4. Drill two $\frac{1}{16}$-inch-diameter holes in the copper pads spacing the holes about $\frac{3}{4}$-inch apart. Drill two $\frac{3}{8}$-inch holes at the connector midline about $\frac{5}{8}$-inch apart, center to center, to pass the feed line and secure it.

Cut two pieces of #18 to #12 wire each about three inches long. Pass one wire through one of the $\frac{1}{16}$-inch holes in the connector board and bend over about $\frac{1}{4}$-inch of wire on the nonfoil side. Solder the wire to the pad on the opposite side and cut the wire so that about oneinch of it extends beyond the connector. Repeat this procedure with the second wire. Next, strip about two inches of webbing from between the feed-line conductors and loop the feed line through the two $\frac{3}{8}$-inch holes so that the free ends of the two conductors are on the copper-pad side. Strip each lead and solder each one to a pad. You now have a solid TV-ribbon connector that mates with the binding-post connections found on many antenna tuners. Figure 6 shows the connector mated with a Squirt tuner.

Center Insulator

Strip all the foil from this 3-inch-square piece of board. Use Figure 3A as a guide for the hole locations. The top support hole and the six wire-element holes are $\frac{1}{8}$-inch in diameter; space the wire-element holes $\frac{1}{4}$-inch apart. The feed-line-attachment holes are $\frac{3}{8}$-inch diameter spaced $\frac{1}{2}$-inch apart, center to center; the two holes alongside the feed-line-attachment holes are $\frac{1}{16}$-inch diameter. These $\frac{1}{16}$-inch holes accept a plastic tie to secure the feed line. I trimmed the insulator shown in Figure 2 from its original 3-inch-square shape to be more esthetic. Your artistic sense may dictate a different pattern.

Bevel all hole edges to minimize wire and feeder-insulation abrasion by the glass-epoxy material. You can do this by running a knife around each hole to remove any sharp edges.

Putting It All Together

The Squirt is simple to assemble. Once all the pieces have been fabricated, it should take no more than an hour or two to complete assembly. Begin with the center insulator. Cut each of the two element wires to a length of about 34feet. Feed the end of one wire through the center insulator's outer hole on one side, then loop it back and twist around itself outside the insulator to secure it. Now loop it through the other two holes so that the inner end won't move from normal movement of the wire outside the insulator. Repeat the process for the other insulator/wire attachment. Separate several inches of the TV-ribbon feed-line conductors from the webbing; leave the insulation intact except for stripping about $\frac{1}{2}$inc h from the end of each wire. Pass the TV ribbon through both $\frac{3}{8}$-inch holes. Strip a $\frac{1}{2}$-inch length of insulation from each dipole element, then twist each feeder wire and element lead together and solder the joints. It might be prudent also to protect the joint with some non-contaminating RTV or other sealant. Finally, loop a nylon tie through the holes alongside the feeder and tighten the tie to hold the feeder securely. A close-up of the assembled center insulator is shown in Figure 6.

Attach the end insulators to the free ends of the dipole wires by passing the wires through the insulator holes and twisting the wire ends several times to secure them.

So that the antenna/feed-line system can be tuned with the Squirt tuner, the 300-Ω feed line needs to be about 45 feet long. If you use a different tuner, you may have to make the feed line longer or shorter to be within that tuner's impedance-adjustment range.

Tuner Assembly

This tuner (see Figures 7 and 8) is about as simple as you can get. It's a basic series-tuned resonant circuit link-coupled to a coaxial feed line. At C1, I use a 20 to 200-pF mica compression trimmer acquired at a hamfest (you *do* buy parts at hamfests, don't you?), although almost any small variable capaci-

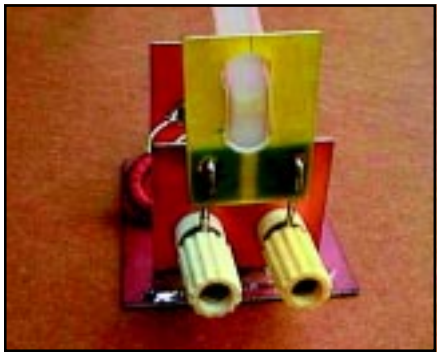

Figure 6—View of an assembled center insulator fashioned from a 3×3-inch piece of PC board from which all the foil has been removed.

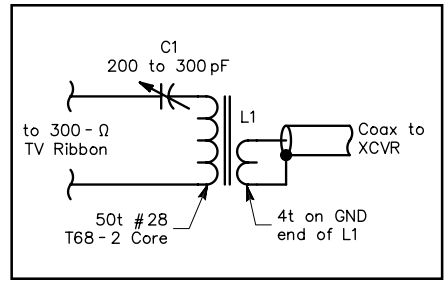

Figure 7—Schematic of the Squirt antenna tuner. See the accompanying Parts List.

Figure 8—This Squirt tuner prototype uses a 2×3-inch piece of PC board for the base plate, two 1½ × 1½-inch pieces for end plates and a ½-inch square piece as a tie point for the toroid and tuning capacitor.

tor of this value should serve. The inductor, L1, consists of 50 turns of enameled wire wound on a T68-2 iron-core toroidal form. An air-wound coil would do as well, although it would be physically much larger. Figure 8 shows the tuner built on an open chassis made of PC board. My prototype uses several PC-board scraps: a 2×3-inch piece for the base plate, two 1½×1½-inch pieces for each end plate (refer to Figure 3). A ½-inch square piece of PC board (visible just beneath the capacitor in Figure 8) is glued to the base plate to serve as an insulated tie point for the connection between the toroid (L1) and tuning capacitor (C1). The tuner end plates are soldered to the base plate to hold a pair of five-way binding posts and a BNC connector at opposite ends. L1 and C1 float above electrical ground, connected to the TV ribbon. One end of L1's secondary (or link) is grounded at the base plate and the coax-cable shield. The hot end of L1's secondary winding is soldered to the coax-connector's center conductor.

Tuner Testing

C1 tunes sharply, so it's a good idea to check just how it tunes before you attach the tuner to an antenna. You can simulate the antenna by connecting a 10-Ω resistor across the binding posts. If you use an antenna analyzer as the signal source, a ¼-W resistor such as the RadioShack 271-1301 is suitable. But if you use your QRP transmitter, you need a total resistance of 8 to 10 Ω that will dissipate your QRP rig's output, assuming here it's 5 W or less. Four RadioShack 271-151 resistors (two series-connected pairs of two parallel-connected resistors) provide a satisfactory load if you don't transmit for extended periods. Or, you can make up your own resistor arrangement to deliver the proper load. Adjust C1 with an insulated tuning tool to achieve an SWR below 1.5:1.

Once the tuner operation is verified using the dummy antenna, it's ready to connect to the Squirt. Tuning there will be similarly sharp, and a 2:1 SWR bandwidth of about 40 kHz or so can be expected as normal.

A Multiband Bonus

Although the Squirt was conceived with 80-meter operation in mind, it can double as a multiband antenna as well. The simple Squirt tuner is designed to match the antenna only on 80 meters. However, a good general-purpose balanced tuner such as an old Johnson Matchbox or one of the currently popular Z-match tuners (such as an Emtech ZM-2) will give good results with the Squirt on any HF band. The Squirt prototype was recently pressed into service at N2CX on 80, 40, 30, 20 and 15 meters for several months. It worked equally as well as a similar antenna fed with ladder line. Although no extensive comparative tests were done, the Squirt has delivered QRP CW contacts from coast to coast on 40, 20 and 15 meters and covers the East Coast during evening hours on 80meters.

Build one! I'm sure you'll have fun building and using the Squirt!

Parts List

Squirt Antenna

Numbers in parentheses refer to vendors presented at the end of the list.

1—3×3-inch piece of 1/16-inch-thick glass-epoxy PC board for the center insulator (1)
2—½×1½-inch pieces of PC board for the end insulators (1)
1—1⅛×1¾-inch piece of PC board for the feed-line connector (1)
2—34-foot lengths of #20 (or larger) insulated hookup wire (2)
1—6-inch length of #16 (or larger bare) copper wire; scrounge scraps from your local electrician.
1—45-foot length of 300-Ω TV ribbon line (2)

Squirt Tuner

1—2×3-inch piece of PC board for base plate (1)
2—1½-inch-square pieces of PC board for end plates (1)
1—½-inch-square piece of PC board for the tie point (1)
1—200- to 300-pF (maximum) mica compression trimmer (3)
1—T68-2 toroid core (3)
2—Five-way binding posts (2)
1—55-inch length of #26 or 28 enameled wire (2 and 3)

Note: You can use 3/16-inch-thick clear Plexiglas for the Squirt's end and center insulators. Commonly used as a replacement for window glass, Plexiglas scraps can be obtained at low cost from hardware stores that repair windows.

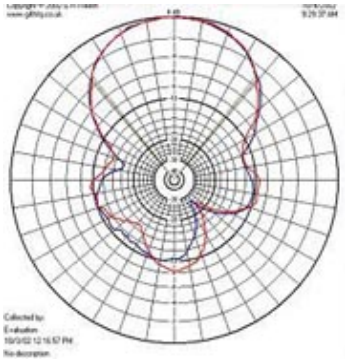
80m & 40m DUAL BAND HOMEBREW 2 EL SHORT BOOM YAGI

Follow the links at the left to see various pages of design and construction details. (Click to see a full size photo of the Yagi)

The VE6WZ QTH is a small city lot, so achieving gain on 80m has been difficult. A vertical 4 sq. wire array was considered but would have been a compromise design because of the crank-up tower and limited space. The surrounding ground clutter and variable terrain would have made vertical performance questionable. Good DX results have been experienced using the Force-12, EF-180B, 80m rotatable dipole at 100' so it was decided to design a 2 el 80m yagi around similar elements. (F-12 markets such yagis). The VE6WZ yagi design uses high Q "mostly air core" loading coils instead of the linear loading on the 68' elements. Because of dimensional constraints at the VE6WZ city QTH, a 28' short boom reflector design was built with the 2 el 40m yagi sharing the same boom.



Above: Field measured azimuth plot of the Yagi on 3.8 and 3.793 MHz.

80m 2 el Yagi specifications

Max F/B:	20 dB peak (10 dB within SWR bandwidth)
Max gain:	8.95 dBi (at 100', 33 deg ele. angle)
2:1 SWR bandwidth:	26 kHz (with switching 55 kHz) 3810-3760, 3550-3500.
Feedpoint impedance:	15-20 ohms (hairpin match)
Longest element:	66'
Boom :	28' (2-1/2" X .125) Trussed
Weight of 80m only:	170 lbs
Weight total with 40m elements:	210 lbs
***Estimated* windload:**	13 sq. feet

Working DX is not proof of good performance, however in the first 7 months of the 2002-3 winter season from Sept.1 to Mar.31 at VE6WZ 112 DXCC countries were worked on 80m, and 187 were worked on 40m.

Listen to the directivity of the Yagi on 80m: In this QSO with Jose, F5JD at first the Yagi was pointed at 90 deg. with very poor copy. Part way through the recording the beam is rotated to direct path at about 40 deg. and the copy is Q-5. This IS NOT a F/B test...the beam is only rotated about 50 deg. Click here and your sound player should play this .mp3 file: F5JD_80m-03-10-12.mp3

More sound recordings can be heard on the Sound File Page.

Compromised performance issues (80m):

This Yagi is almost ½ full size on 80m and is a great DX performer. It has about 1 dB less gain but shows *better* F/B than a design using full size elements (see here). The small size makes it feasible to install in many situations where a full size monster would not be possible.....however some performance and operational issues arise:

1.) This would NOT be a great contest antenna because of the *very narrow bandwidth* and requirement to use switching to move around the band. The bandwidth could be expanded by retuning the reflector to sacrifice some gain, but some switching would still be required.

2.) The large coils are susceptible to inductance change when covered with snow, ice or frost. In severe cases this can render the Yagi unusable.

3.) Because of the narrow bandwidth and tight coupling of the elements the SWR will "swing" during windy conditions as the elements move.

4.) The narrow bandwidth and close coupling of the elements makes tuning critical. Great care and effort must be taken to adjust the elements for best performance. On the tower, field testing will almost certainly be required to get the tuning right. **WARNING...This is not a "plug-and-play" design.** If you build this design be prepared to spent much time tuning the elements for optimum performance.

(see here for comparison plots to a full size design)

WHY INDUCTOR LOADING ??

VE6WZ displays one of the 80m loading coils.

The Cushcraft "shorty-forty" experience.....

The Cushcraft XM-240, 2 el 40m yagi has been used at VE6WZ for 3 years. It has 43' inductor loaded elements mounted on a 22' boom. The loading coils are 68 turns of 12 ga. wire close-wound on a small diameter (3/4 inch) fiberglass form. Other sources have indicated a coil loss of around 3 ohms, and software calculations indicate a loss of up to 8 ohms !! (see photo of the Cushcraft coil). The coils are placed about 61 % out from the center along the element half length. The split element is fed directly with 50 ohm coax through a 1:1 balun. In spite of these poorly designed lossy coils, this yagi is a proven performer. The thesis is that an 80m design using well designed high Q coils should perform well.

The Force 12 linear-loaded 80m dipole experience.....

The F-12 80m dipole (EF-180B) is a 68' long, linear loaded element and has performed well at VE6WZ for two years. The linear load wires extend from the mid-point of the half element inward toward the element center. The wires are aluminum clad 12 gauge steel wire. The split element is fed with 50 ohm coax in combination with a "helical hairpin" to match the 18 ohm feedpoint. MININEC was used to model an 80m dipole using 68' elements and lumped inductance (coils) at 50 % from center. The feedpoint impedance is calculated at around 32 ohms. This is almost double the 18 ohms realized when using linear loading where the wires come in toward the feedpoint. Others have explained that this low impedance is because the "effective" load point is moved inward toward the center due to the loading wires running inward along the element. A low feedpoint impedance will tend to decrease efficiency. Tests on the tower support the 32-ohm feedpoint using low loss (high Q) coils. The 2el yagi design using 18 ohm linear load elements would end up with around a 10 ohm feedpoint !!!! due to mutual coupling. This could greatly degrade efficiency. Modeling the 2 el inductor loaded design yields a reasonable 16-20 ohm feedpoint. The total wire length used in the coils is much less than that needed for linear loading, and the ¼ " copper tubing used for the high Q coils has less resistance than the 12 gauge AL clad wire. The element connection points can introduce further resistive losses and these are minimized at the coil-element connections by implementing electrical redundancy.

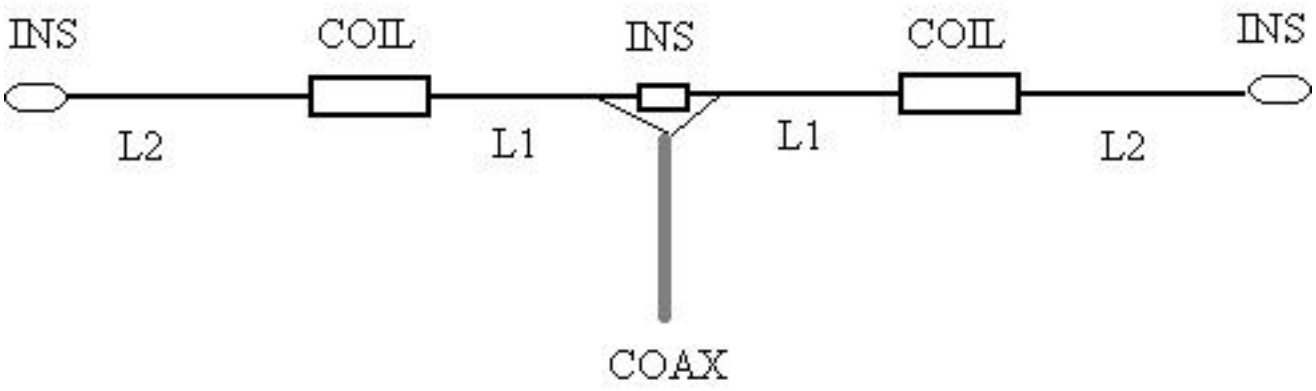
NEXT.....Design and modeling

Below...the Yagi at 100' at sunrise.

13883

A SHORT DIPOLE FOR 80m

4S7NR



The antenna above has been described by Nadisha, 4S7NR and may be of interest to anyone wishing to get on 80M (3.5MHz) that have limited space available.

L1 is 12 feet. L2 also is 12 feet and the overall length is 48 feet.

The two loading coils are described as 67.83uH and can consist of 104 turns of insulated wire, wound over 3.5 inches. The coil diameter is not stated however. Maybe it will be a case for experimentation here.

I have a file, a dipole for 20M (Click to view) which also is a loaded dipole and works well.

It would be interesting to try loaded dipoles for other bands. I will have a try at one for 40M soon.

if you have any ideas on such dipoles or experiences with them, let me know.

Updated 23rd July 2004

Technical questions? Visit the Messageboard.

Welcome to Harry's Homebrew Homepages; a resource for radio, hamradio and electronics in general. I hope you have fun with my homepages, regards from Harry - SM0VPO, (Lunda), Sweden.

Sites Summary

Homebrew Projects are located at:

http://w1.859.telia.com/~u85920178/	Unlimited bandwidth, Full site, No advertising, SWE

Visitors Circuits are located at:

http://hem.spray.se/lythall/	Selected visitors submitted circuits - SWE

A small PDF library is located at:

http://hem.passagen.se/sm0vpo/	Unlimited bandwidth, Full site, SWE

= Photograph illustrations included with the project.
UPDATED = I have recently updated this project (Obvious, really!!!)
NEW = Recently added (no timeframe - I'm quite informal)
OLD = Not new (but I want it to be noticed by someone)
= The picture file is missing - please let me know.

Here you can e-mail Harry, but if it is a technical question then **please** be so kind and use the MessageBoard. Thank you.

"Taylor Space Miser 80m antenna"

Roger Harrison (after James Taylor W2OZH)

Published: "Australian Electronics Monthly" magazine, September 1987

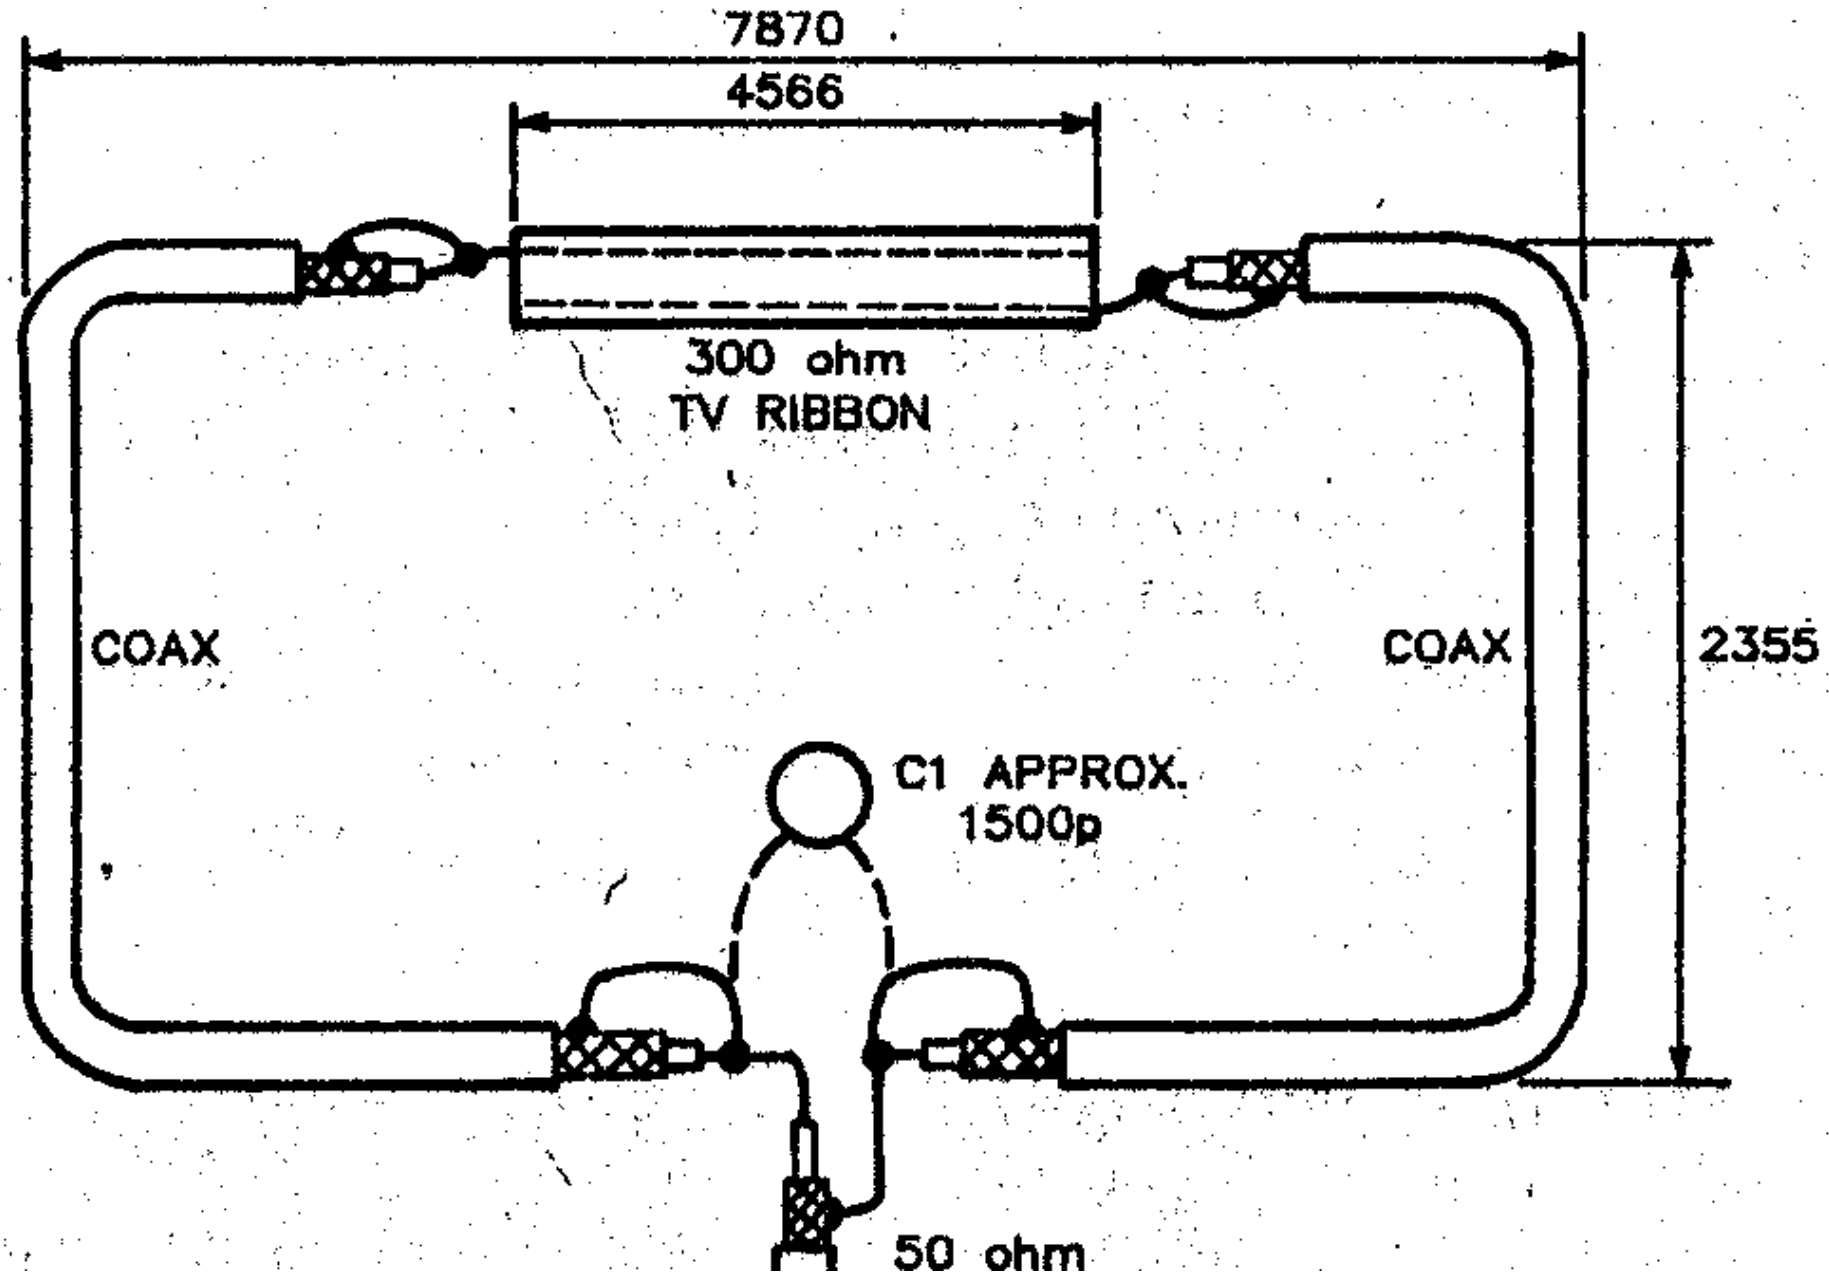

Figure 1. The general form and dimensions of the antenna. Now you can see why it's called the "space miser"!

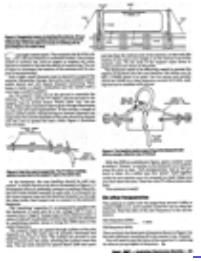
PLEASE NOTE:
Copyright 1987 Roger Harrison VK2ZRH. Reproduced with permission. This work is not to be mirrored or otherwise reproduced by electronic means without permission of the author.
Among other ways to contact Roger Harrison, you can also do so through the author this web page, at prellis@pcug.org.au]

176kB



180kB

(January 2004) This antenna has been given new life in Canberra's Amateur Radio circles through the efforts of Tony Bennett VK1TB. Please look back for Space Miser 80m dimensions that he is developing for a "town-house roof-space".

"Here are the results with my antenna mounted in the ceiling.

Taylor Loop 80M antenna RG-213 or other 10mm co-ax.

8.120M f=3.854MHz
9.370M f=3.580MHz
9.640M f=3.531MHz

300R TV ribbon 4.65M

Bandwith at SWR=1.5: 3.59 - 3.53 for 9.370M co-ax."

Tony's loop is tilted because it follows the pitched roof of his town-house. Note: There is no aluminium-foil lining in his roof.

I also repeat here the text of an email message I received from Roger Harrison.

Hi Peter,

Thank your for the email.

I am happy for the Space Misrer antenna and my article to be given a "new lease of life."

However, the proprietaries should be observed.

The Copyright Act 1968 governs use of the article. Any "work" printed, published or produced by some means is automatically copyright. No registration is required. Copyright can be sold or licensed by the creator of a work.

Although Australian Electronics Monthly is no longer published, I have retained copyright in all my "works" published in AEM (and, incidentally, a lot of other material). Similarly, I have retained copyright in all articles authored by me and published in Electronics Today.

Hence, I hold the copyright to the Space Miser antenna article published in September 1987 AEM.

However, I am happy to give you permission to reproduce the article on your website, as-published (ie. scanned pages reproduced as images), with the proviso that you add this note:

Copyright 1987 Roger Harrison VK2ZRH. Reproduced with permission. This work is not to be mirrored or otherwise reproduced by electronic means without permission of the author.

With that, the proprietaries are observed. Good luck experimenting with the antenna. I built one and mounted it on the outside back wall of our (then) office in Balmain - which overlooked a rear balcony. Nothing flash, but it did the job remarkably well.

73, Roger Harrison VK2ZRH

"Taylor" Space Miser 80m antenna

Love My Loop!

A Small Loop Antenna
for Forty Meters

By Ben Smith, W4KSY

I promised Jack Stone, Publisher of ***antenneX***, if the short loop worked as well as my phased verticals on forty meters, I would write an article. I didn't promise a GOOD article because I am no writer, but it is a GOOD antenna. It does perform as well as my phased verticals. I am satisfied the effort in building this test model was worthwhile. Here is an attempt to tell you about my experiences, including mistakes. It was challenging and fun. Perhaps this will spur you into taking on the endeavor of building a loop. Time flew, and it certainly renewed my interest in Ham Radio. There is nothing like a new antenna for a conversation piece. You get extra bragging rights when you build it yourself. (My friends hate me!) If you do bite the bullet and build one, it is hoped you will save frustration, time, and money. If you don't build it you will have a good time thinking about what a nut this guy must be! So, read on!

THE LOOP BOOK

I clicked on an ***antenneX*** link and read some of the free stuff. I wanted to know more about "shortened loops," and bought ***The Loop Book*** found in the Shopping Shack on this web site. After reading, or rather, "Screening," the book, the decision was made to build a short loop. I read about the "Special Capacitor" requirement—the need for welded construction, and of course, the capacitor has to be controlled remotely. I did a little research and found that suitable vacuum capacitors cost a lot of money. I wasn't going to invest any more than I had to in order to see how well one of these Shortened Loops worked. A stepper motor and control would cost a hundred bucks plus the cost of the capacitor. ("A steel shaft in the capacitor inserts too much loss!!!!") Hmmmm!

CAPACITOR CAPER

I am a creature of habit. I only work in a small portion of each band most of the time. For an eXperimental antenna, I could use a trimmer capacitor. I don't need to go from one end of the band to the other. Servo, and/or stepper motors and remote controls are not my cup of tea. The capacitor has to withstand high voltage and current, be efficient, and adjustable. I ended up building a capacitor out of a one inch piece of copper tubing sliding over a piece of half inch copper tubing that had an insulator separating the tube into two pieces. The separator is made of acrylic tubing inserted a little off center. The spacing for the two tubes was facilitated by making two acrylic washers, or bushings, to fit in the end of the one inch pipe with half inch holes so it would slide over the smaller tubing. ***Voila!*** A concentric or ***trombone*** capacitor!

I had a drill press, the plastics store is three miles away, Home Depot is four miles away, and I had a few bucks in my pocket. I bought the tubing (one inch copper tubing costs a little over a dollar a foot), took my treasure home and the fun began. But, the hole saws on hand were not suitable. Three hole saws were purchased, one was a mistake, (a little over eleven dollars wasted!) and the air soon was filled with the aroma of burning plastic—cough, cough! Acrylic melts! Slow and easy are the watchwords. Now how does one secure three eighths of an inch acrylic washer in copper tubing? Drill some holes through the edge of the tubing and into the washer which is epoxied in place and screw in some little nylon screws, also imbedded with a little epoxy. One must remember to have everything working before you glue and screw.

I found some acrylic rod that fits into the smaller copper tubing. I pushed one piece of the half inch tubing over the rod and then pushed in the other piece, leaving about a half inch of space in the middle. I used some epoxy on the rod before assembling the "inner plate." Then, for good measure, a center punch was used to peen the tubing in a few places to make sure that it was going to stay together. Glue is good, but mechanical means is better. I found a formula for capacitance somewhere and estimated I would have a fifty pF capacitor. It turned out to be forty-four picofarads. Which means that only twenty-two of it is useable, because it is used as a split stator capacitor. No wipers, no contact resistance. Efficient air dielectric with quarter inch spacing. ***Ain't dat sumpin!***

GREAT MINDS?

A little shy of C for my design. ***My design?*** I took the forty foot job (forty feet in circumference, a little over sixteen feet in diameter) from ***The Loop Book***. I thought I had created something when I built that capacitor. Well, don't you know, the very next issue of ***antenneX*** had a trombone capacitor in it!!!! However, I had an air dielectric, which is nicer, neater and more efficient than plastic tape—but, on the other hand, the guy didn't have to have a drill press and access to acrylic, nylon screws, epoxy, etc. If I remember properly my capacitor was about forty-five inches long. So you get approximately one pF an inch for one inch tubing over half inch tubing. You had better do your own numbers though if you are going to take on one of these things because I am not an engineer. Enough of the capacitor.

BUILD THE LOOP

So get out the butane torch, flux, emery cloth, tubing cutter, shine and clean tools, for three quarter inch tubing—eight pieces of three quarter inch copper tubing (I used thin wall...another mistake.) I Should have used the thick wall stuff and one inch tubing. This thing looks and feels flimsy when you try to pick it up and get it in the air. Supports could be made from wood and acrylic insulators, but why go to the trouble if it will hang together long enough for testing??? No more mechanical work than necessary is my motto. Besides the elbows I had to get a couple of tees, some reducers from three quarter to half inch

tubing. Why the reducers? To mount the capacitor on top and, parallel to the topmost member of the loop. Also, the top member of the three quarter inch tubing has to be broken and spaced in the center with another piece of acrylic rod. I had some plastic milk crates which served as supports for the loop while it was under construction and also testing after it was built.

CLICK TO LOAD PICTURE OF LOOP ON CRATES

PLUMBING SPECIAL

Now, here was the easy part, a plumbing special. Be sure to get everything clean and shiny. Where the tubing goes into the elbow, do a good job on the outside of the tubing and the inside of the elbow. Apply a little, but uniform coating of flux on both members. Apply heat to the elbow. I was surprised to see how well it sucked up the solder. I had done a little plumbing before and it was messy. But by heating up the outside member it sure pulls in the solder and it makes a neat job. A judicious wipe (careful) while the solder is molten will get rid of any pile-up.

Holy Buckets! Here is a forty foot octagonal of copper pipe with a capacitor in the middle. It looks real different out in the backyard. My cat came out to supervise on good days. He would sit up on a milk crate and sneer and make snide meows.

FEEDING

Now how do we feed this thing? ***The Loop Book*** suggested three ways. Well, before we match an antenna, we have to make it resonant at the desired frequency. I have built many antennas, dipoles, coaxial, bazooka, verticals, quads, rope Yagis—so, I know all about this stuff. I got out my homebrew noise generator, took about ten turns around the bottom of the loop. I connected it, then took another ten turns and coupled it to my coaxial feedline. Then, went in the house and turned on the receiver to find the resonant frequency of the loop. I was measuring the resonant frequency of the coupling coils, the feedline, the response of the receiver, ***everything except the loop.***

Okay another tack! Got out my fancy DDS VFO with digital read out and my trusty Fluke digital MM with RF probe. I just about wore out the knobs on the VFO. I was getting peaks, but none of them were where they should fall. One consistent QRG (I am a CW operator, ahem!) was 6960. Moving the capacitor didn't change the frequency, but the peak was broad. Maybe the loop was too long. I took out two members from opposite sides and sawed out a foot, then two feet. No change.

Maybe, I need a dip meter. Couldn't find one locally. Build it...? Yeah, bought some banana plugs for the coils, searched and found suitable capacitor, knob, dial, box. Then while surfing The Internet one evening, I ran across the homepage of a Ham Distributor out in the Midwest. Sent him an E-Mail and whatdya know, they had one. I Bought a dip meter.

While awaiting the delivery of the dip meter, the Publisher of ***antenneX*** sent me an E-Mail telling me that I had received a compliment on my Over/Under Quad article published in the November 1997 issue. I sent him a reply of thanks and told him the blankety-blank loop was driving me up the wall because I

could not find its resonant frequency. A few hours later, Jack sent me an E-Mail saying that the old maestro of loops, K5CNF, Richard Morrow; said I wouldn't find it by the methods I was using. I would need to put in a matching system and go for lowest VSWR. Now that really blew my mind!

So the Dip Meter arrived. Hot Dawg! I decided to use the tapped capacitor method of feed as outlined in ***The Loop Book.*** I went down to the hardware store, bought some quarter inch copper tubing, wrapped it in plastic tape, flattened one end, drilled a hole in it, then drilled a hole in the loop, secured that end with a self tapper. After I found the proper place for the tap, the tubing could be soldered to the loop—how clever! I taped the quarter inch stuff to the loop and mounted a coaxial connector on the loop by soldering on a strap. I connected the other end of the quarter inch tubing to the center of the connector with a piece of heavy flexible wire inserted in the tubing, and then crimped and soldered.

MAKING CONNECTION

The tubing came in a twenty-one foot length. So, how far out from the connector do I go? I figured, it would be better to start long than to be short and have to splice. I used the whole thing! After drilling numerous holes, cutting, flattening and boring holes in the tubing, I was within two feet of the connector and no pay-dirt. Once or twice I would see a small drop in VSWR. But moving the tap either way, or spacing the matching section away or closer to the loop did not make the desired effect!

I bought an MFJ VSWR Analyzer—two hundred bucks !—but, great piece of equipment. Now I had the whole mess of test equipment in one box with a VSWR Meter and a Resistance Meter side by side, a signal generator with a digital readout. Alas, it told me nothing new.

GAMMA MATCH

The next trial was going to be by the pick-up loop method. One loop shown in ***The Loop Book*** had a pick-up loop one-fifth the size of the main loop. Okay! I need an eight foot loop to place inside my forty-footer. I had the tubing cut, elbows in place and ready to solder when a light came on. How about a ***gamma match?!***

Wow! Found an old ARC-5 Transmitter Capacitor. It was nicely made with good wide spacing. I measured the capacitance with my new capacitance meter. It was 144 pF max. I mounted it on a piece of acrylic sheet, fastened the sheet to the loop with a couple of straps, recovered the remains of the quarter inch tubing and went to work. BY GOLLY it worked. A few taps up and down, pulling the small tubing away from the larger one, shoving it back and forth, and adjusted for resonance at the desired frequency with my highly efficient, and beautiful homebrew capacitor. Inside of five minutes after installation, I had an honest-to-heavens one-to-one match, with 50 ohms indicating on my shiny new analyzer at 7020 kHz!

I pulled off the analyzer, connected the feedline, ran in the house, plugged the analyzer into the other end of the feedline and whoopy-de-do!—one to one and 50 ohms. A little "smidgin" over one to one, but it wasn't to the first calibration point. We won't quibble over One point, Oh, One to One!

SIGNALS GALORE!

Next steps: plug in to the coaxial switch. The switch facilitates connecting to an eighty meter dipole and a phased vertical array for forty. Then connect the coaxial switch to my Icom 765. A quick check to where I set the lowest VSWR-7020 KHZ. Sure enough the ICOM'S SWR meter agreed. I hear signals. Lots of signals. Spent the next couple of hours making comparisons between received signal strength on the loop and my phased verticals—aiming the verticals at the received station. The loop was two S units down most of the time relative to the verticals. On occasion the loop was as good. Most of the time the verticals were better. ***But,*** the loop was only supported by plastic milk crates, laying down horizontally to the earth and just one foot above it!

While making a VSWR check at reduced power (eight watts) I sent three Vee's de W4KSY. I got a call from K1LGQ. Dennis, in Nashua, New Hampshire; gave me a 599 report before he knew I was on a loop and aching for a decent report. I must admit that I went to full 100 watts when I responded to his call. Never-the-less, I was elated. I made several more contacts and received good reports compared with the received signals. W9OVY, Wally near Charleston, S. C., was most helpful in assisting with tests very early in the game.

HAUL TO VERTICAL POSITION

Somewhere along this adventure I had decided the tuning capacitor was coupling to the top member of the loop, since it was only a few parallel inches away. I cut it out! Later I replaced it with an acrylic rod. This will be a great insulator to use to support the antenna! Ho!

Next day I was out in the backyard with slingshot, line, pulley, etc., etc. Got a line , with pulley attached, over a limb and hauled the loop up into a vertical position. No mean feat, single-handed. That thing sure is wobbly with no extra support. (Note to me: NEXT TIME: USE ONE INCH TUBING FOR A FORTY FOOT LOOP, or heaven-forbid, use insulated wooden supports.) Got out my trusty Analyzer, retuned to one-to-one quickly, then went inside and had a ball. Numerous contacts were made with good reports.

EARLY COMPARISONS

Summary: In most cases the loop was as good as, or superior to the phased verticals at distances out to about 800 to 1000 miles. Then the verticals seemed to take over. There were times when, even with long haul DX, the loop was better by an S Unit or two. Remember, I was aiming my phased verticals. The pattern is broad, but worth about an S Unit for locals and sometimes three S Units for DX. The loop was fixed north and south. For the past few days November 18th to November 22 there has been deep QSB,

even in daylight hours. This afternoon a South African Station at 7010 was S5 on my phased verticals and S5 on the loop. The QSB seemed slightly more prevalent on the loop then on the verticals. Background noise was about the same. Some QRM from US Stations west of me, and in the null of the phased array, was less on the array and more on the loop, of course. Figures! I hang around 7020 kHz with keyboard, or keyer, and LOOP. Demonstrations gladly given.

ANOTHER LOOP PLANNED

OKAY! This is Mark One! It is a good antenna. The performance is better than I expected. Therefore: MARK TWO is in the works. I have a new acquisition. I bit the bullet and bought a 5 to 5000 pF @ 15000 Volts, Vacuum Capacitor; with gearing, motor, limit switches and positioning pot. That monster weighs eight pounds, is almost a foot in length and five inches in diameter. The capacitor lists for $900.00! I got the whole thing Surplus for $187.00. Did I hear someone say something about anchoring boats? At ***antenneX,*** Richard, K5CNF, says to be careful with vacuum capacitors. Sometimes they are unable to handle the high current produced by the loop. According to ***The Loop Book***, I should be able to make a loop forty feet in circumference, sixteen feet in diameter work on 40, 80, and 160, with my vacuum capacitor, providing it will handle the current. ***Here I go, again!*** **-30-**

established endeavor - QSLWorks - where we design and produce full color, custom QSL cards as a means of supporting this site, it's a "no digital zone", with absolutely no attention given the concept of political correctness. For that reason, the theory, practical experience and simple humor is entirely analog.

For those new to ham radio, a special welcome is extended to you! Here, you will find years of practical experience offered simply for the taking; the kind of experience gained by hams that fearlessly applied theory and the use of available (often scrapped) parts and supplies (with mixed success and occasionally shocking results) to the design and construction of a variety of station accessories. If you are just getting started and are looking around for equipment, we've added a new section to help you get off on the right foot. Your First Rig provides info on a number of older rigs on the market that will get you up and running with a great signal, and without breaking the bank. Once you know what you're looking for, you might check out Associated Radio. They're a fine bunch of hams with a great line of new and used equipment, as well as many hard to find parts and supplies. I've personally done business with them and was very pleased with the personable service they offer. In Parts is Parts, you'll find information on salvaging parts and supplies, as well as articles on a variety of ideas such as how to wind your own chokes, and creating custom meter faces. In Reference Material you'll find an assortment of resource material that will be of use if you're seriously interested in home brewing equipment and accessories. And, if you're looking for the highest quality, full color, custom QSL Cards, then check out our QSLWorks! We established the business as a way to help support this site and are currently the only QSL printer offering premium, full custom, full color QSL cards in the US. According to the feedback we've been receiving, we are also very likely one of the Best.

So, grab a fresh cup of coffee (or stick with the one you've got), sit back and enjoy. Check out the tutorials, projects, and ideas that are featured. And, if, in the process, you think of something you'd like to see added, or perhaps make a comment on the site, or even better yet want to meet any of us on the air, just drop us an e-mail at your leisure.

- **Contruction:** I made and put this antenna up the Friday afternoon before the ARRL RTTY Roundup (1999)! It took me about 3 hours to make and install on the tower. Most of that time seem to be used untangling the wire..hi hi

- I made the antenna 142 feet long. Use tiewraps at each of the three points to form a small loop at each end so that A 3/16" rope could be used to support the antenna. I used a center insulator that I had for a dipole--it already had a SO-239 which made it easy to attach the coax feedline. The feed point was

- KC4HW

12' from the bottom of one leg.

- This antenna requires a matching element of feedline made out of RG-59 (75ohm) coax. The formula for the length is a 1/4 wavelength at the operating frequency times the velosity of the RG-59. The RG-59 I had, had a polyprolene dialectric therefore the length turned out to be approximately 22 Feet. It was Easy to figure, a 1/4 wavelength at 7.050 (234/7.050) = 33.19' times 66 percent equal 21.9.

- Since I had the center insulator with the SO-239, I put PL-259s on each end of the matching coax and then used a bullet splicer to put the regular 52ohm coax feedline to the antenna..

- Because my mounting point was only about 42' above ground, which was insulated from the tower by a 3' fiberglass pole, I move the legs of the antenna out from the bottom of the tower approximately 25' to give a clearance under the antenna of about 7'. The legs of the antenna were secured East and West, and North and South was broadside to the antenna.

- **Results:** Actually, the antenna played better than anything that I have had previously. The SWR was flat from 7.0 to 7.1 only rising to 1.7 at 7.3. This was perfect because I wanted it to play RTTY and CW... I did find that the antenna appeared to be less effective broadside, to the North. Stations in New England were difficult to get, however, the Europeans and Western USA were answering on the first call. Also, a few days after the contest, I talked to K4HXW/Mr Tucker, he indicated that he thought the antenna was playing much better than the inverted Vee that I had previously.

- **Conclusion:** I believe that this makes a great DX antenna. Also the antenna did work on 15M. I did not try it on any other bands, but it should work well on 10 thru 40 with a tuner.. Making it a nice choice for a second radio antenna during a contest... Hopefully, I will know more about it in future contests... cu in the pile!

  Added 31 Aug 2002 Update: I have put this antenna back up recently and found that the correct length was a little off on my original antenna. According to ON4UN's Low Band DXing book, the proper length for a delta loop should be 1.05 to 1.06 wavelength. The correct formula to calculate this length in feet is to divide 983.59 by the frequency in Mega Hertz (983.59/7.150=137.56'). I also have changed where the antenna is feed to horizontal by feeding the antenna in the middle of the bottom. This is so that I could have better effectiveness in domestic contest. After several days testing, the antenna seem to work well. Only time will tell... hi hi

2 Meters - Diamond - Base is @ 80 Feet in Pine Tree

DESCRIPTION OF K4TX DELTA LOOP

The Delta Loop array used at my QTH is a simple and inexpensive way to achieve substantial gain and reasonable F/B ratio. I took the idea from Dave Pietraszewski, K1WA's article in the ARRL Antenna Book when he wrote about 5 Sloping Dipoles suspended from a single tower. The sloper parasitic array he described had an "ungrounded" coax switch mounted in the tower. He used 3/8 electrical wavelength feedlines to each element. He would transmit with a single sloper & the other ones acted as reflectors. Why? Because the 3/8 wavelength feedline going to the other slopers (each being open circuited due to the ungrounded coax

switch) added inductance making the element appear 5 % longer - thus acting like a reflector.

I decided to see if it would work with a pair of equilateral loops. I already had one up, and I was disappointed with the performance. I had tried all sorts of things (i.e. switching the feedpoint to change polarization, inverted, sideways, you name it. . .to no significant avail.)

I put up the second loop - same size - spaced about 20 feet apart. It was no easy feat using my slingshot to get the ropes in the pine trees and maintaining some semblance of symmetry. I cut the feedlines (RG-8x) to the proper length. The velocity factor of the RG-8x was .81 according to the manufacturer.

Lastly - The switch. . .Ameritron's RCS-8V comes from the manufacturer with the coax ports "ungrounded." Voila! I fed the loops direct - NO quarter wave matching transformer needed!

PERFORMANCE RESULTS

Absolutely phenomenal!! On air reports confirm that this antenna is equal or better to most 2 element yagis and competitive with most 3 element yagis - albeit at the same height. And - you have to remember that "average height" of my Delta Loops are only 30 feet. The top is at 60 feet and the feed point is only about 15 or 20 feet. Typical reports? VK/ZL usually give me +20 db over S-9. I can also work them long path. Europeans typically give me the same reports or better. The front to back ratio is only about 10-15 db - but what a difference it makes to cut the European broadcast QRM when I work stations to the West! They literally go from unreadable to solid copy. Best of all is the antenna is very inexpensive and INSTANEOUS SWITCHING.

PERSONAL INFO

I'm 52 years old, and still enjoy the hobby a great deal. It's difficult to

fit all of my interests into my day to day living. These interests Include: Golf, Relic Hunting, American Civil War History, Writing, and a host of others too numerous to list.

I have an MBA degree, am a Vietnam vet, and work as President for a Cable TV Construction Company. I've worked for the various large CATV companies in the past, and I was even fortunate enough to begin my own cable TV system that was ultimately sold to a large company after only 3 years. That was back in late 1989. My company now provides turnkey aerial and underground construction of coax and fiber optic cable with services predominately in the Mid-Atlantic region of the US. I'm married to a beautiful wife. I have a 23 year old daughter, a 13 year old son – AND Twins were born November 17th, 2000. Sean & Shelby. . .a boy and a girl!

The 40 meter Stealth Vertical

As published in www.antennex.com Dec. 2001

"You're 30dB over 9 here..." So goes the consistently fine signal reports received from around the USA and beyond - on 40 meters at the peak of Sun Spot Cycle 23. The most common antenna used in ham radio mounted over poor desert soil conductivity still performs beautifully!

This is the view of our second floor deck as seen from the closest street. The need for a 40 meter antenna that would perform well and not violate the spirit of the Home Owner's Covenants protecting the aesthetics of the neighborhood was the driving force behind the design of this vertical.

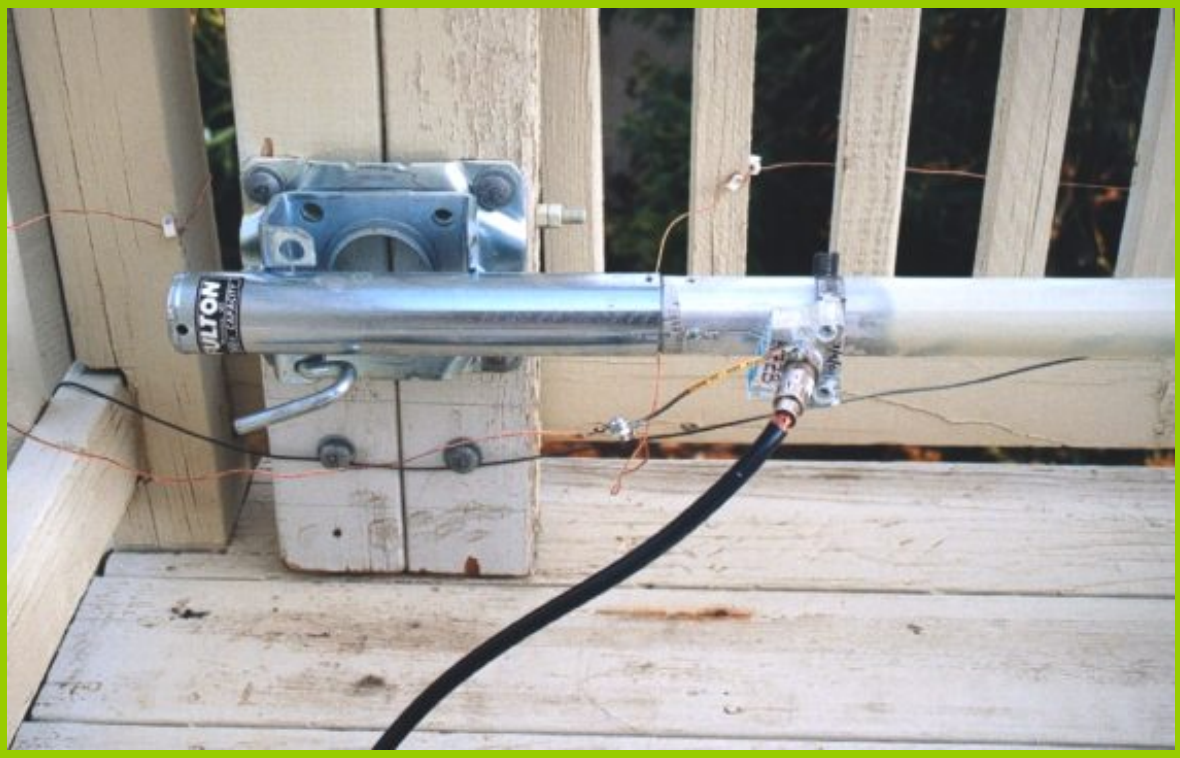
This antenna was designed to provide low angle radiation for good DX performance during the night time hours. DX on 40 meters is best when the local sun is down and this makes it convenient to use the cover of darkness to hide the size of a quarter-wave antenna. Especially one which is mounted 12 feet above ground which puts the top of the vertical at nearly 50 feet!

The basic concept is to mount a standard 1/4 wave vertical element on a swivel mount, secured to the deck railing. The mounting must be extremely secure when the antenna is in the upright position. It should also be easy for one person to put up or take down in less than 5 minutes. This design meets these criteria with excellent results.

The 40m vertical in its down position rests along the bottom of the far side deck railing. It is supported by plastic coated hangers of the type sold in hardware stores for hanging bicycles, etc, on garage walls. These hangers also make excellent supports for the antenna in the intermediate position for extending the telescoping top section and for supporting the vertical in the upright position.

Shown below is a view of the vertical with the telescoping top 5' section removed and stored in the down position. The swivel assembly has a spring-loaded locking pin which secures the base in either the upright or down positions. Putting up the antenna is simple: the top section is secured with a wing nut then the

vertical is walked up hand-over-hand into the upright position and locked in place with the pin. The hanger also stabilizes the antenna so it does not sway in light wind.



The swivel assembly I modified is a Fulton TJ503 swivel jack stand with snap ring, purchased at Walmart's. Fulton's website is available here.

The swivel assembly has been modified to support the vertical base element. Its load rating is well in excess of the load imposed by the vertical. Since the 35' - 7 1/2" vertical is only intended for use during good weather conditions it is only guyed with two light guy lines to ensure that in case something did happen to the antenna while up, it will not fall across neighbor's property. In our neighborhood there are no above-ground wires for power, cable TV or telephone, so there is no possibility of a crossed-wire mishap.

The coax attachment is made through an SO-239 connector mounted on an acrylic plastic block drilled and U-clamped to the base tubing. Also visible are the two radials connected to the shield of the coax connector. The two radials are 33' long, and slope from 12 to 7 feet above ground at their end. They slope because that's the available tie point height in the yard. The radials are oriented 145 degrees apart - not quite the 180 degrees desired but close enough. The EZNEC antenna azimuth plots do show the minor skewing of the pattern due to the asymmetric radial placement, but this has little effect on its performance.

The net active dimensions (not including the length inserted into lower elements) for each element of the vertical are as follows:

Base element: 11' 5" (1 3/4" Dia. Al tubing)

2nd element: 10' 2" (1 1/4" Dia. Al tubing)

3rd element: 5' 7" (3/4" Dia. Al tubing)

4th element: 4' 11 1/2" (1/2" Dia. Al tubing)

5th element: 3' 6" (3/8" solid Al rod)

The tubing diameters were based on what I had available. Good mechanical design technique should be used in attaching each element securely into the lower one.

This antenna does bow substantially when being put up and down. This droop could be minimized by going to a higher strength alloy. The best strength-to-weight ratio for vertical tubing is probably titanium-aluminum alloy, although it costs substantially more than the material I used.

Raising and lowering 35 feet of aluminum tubing up over one's head in low light conditions leads to safety considerations. I wear a hard hat and safety glasses when raising or lowering the vertical.

A Word document is available which contains a few more construction details and EZNEC plots for this antenna. Send me an email and I will provide a copy.

Shown below is a night-time photograph of the vertical in the upright position. The stabilizing hanger is seen approximately 2' above the swivel assembly. Notice a 6 turn coax loop in the line which serves to help keep RF out of the shack - which is about 20' from the vertical. The RF exposure on 40 meters with 500 watts output is within the FCC's Maximum Permissible Exposure limits.

An advantage of verticals mounted above ground like this one is the safety aspect of proximity to RF-hot radial wires or vertical elements. Our yard is walled and the RV gate kept locked, and the access out to the deck is past my operating desk - so there is little danger of anyone's unexpected exposure to hot wires.

Here is Brian (KD7Z) looking up at the top of the vertical with Dave (AB7E) out on the deck.

Brian helped with the design concept when he directed my attention to a Hints & Kinks article in QST (May 2000, page 56) that featured the fold-down mobile-antenna mount design of KB5YA. It was this use of the swivel jack that led us to conceive its use for a deck-mounted 40m vertical design.

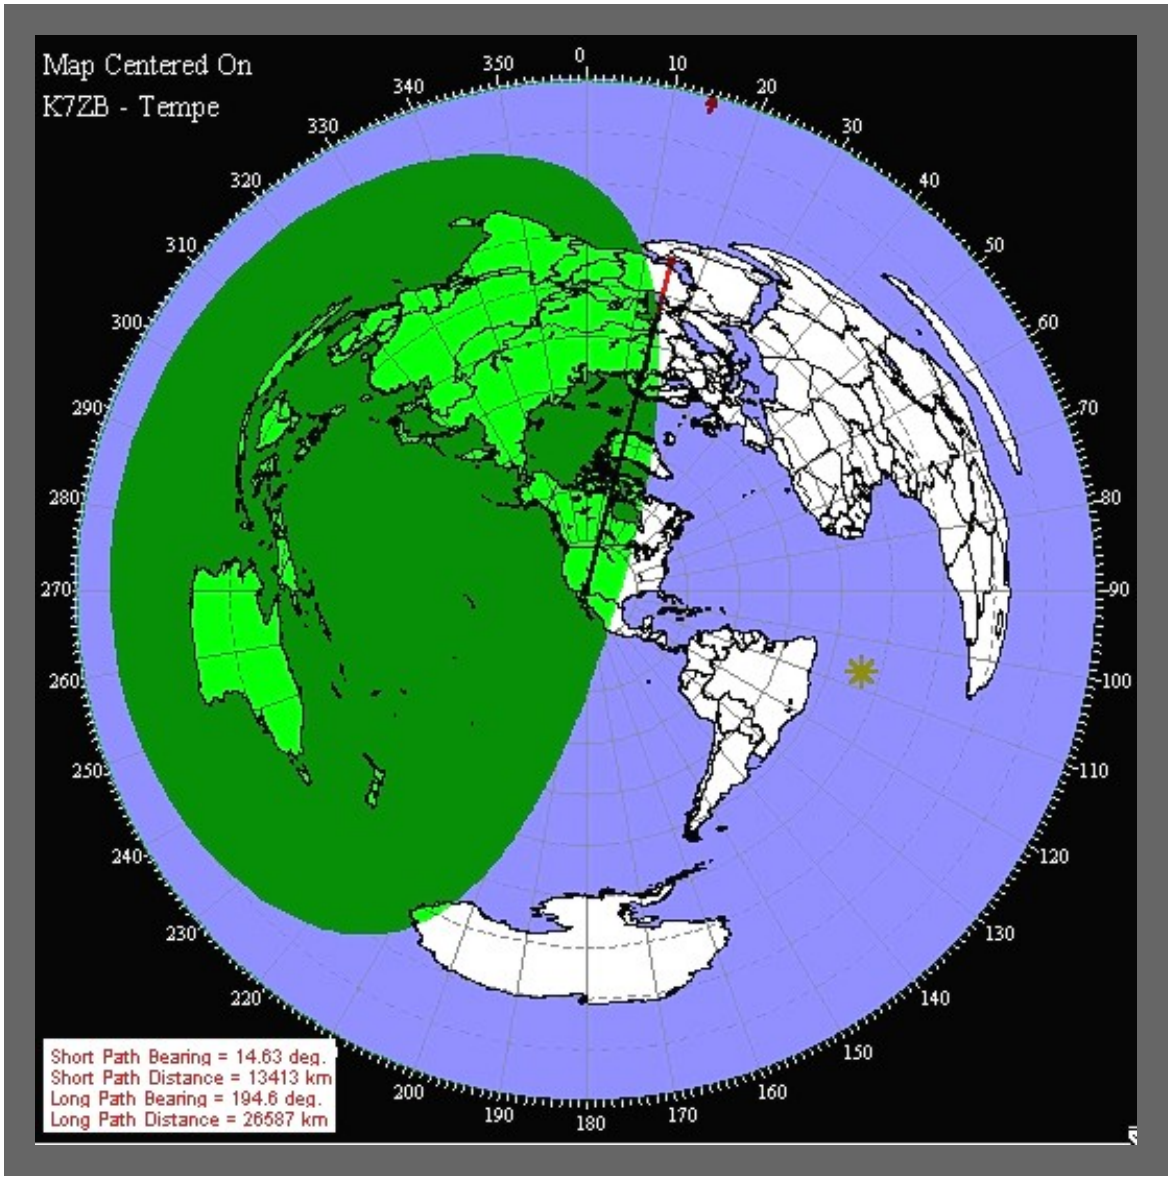
Dave provided EZNEC computer simulations for the vertical dimensions used here, which when implemented were right on target.

The photo below is of the vertical in daylight - up just long enough to take the picture to show how it looks at night! You can faintly make out the guy lines and one of the radials running out to the spot where I was standing to take this picture. Above the doorway on the deck is the coax feedline to the center insulator at the eave under the roof peak for the 75m antenna.

An excellent reference for understanding vertical antennas is provided by L.B. Cebik, W4RNL. Dr. Cebik is an authority on antennas and his website contains a vast amount of excellent information. The webpage specifcally covering verticals is shown below.

"Verticals Without Vertigo" by L.B. Cebik, W4RNL

Here's a QSO I made with A61AJ in the United Arab Emirates on 40m CW using this antenna and 100 watts. The Great Circle Bearing map below (AZ Map by Paul Burton AA6Z) shows the conditions. Gray-line propagation makes contacts like this possible and a vertical antenna can help you take advantage of it.



Signal path analysis:

This QSO illustrates a typical ***Long Path*** communications link. It is possible that the path was established with multiple hops of our signals in both directions. RF leaving my antenna would have launched at the low take-off angle associated with vertical antennas then skipped off the F2 layer of the ionosphere and returned to earth somewhere near the maximum single-hop skip distance of 4,000 km. This would place the first approximate reflection point out over saltwater on a bearing of about 195 degrees South of my QTH and in the South Pacific. The excellent conductivity properties of saltwater would allow efficient rereflection of the signal back up at a low angle and the process repeated for about 6 hops when the RF finally arrived from offshore into the United Arab Emirates. Other propagation modes like chordal hopping could have been involved as well. The enhanced propagation due to the sun's terminator made the path work with a mere 100 watts

at my end. The picture below was taken of this sunrise just minutes after the QSO.

The sunrise at the time of the A61AJ QSO...

Both 40m and 20-10m verticals are up. Note the stars still visible so early in the morning!

Shorty Forty Antenna

City dwellers and other flat dwellers know the practical difficulties they encounter when they try to put up an antenna for 40 meters. Finding space enough to accommodate 67 feet of wire is a real problem for them and most of them have to be satisfied by the inverted V. Whatever the book say, in practice the inverted V does not come up to the standard of a dipole antenna.

The Shorty Forty Antenna can be put up in the space required for a 20 meter dipole. If is a compact 40 meter dipole for limited space application by Jact Sobel W5VM. It is a center loaded antenna with a loading coil at the center. The two arms are 18 feet 6 inches long connected to the two ends of an inductor at the middle. The inductor consists of 30 turns of 12 SWG enamelled copper wire wound on 2.5 inch diameter PVC tube 5 inches long. There is six turns per inch so 30 turns will require 5 inches long. The shield of 50 ohms coaxial cable is connected to the center of the coil. The center conductor is connected to 2 or 3 turns away from the center, to a point which gives the lowest SWR. Compare this to a 67 feet dipole the saving in space is substantial.

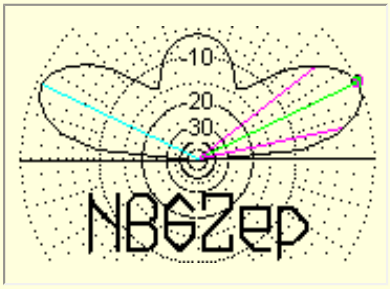
NB6Zep Antenna

Basic Design: A modified 20 meter Extended Double Zep ***Operating Bands:*** 40 thru 10 meters (with tuner)
Dimensions: 66 feet horizontal, 5 feet vertical ***Transmission Line:*** Open Ladder or TV Twin Lead
Materials: Conventional low-cost wire antenna construction (see below for details)



- The Super Zep is an elegant multi-band wire beam found **here**.
- Build a wire dual band DX Dipole or Yagi antenna system **here**.
- Instructions to add 80 meters to the NB6Zep are found **here**.
- Instruction for the smaller NB6Zep Jr are found **here**.
- A Space Saving 80 meter antenna is found **here**. New

The NB6Zep antenna is a simple inexpensive wire antenna, easy to build, that will yield excellent results on all bands. Only a dipole would be easier to construct and maintain. Unlike a dipole, the NB6Zep will operate on all ham bands 40-10 meters (including the WARC bands) with no strain on the antenna tuner, transmission line or operator. When you follow the basic rules for this antenna and use good common sense construction techniques to build this antenna, you will receive reliable results as shown in the documentation I have provided here.

> *"I wanted a portable antenna I could throw up between trees while camping so I made the NB6Zep on your web page. To test it at home I (naturally) set it up between a tree and a old section of TV mast tied off to the field fence. It's all of 15' off the ground but is noticeably better when I A-B compare it to a G5RV at 35'. The antenna is still up proving there is nothing so permanent as temporary when it works!*
> *Thanks for putting the design on the web. Easy to build and the darn thing works..." Jim Edmondson WA7KQG*

I live in an area with severe antenna restrictions. Not even TV antennas are found on the houses in my neighborhood! For the last eleven years I have been operating successfully on the HF ham bands by hiding my "evil activity" in the pine and fir trees that line the back yard of my home in Beaverton, Oregon. I have experimented with many designs and techniques for low-profile wire antennas over the years and have learned what works and what does not work. I have 5 wire antennas integrated into the back yard, but the single most valuable antenna I have is the NB6Zep at 40 feet above the yard! An NEC wire modeling program is needed to keep all of my wires operating properly in the space of a typical back yard. I have spent many hours using EZNEC to model the NB6Zep antenna. The total length is optimized to fit in the space of a 40 meter half wave dipole and the feed line length is optimized for good operation when attached directly to a tuner with balanced output. A coax termination to the tuner can be used with a 4:1 balun device at the end of the balanced line. I am happy to share with you the details for building your own NB6Zep.

Basic Construction: The wire must be installed as horizontal as possible. Do not invert or "dog leg" the wire as this will impact expected performance. The wire and feed line are light enough that it can be mounted with just the two ends supported. A strong 18 AWG wire is used to make both legs of the center fed antenna. Cut each leg exactly to the same length of 38 feet. (33 feet horizontal and 5 feet to hang down vertical.) Use a heavy duty ceramic or plastic insulator for the center to connect the wire legs to the feed line. ***CLICK for DETAIL*** The modeled feed line

length was 49 feet long for open ladder line and 41 feet long for TV twin lead.
Use a medium duty ceramic or plastic insulator at both ends of the horizontal wire to serve as a tie off point for the antenna support and to support a 90 degree bend to drop the last five feet down vertically. ***CLICK for DETAIL*** Attach a medium size lead fishing weight at the end of the wire to keep gravity working for you. Use a section of nylon twine (string) to hold back the vertical wire from wrapping itself around the support mast or other objects when the wind blows. ***CLICK for DETAIL***
Mount the NB6Zep as high as you can manage to support it. Drop the feed line down or away from the antenna at 90 degrees for as far as possible. Keep the feed line away from metal objects if possible. The line may be attached directly to the balanced line output posts of any tuner. ***CLICK for DETAIL*** If that is not possible, construct (or purchase) a 4:1 voltage balun and connect the step-up balanced side of the transformer to the twin lead and connect a short run of coax to the unbalanced side. You connect the other end of the coax to the unbalanced output connector on the tuner. This technique is useful for bringing twin lead from the outside into the shack through a window or other entry. Make a loop at the balun transformer to keep rain out of the device. ***CLICK for DETAIL***

Basic Performance: While waiting for the rain to stop so that I could install the antenna at 40 feet, I operated for several days with it stretched between two trees at 6 feet off the ground. Good psk31 contacts were made from Oregon to the East coast with 50 watts on the 40 and 30 meter bands. (High angle radiation is very under rated on the low bands). The antenna was brought to 40 feet, supported by two light gauge steel Radio Shack masts strapped to the upper trunks of two pine trees about 70 feet apart. The antenna is broadside to the SE and NW. All of the design data from EZNEC is based on the NB6Zep at 40 feet off the ground and with no large objects or other tuned antennas in the near field. The gain of the NB6Zep is based on the maximum field from a 1/2 wave dipole at a 1/2 wave length above ground. Your performance will differ if, for example, you have dipoles, yagis or any horizontally tuned antennas in the same yard as the NB6Zep. Your results may differ if your antenna height is less than 35 or greater than 45 feet. You should consider removing other horizontal antennas as they will be mostly obsolete with the NB6Zep installed. If possible, align your NB6Zep in the direction that places lobes where they will reach the largest population of ham operators. Nulls in the antenna above 30 meters can be useful to reduce QRM and interferences sources that are picked up by the horizontal polarity of the NB6Zep.
The NB6Zep should perform well at lower heights, even down to 20 feet. The take off angle will be effected by becoming lower at heights above 40 feet and higher for lower construction. It is possible to have good operation with the legs inverted down from the center feed point, however, the diagrams provided here are not valid unless the antenna is horizontal with the ground and in a straight line.
The NB6Zep is not a "tuned" antenna and will not interact significantly with other antennas in the yard. You could construct several NB6Zeps to have selectable directivity for the bands above 30 meters.
40 and 30 meters: The NB6Zep performs like a half wave dipole, with broad, medium to high angle lobes running off the sides of the antenna. Very good for regional and for long distance skip. The antenna displays very little directivity on the low bands and is performing very well in all directions.
20 meters: On this important DX band, the NB6Zep has it's highest gain, over 3 dB. There is a sharp medium angle lobe running 90 degrees from both sides of the antenna. ***CLICK for DETAIL*** For the first few contacts on 20 meters with the NB6Zep, I reached Texas, Utah, Alaska, Korea, Japan and Argentina, all with strong reports. A good QRP contact to Japan was made on PSKHELL mode. ***CLICK for DETAIL*** The antenna produces very sharp lobes from each side, good for long distance and regional skip.
17 and 15 meters: On these bands the NB6Zep produces two broad lobes spaced 45 degrees from both sides of the antenna; each lobe has gain. This looks like a butterfly pattern when viewed from above the antenna. ***CLICK for DETAIL*** The antenna performs very well for long distance with it's low angle radiation and also has medium angle radiation for shorter skip operation.
12 and 10 meters: On these higher bands the NB6Zep produces two narrow lobes with gain, separated by 60-80 degrees from each other on both sides of the antenna in an "X" configuration. ***CLICK for DETAIL*** Two layers radiate from the antenna giving very good operation for long skip and shorter skip conditions. As on 20 meters, the NB6Zep is very directional on 10 meters.
A diagram showing the current distribution on the NB6Zep antenna system for the major bands is ***FOUND HERE***

Construction Notes: Ceramic "egg insulators" are commonly used in wire antenna construction, but I have had

good results over the years making my own wire antenna insulators from plastic coat hangers. (Use the flexible round type purchased in stores, not the free hangers from the dry cleaners.) They are very strong, UV resistant and low-cost. Cut 3 inch sections and drill holes a 1/4 inch from the ends. Use them at other lengths for wire spacers when making a "fan dipole" or open ladder feed line.

Always solder every wire connection and then insulate connections from water seepage. Also insulate around all exposed coax braid. Use "hot melt" glue or a silicon rubber sealant like RTV. ***CLICK HERE*** to see some of the basic materials and tools I use to construct wire antennas.

You can make your own light weight balun using Iron Powder Toroid cores. The smaller T130 HF material (red) cores work fine for several hundred watts. Follow the diagrams in the ARRL handbooks. Use a hand drill to twist 20 AWG enameled wire into winding sections used in bi-filar and tri-filar transformers. Make about 12 turns onto the core for good performance. ***CLICK for DETAIL*** Wrap layers of electrical tape around the balun to protect the core from damage. (Cores are like glass and once they are cracked the core permeability is altered.)

Use medium weight nylon twine for all of your wire antenna construction and support needs. It is extremely strong and lasts forever.

The NB6Zep Story: Once upon a time, in a land far to the Northwest, there was a full sized 20 Meter Extended Double Zep antenna supported only by two majestic pine trees. The trees both stood at the very outer regions and at opposite corners in the land known as NB6Z. This span of distance allowed the EDZep to spread, although the weight of the feed line at the center could not be supported, causing a rather unsightly and disconcerting droop to be seen. Despite the odd appearance of this stately antenna, it continued to serve its' master well for many years; with many fine contacts on all bands from 40 through 10 meters. It occurred on one winter's day, that a fierce storm blew down one of the two pine trees that had supported the EDZep. This caused much anguish to the master of the land, who immediately gathered his forces to find an acceptable solution to this dilemma. Several seasons of trial and error passed, but no resolve could be made. Finally, after much calculating and re-calculating, a new design configuration was found and a new support tree was christened. Much to the delight of the master of the realm, it was found that this new design had no droop to catch ones eye. Further joy was had when the on-air performance of the new antenna was found to be just as good as the original! Overcome with joy, the master named this new design *NB6Zep*, after the land in which it resides. He further decreed that the new design be shared throughout all the land of Hamdom and with all who seek to enter the Kingdom of Ham.

"Push-button Menu of Stuff"

20m Delta Loop.

This antenna is fed for vertical polarisation, to give a low angle of radiation for DX and also a nearly omni-directional radiation pattern (broadside is the best direction by about 3 dB).

I have built two versions of this antenna; one using coax as a monoband antenna for 20m as simulated below, and the second as presently used with 450 Ohm slotted ladder-line feeder for multiband use (20 and 15m).

In the monoband application, the impedance at resonance on 14.2 MHz of about 100 Ohms is transformed by a quarter wavelength of 75 Ohm cable (3.5m long) to give a good match (better than 2 : 1) across the whole band. The 75 Ohm coax braid is connected to the lower side of the loop element. I don't use a balun as the antenna is not balanced, due to the offset side feedpoint, but do implement a coaxial choke at the 50 Ohm cable connection to the matching stub of 10 turns, 20cm diameter. The antenna is 7.71m per side, with the feed point 3/4 of the way down one side (5.78 m from the top) note; 3/4 * 1/3 wavelength = 1/4 wave, this is important to obtain vertical polarisation.

This antenna is also effective on 15m provided open wire feeder is used up to the antenna instead of coax. I have found 10m DX performance to be rubbish! Simulation confirms this.The pattern is rather directional on both the higher bands.

Photo of the antenna

TBD.

A ONE ELEMENT V BEAM FOR 15 METERS

"I REFER TO THIS AS MY ONE ELEMENT BEAM, IT'S A HORIZONTAL V!
IT OUTPERFORMED 2 ELEMENT BEAMS WE HAD ON 10 METERS AND 20 METERS IN LAST YEAR'S FIELD DAY!
IT HAS GAIN IN A SINGLE ELEMENT DESIGN!

THE db GAIN, IF FIGURED BY THE BOOK, IS 3db OVER A DIPOLE!".....DARRELL REF 1
In log-periodic dipoles, it was found that forward tilt increased gain by a 3 to 4 db over a regular log dipole.
ref 2Horizontal V Antenna for 15 Meters
"The HORIZONTAL V ANTENNA FOR 15 METERS"
This often leds to the asumption of what is a Beam Antenna, in it smallest of states, the Horizontal Vee, must be one of the least researched or understood antennas, after stumbling on misleading data one would think the antenna to be a dud, that efforts to make such a antenna would be a waste of time. This is far from the case.....DARRELL.

This page is GRAPHIC intensive, please allow time to load!

A ONE ELEMENT BEAM FOR 15 METERS

CONSTRUCTION DETAILS

In log-periodic dipoles it was found that forward tilt increased gain by a 3 to 4 db over a regular log dipole. Ref2
A little history , 3 years ago, I was using a rotatable dipole for 15 Meters and had good results but wanted something better. This dipole was built with a DAK dipole mount and used 36 inch extenders with 6 foot 10 7/8 inch fiberglass CB whip antennas. This worked well, but I wanted something a little better. I spent more time reading about antennas and got interested in the Horizontal V antenna and found that the basic V starts at 1/4 wave with a 90 degree angle. Ref 1

Time to build and test my acquired knowledge.
The center of the antenna started life as 2 mirror mount CB antenna mounting brackets, the first piece was flat on both sides of 90 degree angle and a second 5/8 inch hole was added an equal distance on the other side.
The second mirror mount is heli-arced to the first piece, with the top piece horizontal and the bottom piece vertical with the pole mount going down. (**See picture above**) Welding was done at a local welding shop for a $5 bill.

Now I use the insulated CB 3/8 by 24 antenna mounting kits. You can pick these up at Radio Shack but get 2 and get the ones with bolts and stay away from the flimsy screws. The kits come with 2 bolts, 2 long nuts, and the plastic insulators. Use one kit per 5/8 hole on top, going from back to front (bolt, insulator, thru antenna bracket, insulator, long nut). Also while at Radio Shack pickup a couple of heavy duty terminal ends for the end of your coax. The coax is done in a pigtail fashion and connected on the bolt side of the antenna insulator hole 3/8 dia with at least a #10 wire connector for your terminal ends.
My elements consist of two 6 foot 10 7/8 inch fiberglass CB whip antennas with 38 inch extenders.(See picture above) and note that the original dipole used 36 inch but do to the induction between the elements, the resonant frequency raised to 21.350 MHZ. The 38 inch extenders lower the frequency to 21.250 with a l to 1 SWR). I operated field day on 21.205 and only got chased off frequency twice and came back and retook the frequency, minutes later. The extenders were made

from 1/2 inch EMT tubing. On one end a 3/8 by 24 long nut is inserted leaving 1/16 inch exposed for soldering. Soldering was done with a 5% silver solder. On the other end a 3/8 by 24 bolt, 1 1/2 inch long, with a 3/8 by 24 nut attached to leave 1/2 inch of threads exposed was inserted in the other end leaving 1/16 of the nut exposed and the 1/2 inch of threads. The nut is soldered on the exposed 1/16 inch of nut, take care not to weld on the exposed 1/2 of treads. Two of these must be made.

The final assembly starts at the center antenna mount. Connect coax pigtail on bolt side of antenna center insulators, connect treaded side extender to center, connect whip to extender and repeat for the other side. (**See picture above**)
The entire 15 Meter antenna weights around 6 pounds and was used on a 20 foot tower with an 18 inch truck wheel for a base, no guy wires were used and it withstood a 30 mile per hour wind when a thunderstorm hit just after setup for field day 2001. It has performed better then I could ever have imagined. I learned what it was like to be in a pileup and have fun, we even worked **DX** and had 49 of 50 states in the 24 hour period! We had directivity, and rotating from NE to NW we lost the **DX,** but started working the Western States. I figure the gain over a vertical at around 6 db, and a walk around the Horizontal V with a field strength meter (**see diagram above**) was enough to tell me that this antenna will perform.

A fellow ham came by, **AF4HZ** Gordon Blauser and I let Gordon walk around with the field strength meter and he walked away amazed with how good the antenna performed with 10 watts running to it. He got one of the proto type centers and was vowing to try using 2 hamsticks on his V. I also have to get Spencer Whitmire, **W4ERC**'s report on how another proto type center is being tested on 6 Meter with just a couple of stainless steal whips cut down to around 52 inches that will work on the Magic Band.

The center antenna mount could be made with a 6 or 8 inch longpiece of aluminum angle 2 inch by 2 inch and 1/4 inch thick. This should give plenty of space for the mast clamp. Nay sayers may say that the aluminum mast affected the radiation pattern but it worked for the good of the antenna.

Using the 36 inch & 38 inch extenders together with the whips puts the antenna on 17 Meters, Previous experiments with a different length whip on the 36 inch extenders enabled operation on 12 Meters. I lost this bit of research and suppose that with adjustable extenders (which I haven't designed yet) would do the trick of getting multi-band coverage, but below 20 Meters the antenna would lose the ability of 1 man erection. Remember this antenna is directive and is rotated when used in the field and is done by the arm strong method, and if guyed, use guy wires on a slip ring.

THIS IS THE BEST PERFORMING ANTENNA I HAVE EVER BUILT!
DON'T LET THE SIZE FOOL YOU.
All that is required to use this antenna is a willingness to give it a try and then look at the results. It then comes down to operator skill as to how many contacts you can do per minute.
It truly is AMAZING!

FOOTNOTES ADDED BY DARREL..... KB4XJ

The dipole formula of 468/freq will work but, an extra 2 inches must be added to the final result.

The induction between the elements changes the resonant frequency of the antenna, and with a dipole cut for 21.250 Mhz (SWR 1:!) when folded into the V shape, the induction of the elements moves the freqency UP to 21.350 Mhz (SWR 1:1).
The Basic principle of the V antenna, when dealing with the rf radiation lobes are that the lobes in the bisector of the V tend to add and the other lobes tend to cancel.

A CHALLENGE

I'am President of the Local Ham Radio Club, and the chairman of the upcoming Field Day 2002. My 20 Meter operator has vowed revenge for the beating he got in last years Field Day from the One Element Beam and has stated that he's going to give me a run for the money and has bought a NEW antenna which will replace his 2 element butterfly beam.
I accepted his challenge and told him I would be using my V and that I wanted his competition AND that I wasn't going to roll over and give up just because he got a new antenna.

The proto-type 6 Meter Horizontal V will be used by Spencer Whitmire W4ERC, the Vice President of the local radio club, Spencer was on 10 Meters with a 2 element beam and was converted to a believer when he saw the V in operation in last year's field day.
Spencer will give 6 Meters a try with the V.
Our callsign for Field Day 2002 will be K4W (Kilo Four Whiskey).

I became an EXTRA in 12-4-98. The One Element Beam is the results of several years of work on various antennas, I was really depressed with the results of tests on so called big signal antennas and finally went back to the horizontal dipole with good reports. I remembered from my beginning in ham radio about the inverted V that I used on 75 Meters and how I could get into Hawaii. I also remembered that an inverted V could be made directive by the leg angle. This was the turning point which led to the ONE ELEMENT BEAM!

While reviewing the logs of last years field day, I found KH6, VE6, VE3, VE4, VE5, KP4, VE7, NP2, DJ2, NP4, TZ6, GO6, VE1, VE9, XE1, RX3, DL6, EA4, OH4, G4, G0, EA5, EA3, DL1, OH1,

RA3, DJ2, F6, PA3, F5, F6, AND VE2. I found these prefixs in the log book of the DX worked during field day, with the Horizontal V. Darrell...KB4XJ

A comparison of 10 meter verticals using modeling

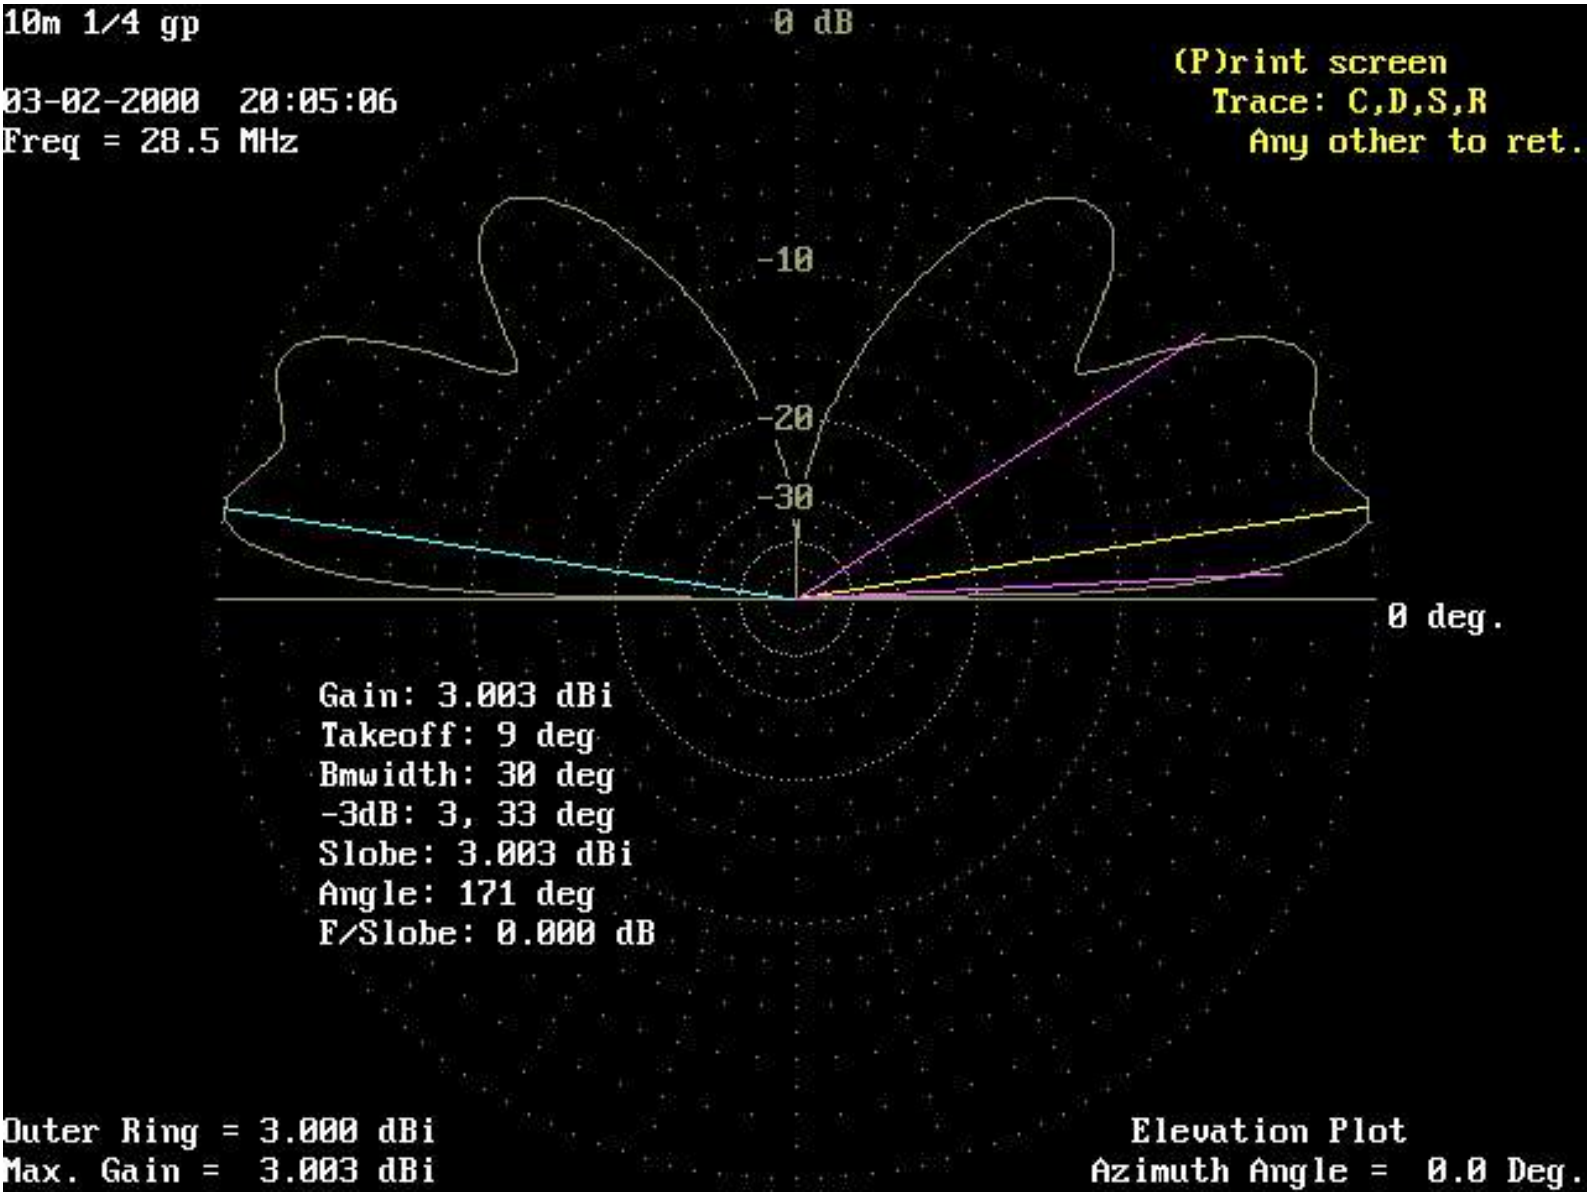
I decided to test a few versions of popular ten meter verticals using elnec demo to test. I have had trouble in the past trying to convince people I was using a 5/8 ground plane with decent success. And I could see their point as normally a 5/8 ground plane has a fairly high angle of maximum radiation. But a major difference was I have been using 3/4 wave radials instead of the common 1/4 wave versions. I found what I think is the reason I have had fairly good success. But I also found a few things I was doing wrong in earlier versions. I found for maximum gain, I would be better off using 5/8 wave radials instead of the 3/4 wave. I had assumed in the past that being the 3/4 wave radial would be resonant and the 5/8 would not be,that the 3/4 would be better. But modeling this antenna, this doesn't seem to be the case. I found using 5/8 radials and sloping at a steep angle to the ground, would give the most gain. With the antenna acting more as a dual 5/8 collinear than a 5/8 radiator with a 5/8 wave ground plane.

Don't have elnec or eznec? You can download a demo version here at http://www.eznec.com/elnecdem.htm

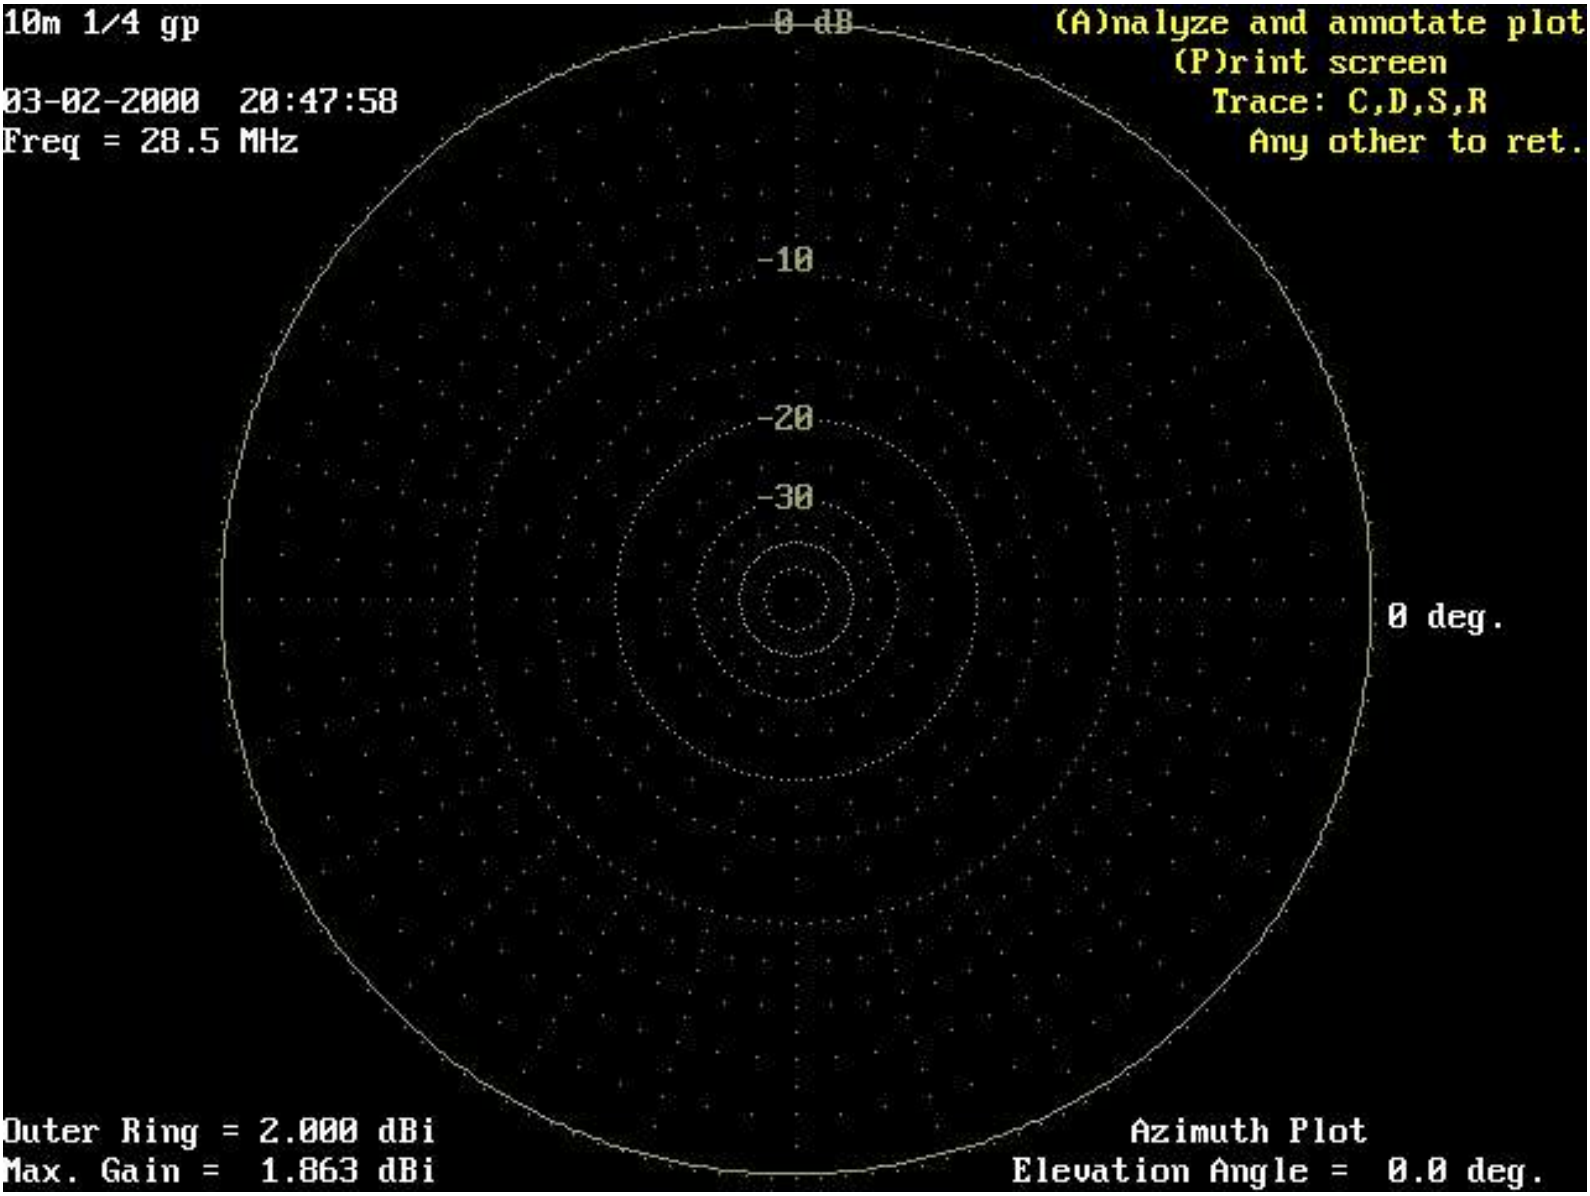
---

I will show the plots of the popular 10 meter verticals. All antennas are modeled at the 40 ft level. I'll start with the 1/4 wave ground plane with 4 sloping radials.

This is the elevation plot over average ground with the antenna at 40 feet.



And the azimuth plot showing freespace gain.



And a view of the antenna showing the current distribution

The DF9CY Three-Element Antenna for 28 MHz

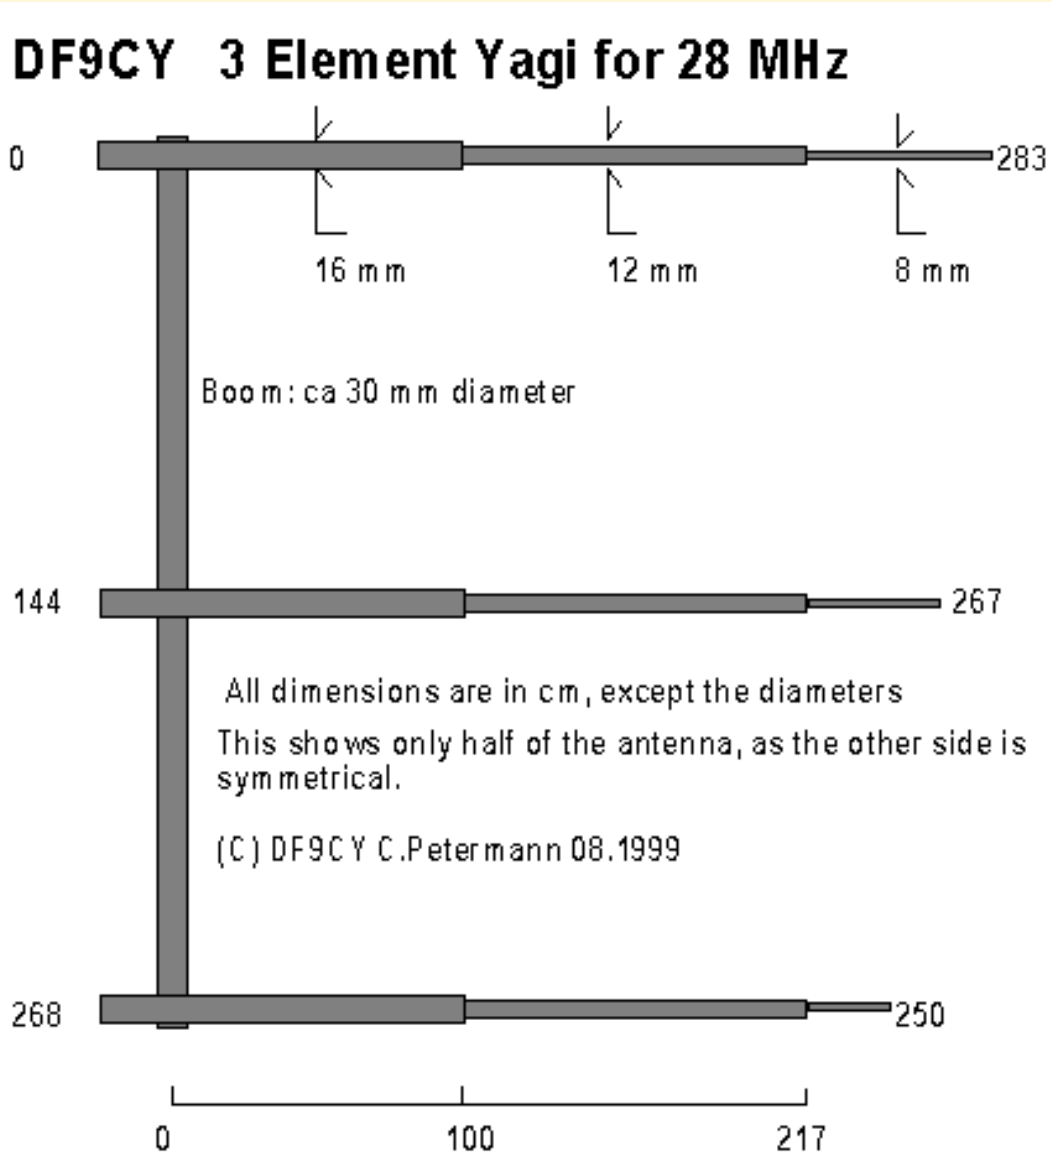
Christoph Petermann DF9CY 1999

A better view of the 3 element for 28 (and the 6 element for 50 MHz)

My 3-Element for 28 MHz antenna is mounted below my 6 element for 50 MHz

The 3 element is a commercial antenna by PAN International, which I slightly modified for good performance on the 10m Amateur-Radio band.
Design Frequency: 28.300 MHz

- **Usable Bandwidth: 600 kHz**
- **Return loss: better than 20 dB with center at 28.270 MHz**
- **Gain: > 7.5 dBi**
- **Front/Back ratio: > 20 dB**



This antenna is a commercial CB Radio antenna distributed by *PAN International*. For this kind of antenna it looked quite robust and indeed it survived a wind storm with wind speeds up to 160 km/h.

Feeding the antenna

This antenna is fed by a gamma match. Setting up this antenna was very easy. Position of the gamma match as approximately moving the bracket as far inside as possible and the inner conductor "looks out" by 70 mm at the end.

Modify the elements

Calculating the antenna with EZNEC gave already very good results. The redesign for 28.270 MHz resulted in shorting each elements' end by 40 mm. This is indeed very easy, as there exist two holes for self-cutting screws separated by 40 mm. Move the outer element in by one hole, fix it with a screw and drill a hole for the second screw. Ready. You shall better not use the screws delivered with the antenna as they tend to oxidation (rust) very

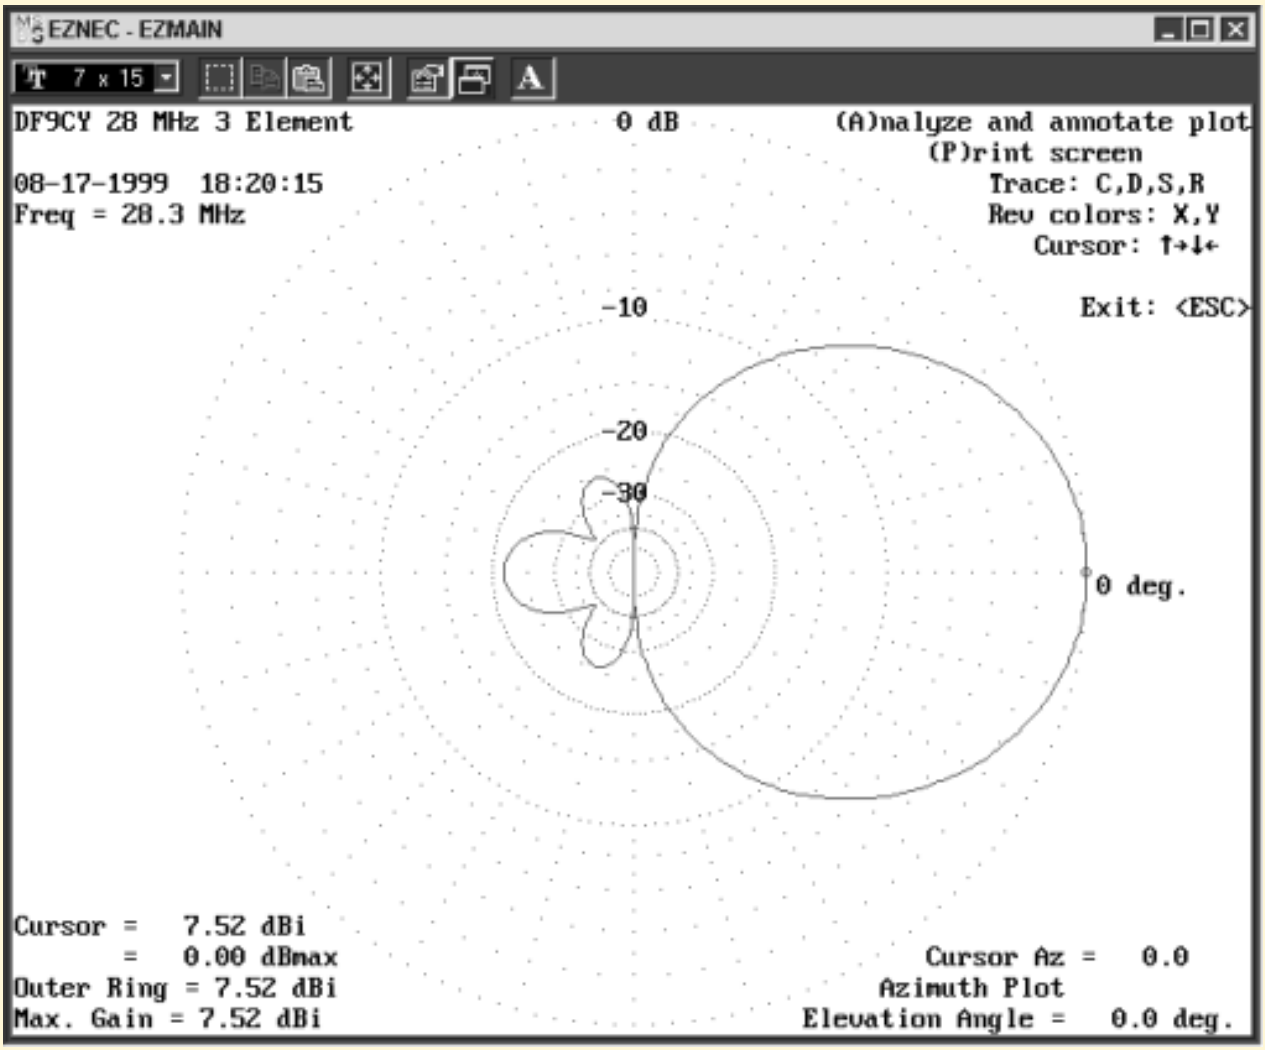
quickly. I bought a complete new V2A set of screws and I have no problems. The elements are electrically connected to the boom. What I dislike is the SO239 connector "popped" to a sheet of metal. I will replace this by a N-Connector now.

Performance

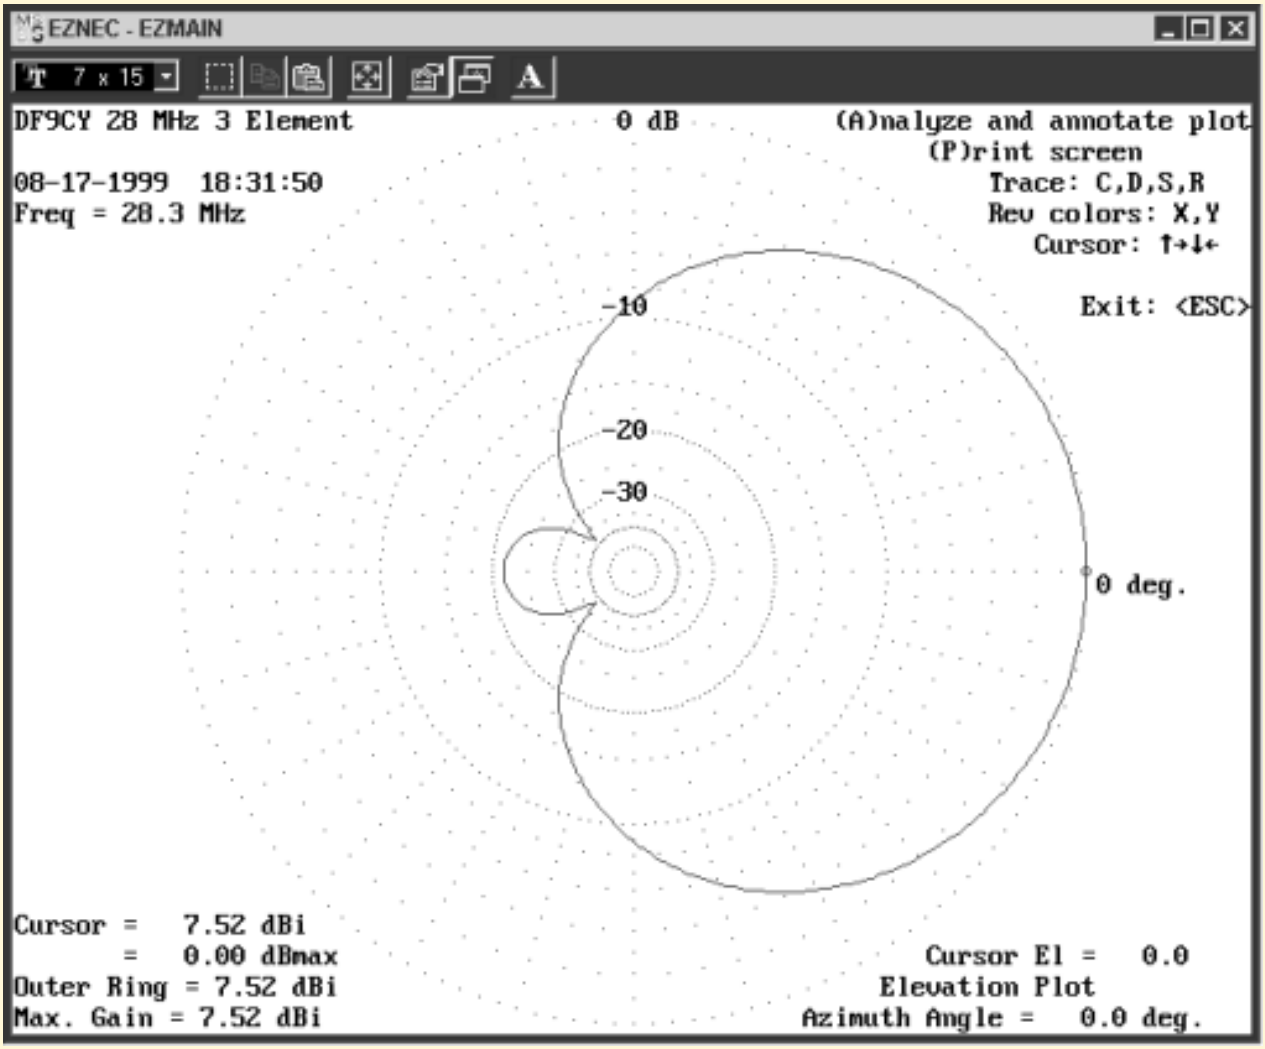
The antenna is up since October 1998 and performance is good. Contacts were made with all continents using my TS690 with about 90 Watts output. It does not perform as our "pile-up-cracker" does, but I feel it works better than a tribander. The antenna is installed at about 9 m above ground. This is indeed not very high, but the surrounding terrain descents in most directions putting the antenna virtually to a higher position. The feedline I use is a low-loss UHF cable (AirCell 2000) with less than 0.4 dB of loss on the 22m run. I also used it with 750 Watts output from a 3-500 for a while and it did a fine job.

EZNEC
Here is the EZNEC simulation file: **cy28-3dopt.zip**

DIAGRAMS AND SIMULATIONS



Azimuth diagram of the 3 Element for 28.3 MHz. Note the good front to back ratio.



Elevation diagram. Vertical attenuation is around 10 dB.

My special thanks go to Roy Lewallen W7EL for programming this fantastic *EZNEC 2.0*

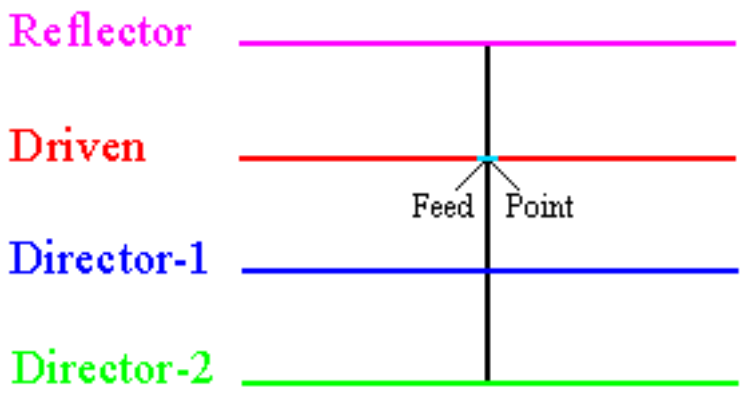
VHF / UHF Direct Connect Beams

Here are some lengths and spacings for various direct connect beams. The layouts are straight forward and are illustrated below. Your SWR should be less than 1.3:1 with these designs.



The driven element is cut into two halves and insulated from the boom with nonmetalic material. Then the two wires of the coax are connected, one to each section of the driven element. You may drill small holes and use sheet metal screws to accomplish this.

The reflector, director 1, and director 2 can be attached directly to the boom by a variety of methods. There are some helpful hints for antenna construction on our antenna construction tips page.

A 5 BAND LOG PERIODIC DIPOLE ARRAY

In ARRL Antenna Compendium No. 4, I desribed how I modified the Telerana which was orginially featured in the July 1979 issue of QST. The unique feature of the Telerana is that the elements are wire instead of aluminum tubing which makes for a light weight LPDA (log periodic dipole array). The array is suspended within a framework made of fiberglass poles emanating from a central hub with the ends tied together with light weight rope around the perimeter.

Here is a picture taken of the Modified Telerana taken from below.

Modifications to the orginal Telerana design included adding parasitic reflectors for 15 and 20 meters to improve the front to back ratio on these bands. I also described how I added a trap 30/40 meter inverted Vee that acts as a top truss system to keep the Telerana from turning upside down like an umbrella might in high winds. Below the modified Telerana is a homemade 4 element 6 meter Yagi. This system allows coverge of all amateur radio bands from 40 to 6 meters without an antenna tuner, on one tower, with only 3 coax feed lines. A very compact system that works very well.

I have been using this antenna system since 1986. It is supported by a Wilson telescoping tubular tower with the modified Telerana at 62 feet and the apex of the 30/40 trapped inverted Vee at 72 feet. I have worked 293 contires and confirmed QSLs from 275 countries with this system! As well, I have worked 121 countries at QRP levels!

Vol 4 of the ARRL Antenna Compendium series is no longer in print however I have scanned a copy of the article, "The Improved Telerana, with Bonus 30/40 Meter Coverage, here

(Copyright ARRL. All rights reserved, used with permission of the ARRL.)

You may also find an abbreviated version of the Modified Telerana article in recent ARRL Antenna Handbooks.

Using Moxon Rectangles for WARC-Band Antennas
Part 2: Some 30-17-12 Meter Ideas

L. B. Cebik, W4RNL

Last month we looked at the Moxon rectangle, cut for 17 meters, as the basis for a very compact dual-band Moxon-Yagi for 17 and 12 meters. The design used open-sleeve coupling between the physically driven 17-meter driver and the slaved 12-meter driver. The Yagi portion was a standard driver-director design with about 0.07 wavelength spacing. The result was a two-band array about 10' long and 20' wide that provided over 6 dBi free-space gain, better than 20 dB front-to-back ratio, and a direct feed with 50-Ohm coax (with, as always, a recommended choke or 1:1 balun to attenuate common-mode currents).

Compactness: this goal was one of the good reasons for using a Moxon as the basis for the dual band beam. The width of a Moxon is only about 70% that of a full size Yagi with a driver and reflector, and the Moxon uses no loading to achieve the shortening. Instead, it bends the elements around to point toward each other. By selecting the correct proportions and tip-to-tip spacing, one can obtain a parasitic driver-reflector array with nearly the gain of the full size Yagi and considerably improved front-to-back ratio over the Yagi. Part of the reason for the excellent front-to-back performance lies in the current magnitude and phasing on the rear element relative to the front element: they are close to what one might obtain with each element driven to perfection for maximum rearward rejection.

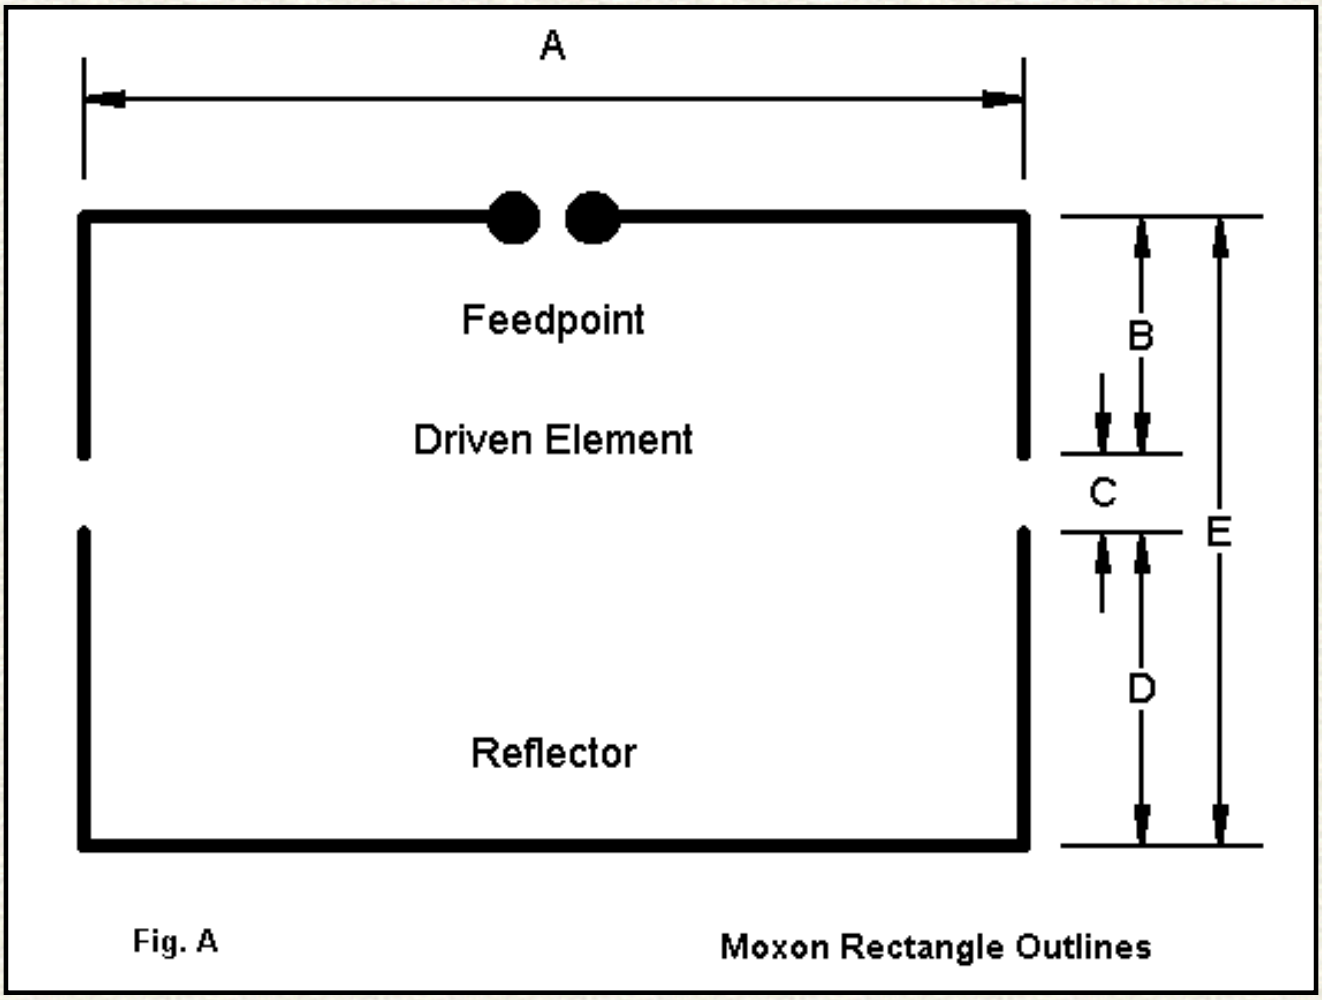

Fig. A provides an outline sketch of a basic Moxon, a refresher. As well, the portions of the Moxon structure are identified, since we shall once more provide some design ideas involving this antenna. However, this month, we shall include 30 meters.

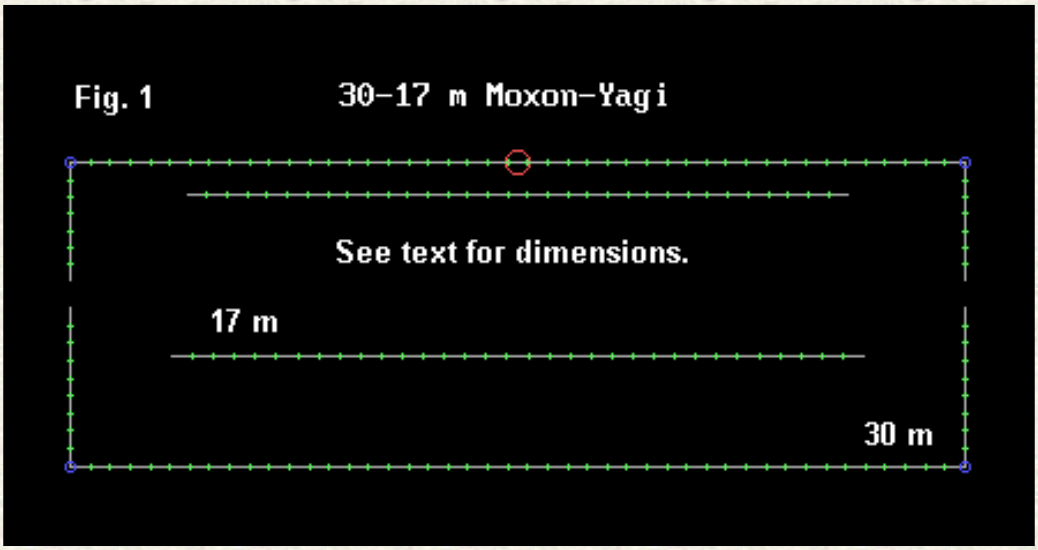
A 30-meter Yagi with unloaded elements would be about 48' to 49' side-to-side. A Moxon rectangle for 30 meters requires only 35' of side-to-side space, and about 13' front-to- back. These dimensions are close to those for a common 20-meter beam. The structure of a 30-meter Moxon might have to be a bit beefier than that of a 20-meter Yagi, since the parallel element must support the "tails" (B and D in **Fig. A**). Nonetheless, for those with space limitations, 35' elements are usually easier to sustain than 48' elements.

A 30-17 m Combination

When we examined the possibilities for 17 and 12 meters, we reached two practical conclusions. First, a dual Moxon array may be too sensitive to minor variations to be truly practical for home building. Second, placing a full size 12-meter Yagi of driver- reflector design inside the 17-meter Moxon was not feasible due to the length of the 12- meter elements--especially the reflector.

Therefore, we shall bypass a dual Moxon for 30 and 17 meters. However, we shall not forego the possibility of a full-size 17-meter Yagi placed within the frame of a 30-meter Moxon. The longest element of a driver-reflector Yagi for 17 meters is 27' and that should be no problem within the 35' dimension of the 30-meter Moxon. **Fig. 1** shows the general outline of the combination.



The following table of dimensions uses the designators of **Fig. A** for the Moxon. The Yagi element spacing entries are distances from the Moxon driver. All dimensions are in feet. The Moxon elements are 1.25" aluminum tubing, while the Yagi elements are 1" diameter aluminum tubing.

Band	Dimension	Length (feet)
30-meter Moxon	(all elements use	1.25" diameter aluminum tubing)
Moxon	A	34.91'
	B	4.89'
	C	1.12'
	D	6.56'
	E	12.57'
17-meter Yagi	(all elements use	1.0" diameter aluminum tubing)
Driver	Length	25.80'
	Space	1.30'
Reflector	Length	27.00'
	Space	8.00'

The spacing between the Yagi elements is 6.7' or about 1/8 wavelength. The spacing of the Moxon elements is about 0.13 wavelength. The Moxon dimensions are unchanged from those optimized for maximum front-to-back and a 50-Ohm feed when used independently. Of course, changes in material dimensions or the use of stepped-diameter elements will require readjustment of the design to yield satisfactory performance. As I did last month, I shall place model descriptions at the end of these notes for those who wish to experiment with other material combinations.

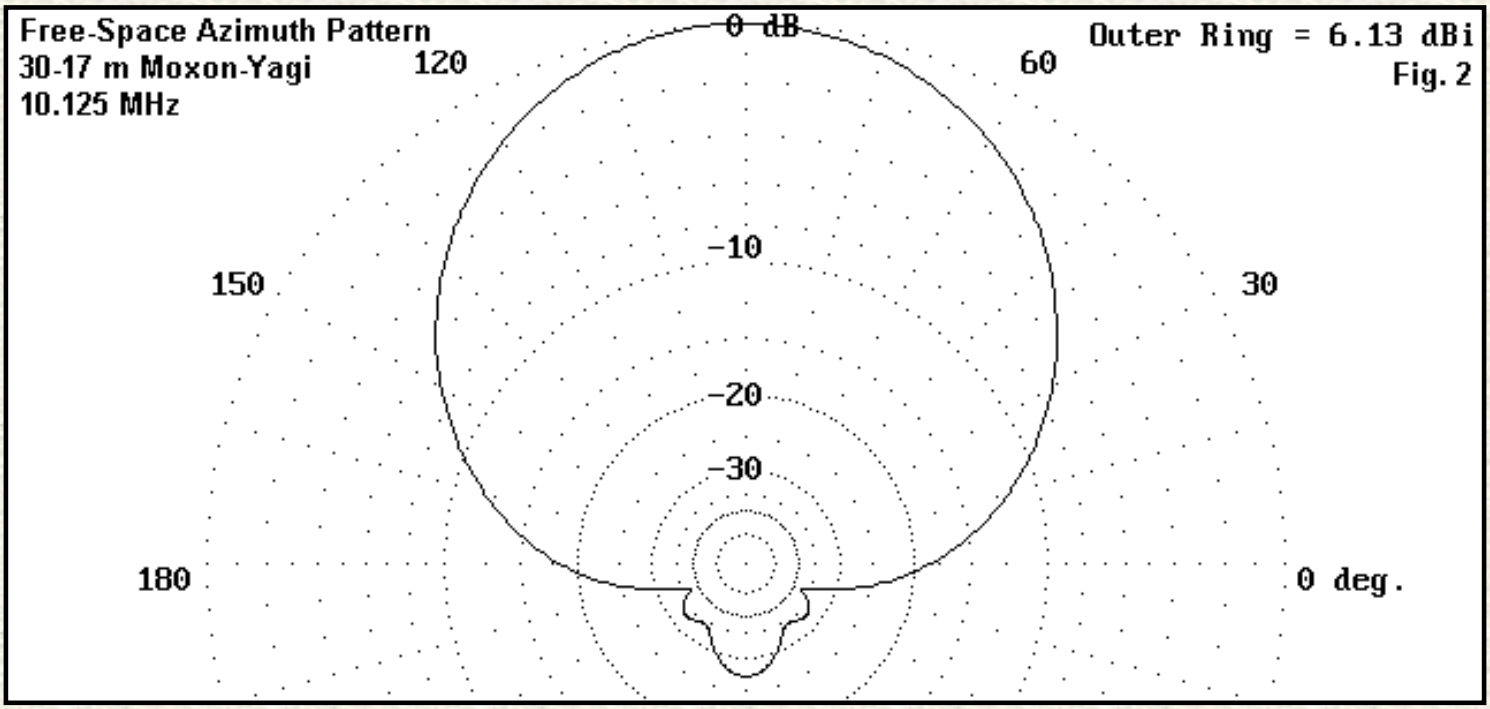
However, once the basics are established, the only post-construction adjustment will be to the slaved 17-meter driver. Its exact length and spacing from the Moxon driver will determine the feedpoint impedance on 17 meters at the physical feedpoint.

The Moxon-Yagi combination is a very well-behaved. The following performance table, listing the gain in terms of free-space gain, gives a good general picture.

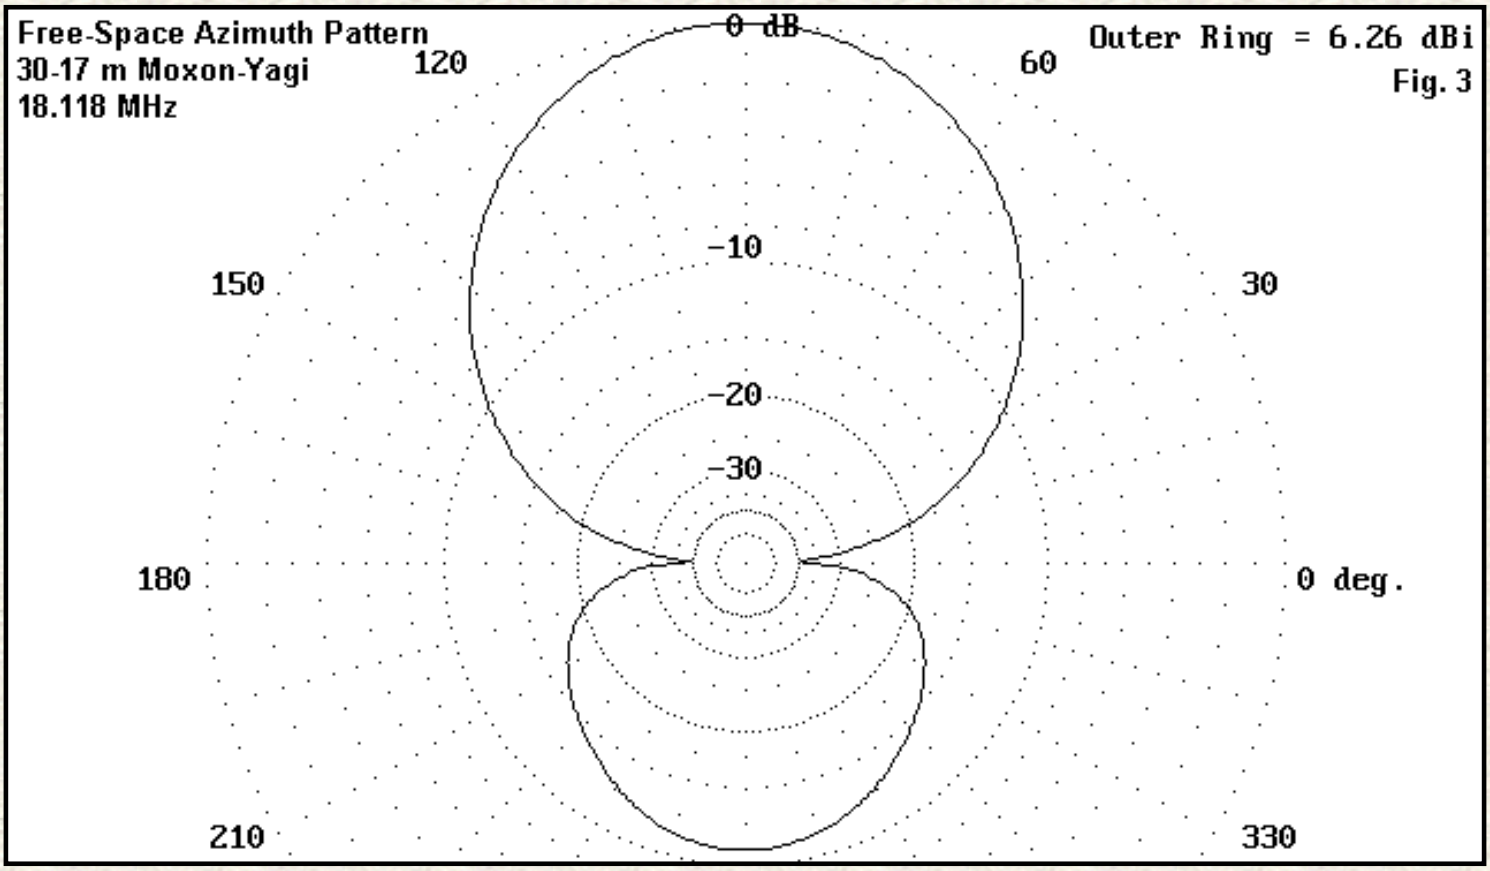
Frequency MHz	Gain dBi	Front-to-Back Ratio dB	Feedpoint Z R+/-jX Ohms	50-Ohm VSWR
10.100	6.21	22.9	47.6 - j 3.6	1.09

10.125	6.13	27.0	50.7 - j 1.4	1.03
10.150	6.05	33.4	53.7 + j 0.6	1.07
18.068	6.37	10.8	52.4 - j22.5	1.55
18.118	6.26	10.9	49.9 - j 5.4	1.11
18.168	6.16	10.9	47.5 + j10.9	1.26

As we saw last month, the addition of a closely-spaced parasitic beam slightly detunes the Moxon in terms of moving the peak front-to-back ratio upward in frequency. However, the gain and the source impedance are mostly unaffected. **Fig. 2** provides a free-space azimuth pattern of the 30-meter Moxon performance at mid-band. One of the side-benefits of the Moxon rectangle design is that it tends to hold its high front-to-back ratio even down to a height of 3/8 wavelength--about 36' on 30 meters. Of course, the old rule that higher is better still applies. Nevertheless, even a modest installation can expect quite reasonable results on 30 meters.



On 17 meters, we must expect the lesser front-to-back ratio associated with the driver- reflector Yagi design. **Fig. 3** shows the mid-band free-space azimuth pattern for the array at 18.118 MHz.

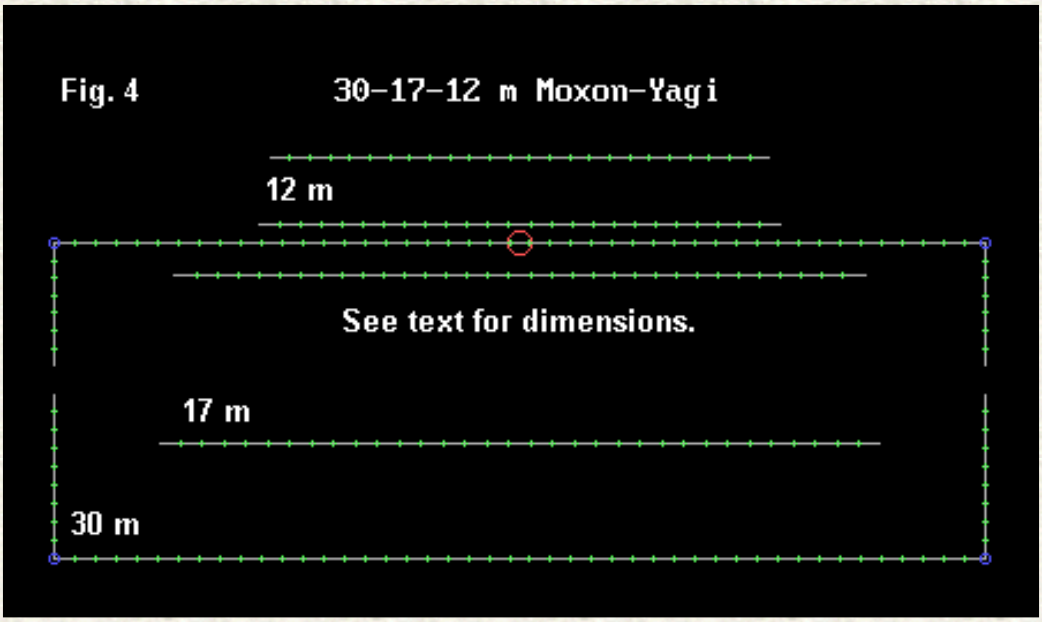


Because the upper band Yagi is behind and within the Moxon rectangle, there is no significant forward-stagger effect. Hence, the Yagi gain and front-to-back ratios are virtually identical to those one might obtain from an independent driver-reflector Yagi for 17 meters. However, with 1/8 wavelength spacing, the feedpoint impedance of an independent Yagi would be closer to 35 Ohms. The near-50-Ohm match is obtained by virtue of the open-sleeve coupling, which can be set for virtually any desired impedance by changes in the length and/or spacing of the driver relative to the physically fed element. As we saw last month, the impedance changes more rapidly on a slaved element than on a directly fed element. In the case of the 17-meter Yagi, it is the reactance that undergoes the most rapid change, while the resistance remain quite stable.

Although the 17-meter Yagi does not gain anything from being inside the Moxon, it does not lose anything either. Moreover, it does not take up an additional space on a supporting tower. The two-band array has identically the same outside dimensions as the 30-meter Moxon itself. Except for the additional weight and wind load of the 17-meter elements, there seems little reason not to add the upper band if one seriously plans a 30-meter Moxon.

A 30-17-12 m Combination

Suppose we might be willing to extend the boom of the Moxon-Yagi from 12.6' to about 16 feet. For the additional 3.4' of boom length, we add one more band to the array--with virtually no change in the design work done so far. A driver-director Yagi with an element spacing of about 0.07 wavelength can be added ahead of the Moxon driver to arrive at a WARC 3-band array of considerable compactness. **Fig. 4** shows the general outline of the arrangement.



For the lower bands, the design once more uses 1.25" diameter elements for 30 and 1" diameter elements for 17. The 12-meter elements are 0.5" in diameter, and everything is aluminum. With these materials we can uses the dimensions in the table below. For the 17-meter elements, the spacing entry indicates the distance behind the Moxon driver. For 12 meters, the spacing entry indicates the element spacing forward from the Moxon driver.

Band	Dimension	Length (feet)
30-meter Moxon	(all elements use	1.25" diameter aluminum tubing)
Moxon	A	34.91'
	B	4.89'
	C	1.12'
	D	6.56'
	E	12.57'
17-meter Yagi	(all elements use	1.0" diameter aluminum tubing)
Driver	Length	25.80'
	Space	1.30'
Reflector	Length	27.00'
	Space	8.00'
12-meter Yagi	(all elements use	0.5" diameter aluminum tubing)
Driver	Length	19.46'
	Space	0.70'
Director	Length	18.70'
	Space	3.43'

For the Moxon and the 17-meter Yagi, nothing has changed. The dimensions of the 12-meter Yagi are very slightly different from those used with the 17-meter Moxon last month. However, that Moxon used elements with a smaller diameter than the 30-meter Moxon in this design. The major change is in the spacing from the Moxon to the 12-meter slaved driver--somewhat wider than in the 12-17 design.

If we see little difference in dimensions, we should also expect little difference in performance. The following performance table provides the numbers.

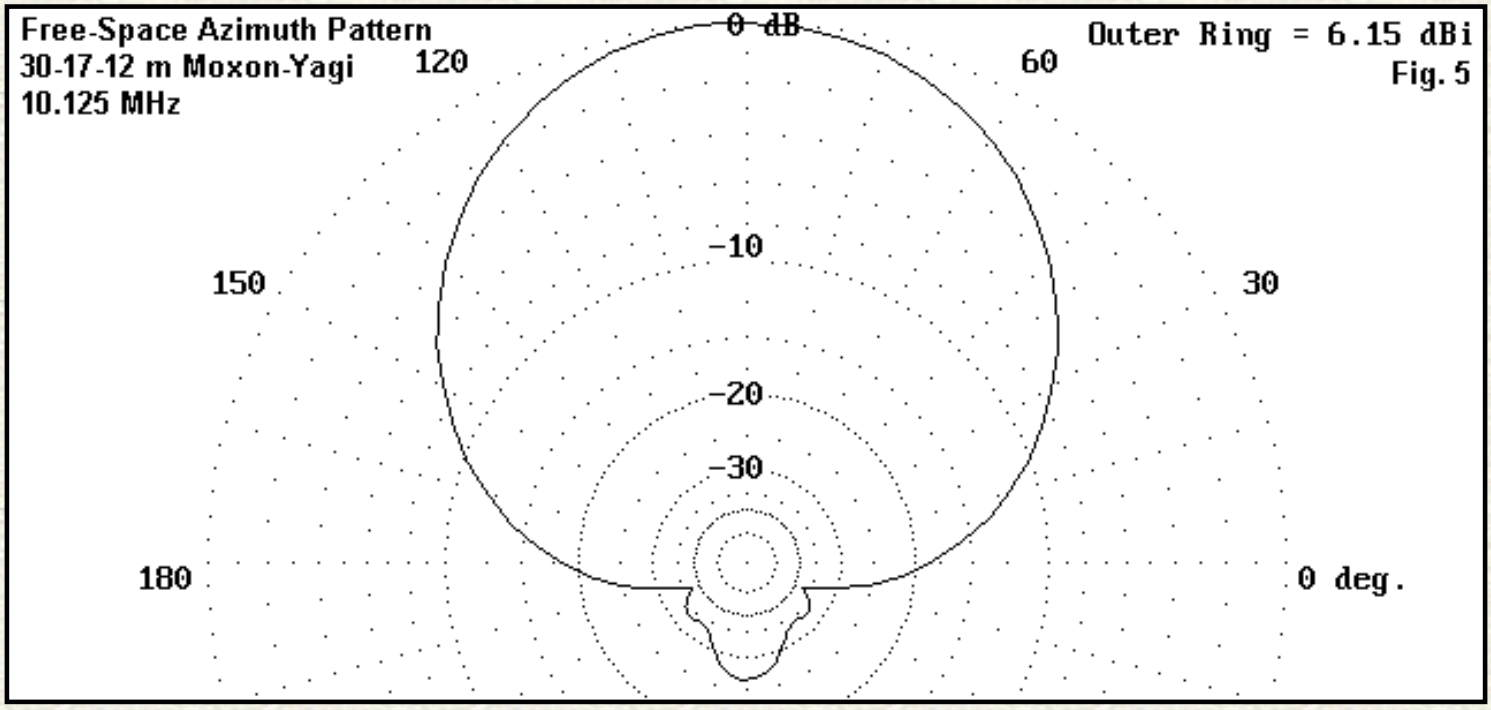
Frequency	Gain	Front-to-Back	Feedpoint Z	50-Ohm

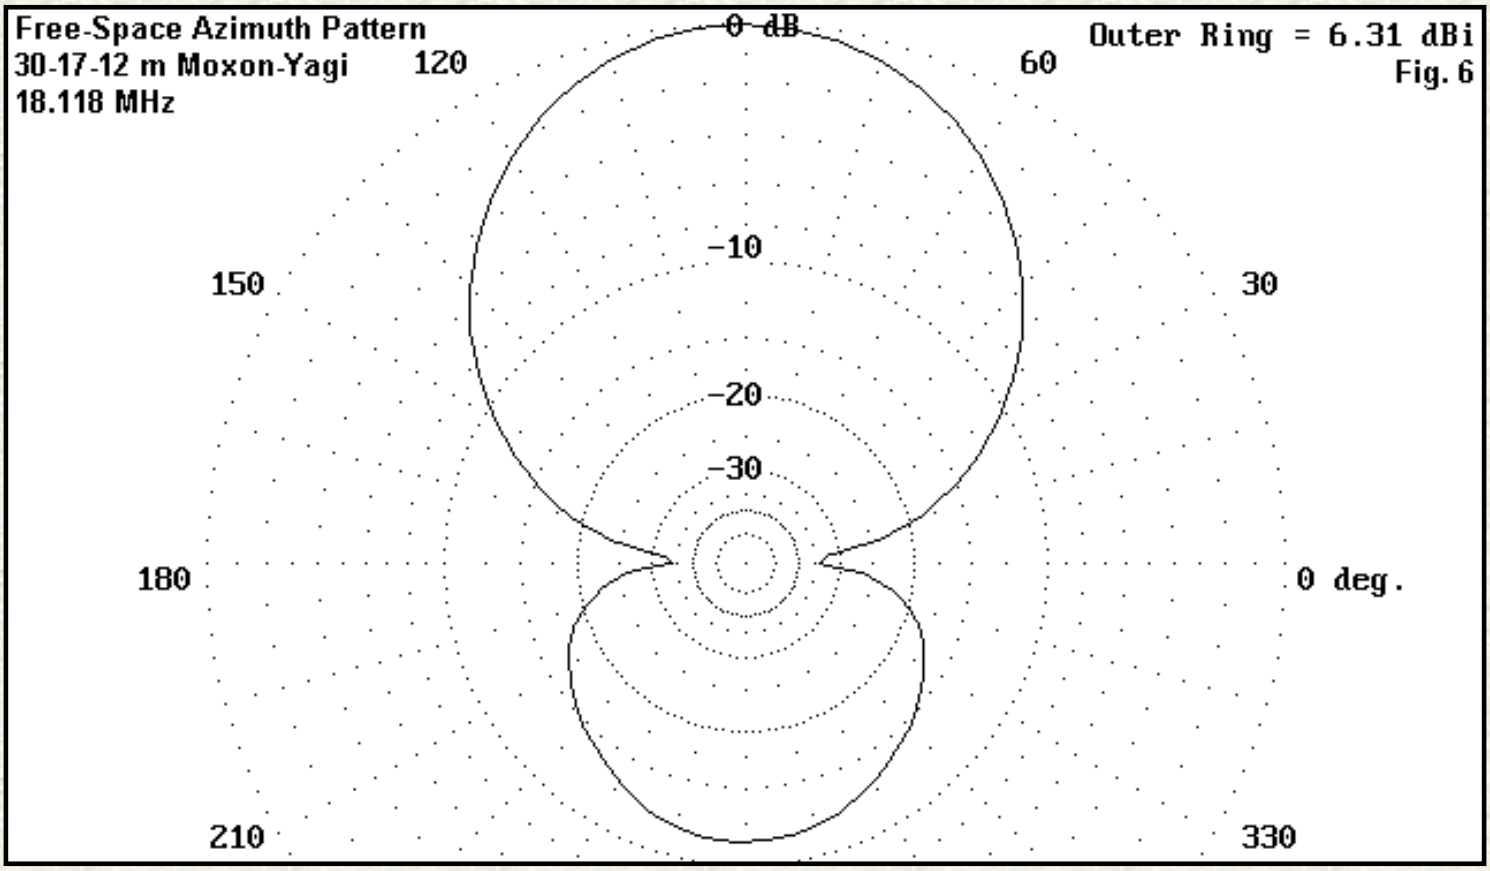
MHz	dBi	Ratio dB	R+/-jX Ohms	VSWR
10.100	6.23	22.5	48.5 - j 4.9	1.11
10.125	6.15	26.3	51.7 - j 2.8	1.07
10.150	6.07	32.1	54.9 + j 0.9	1.10
18.068	6.40	11.3	53.3 - j16.3	1.38
18.118	6.31	11.4	51.3 - j 1.2	1.04
18.168	6.21	11.4	49.4 + j13.6	1.31
24.89	6.57	25.3	59.4 - j 9.9	1.28
24.94	6.67	22.1	48.7 + j 3.4	1.08
24.99	6.76	19.2	38.9 + j18.5	1.62

On 30 meters, performance only shows insignificant changes in the last decimal places of the performance figures. On 17 meters, the performance values are numerically up, but again, not in a way that makes a difference that one could detect in use. The numeric increase is due in part to the forward stagger effect that gives the 12-meter elements a slight director effect during 17-meter operation.

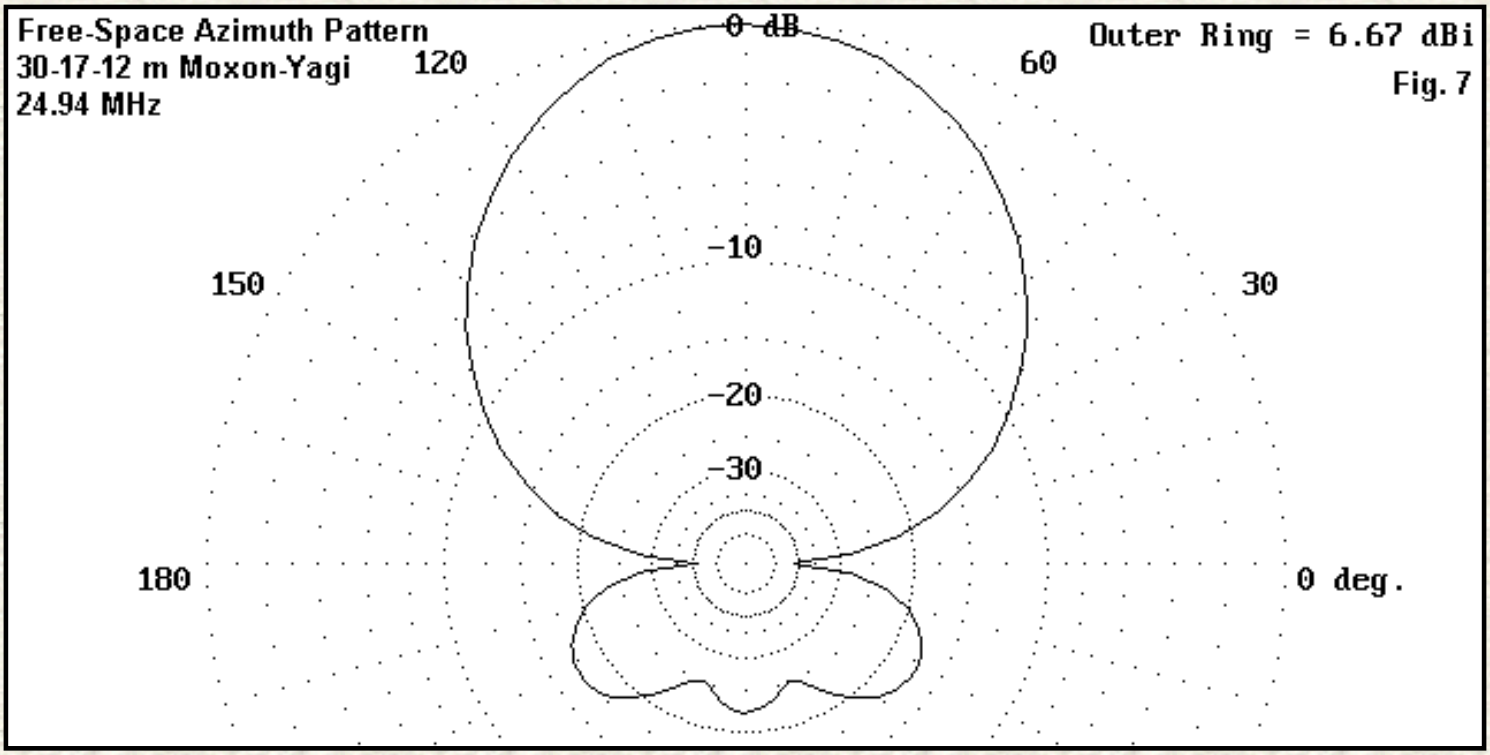
On 12 meters, the 2-element driver-director array performs normally for an antenna of this type, although the independent feedpoint impedance of about 20 Ohms is overcome by slaving the driver to the 30-meter Moxon driver. Last month we saw higher gains on 12 meters. However, the 30-meter driver is farther removed from the 12-meter elements and provides some isolation of them from the interior 17-meter elements. Hence, forward stagger effects are minimal.

Nonetheless, for a beam with a 16' boom length, the tri-band Moxon-Yagi offers excellent potential. **Fig. 5** shows the free-space azimuth pattern at 10.125 MHz.





In **Fig. 6**, we see essentially the same pattern as in **Fig. 3** for the middle of 17 meters. The 12-meter free-space azimuth pattern for 24.94 MHz (**Fig. 7**) is similar to the one shown for 12 meters last month. The same rear quartering lobes are present to moderate the 180-degree front-to-back ratio.



The exact spacing and length of the slaved drivers will require field adjustment to arrive at a final setting to achieve a

good 50-Ohm match on each band. However, those adjustments are about the only critical matters related to construction--once you decide on and design for the precise set of materials you will use. Essentially, you can design an independent Moxon for 30 meters and adjust it to perfection. Then, you can add the 17-meter elements and perform driver adjustments until you are satisfied. Rechecking the 30-meter impedance should show no significant change. Finally, add the 12-meter elements and adjust its driver for a good match on that band. Because element spacing is a bit more critical for driver-director arrays than for driver-reflector Yagis, recheck the element spacing for 12 meters before concluding the adjustment procedure. Once more, the impedances for 30 meters and 12 meters should not have significantly changed by adding the 12-meter elements.

I have good luck in adjusting Moxons and simple Yagis close to the ground by pointing the array as close to straight up as possible, with the reflector anywhere from 4 to 12 feet off tghe ground. The adjustments have held true at heights from 20 to 35 feet up. This technique is not applicable for all beams, but it is worth a try for those who do not relish adjusting beam elements from the top of a tower.

For those who wish to do further design work on models of the two antennas, here are model descriptions that should ease wire coordinate entries for most NEC modeling software.

30-17 m Moxon-Yagi Frequency = 10.125/18.118 MHz.

The 30-17 or the 30-17-12 combination arrays offer some interesting potentials for small WARC band beams. These design notes aim to whet your appetite for further and improved designs. However, you will have to go some to improve performance on all bands while shrinking the size of these arrays. However, if you do manage the trick, I'd be first in line to find out how.

The All-Band Center-Fed Inverted-L

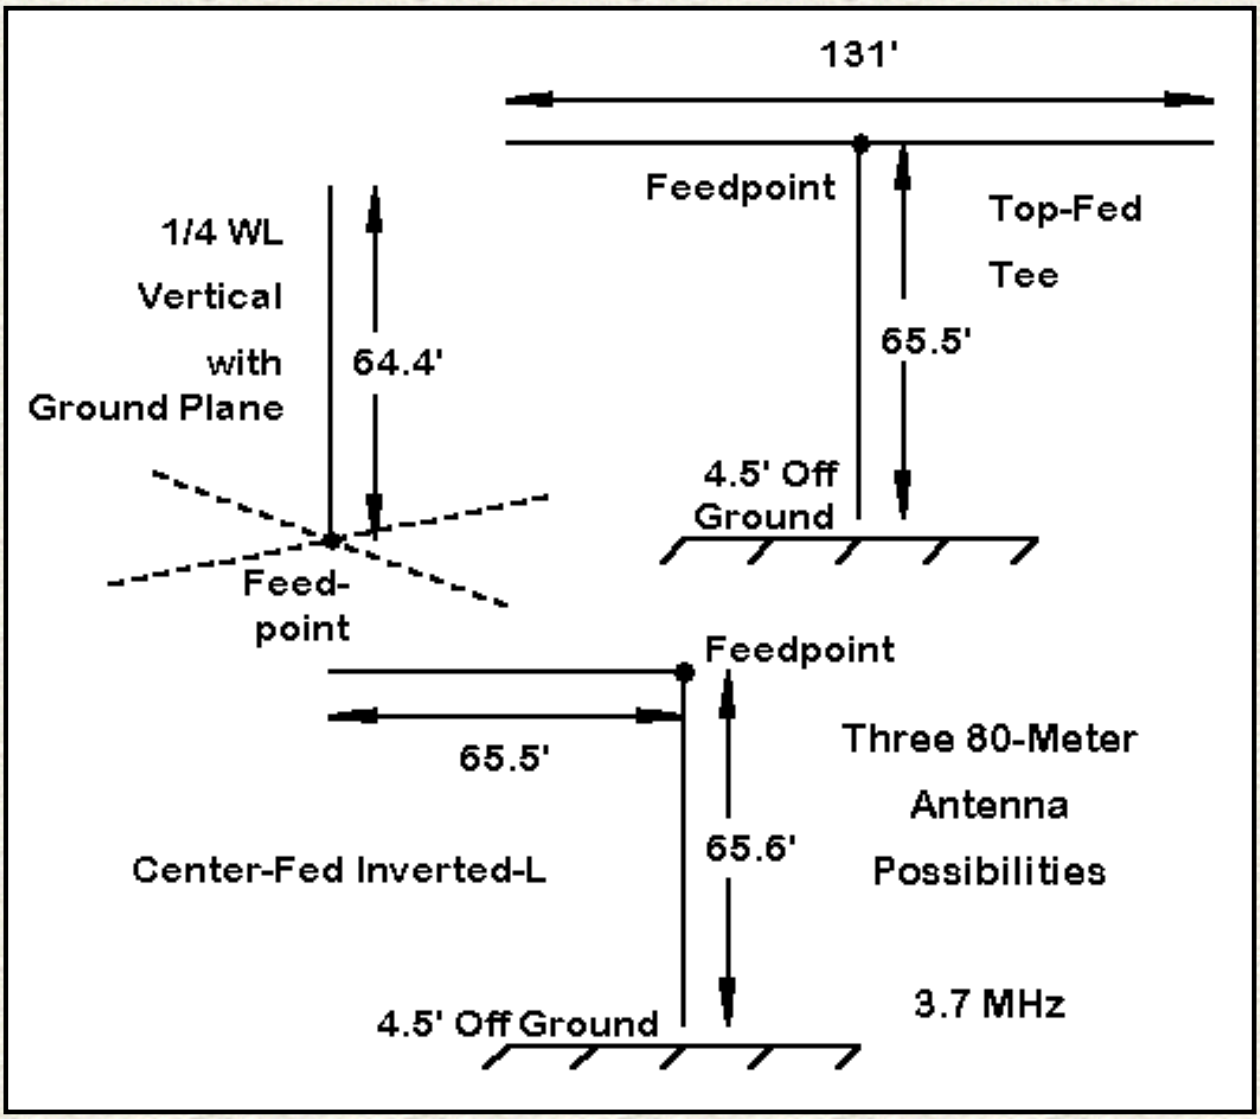
L. B. Cebik, W4RNL

When I wrote on "The L-Antenna" for 10-meters a few months back, I noted that the antenna was not likely new. I have since learned that the basic idea seems to have originated with VK3AM in the early 1950s and is described in L. A. Moxon's (G6XN) classic ***HF Antennas for All Locations*** (pp. 154-156 of the first edition). This antenna is a standing L, although Moxon has no problems with viewing it inverted. Ralph Holland, VK1BRH, includes the L in his computer study of several antennas, including an interesting variant of the L: the 1/2 wl inverted-L. (VK1BRH's interesting modeling studies, published in ***Amateur Radio***, the journal of the Australian Wireless Association, can be found at his web site: http://www2.dynamite.com.au/vk1brh/Antsim.htm) Perhaps the earliest article on the inverted-L as an all-band antenna may have been "The 'Inverted L' Ham Antenna," by Bob See, W5LTD, which appeared in *Radio and TV News*, January, 1959, pp. 64-65. Bob used base feeding to operate the antenna as a standard inverted-L monopole with a ground plane on 80 and as an end- or voltage-fed longer wire above 80, as his measured impedance figures attest. The 1/2 wl inverted-L can also be center-fed using parallel feedline and an ATU. We shall focus on the center-fed version: it is an antenna with excellent potential as an all-band substitute for the 135' center-fed doublet.

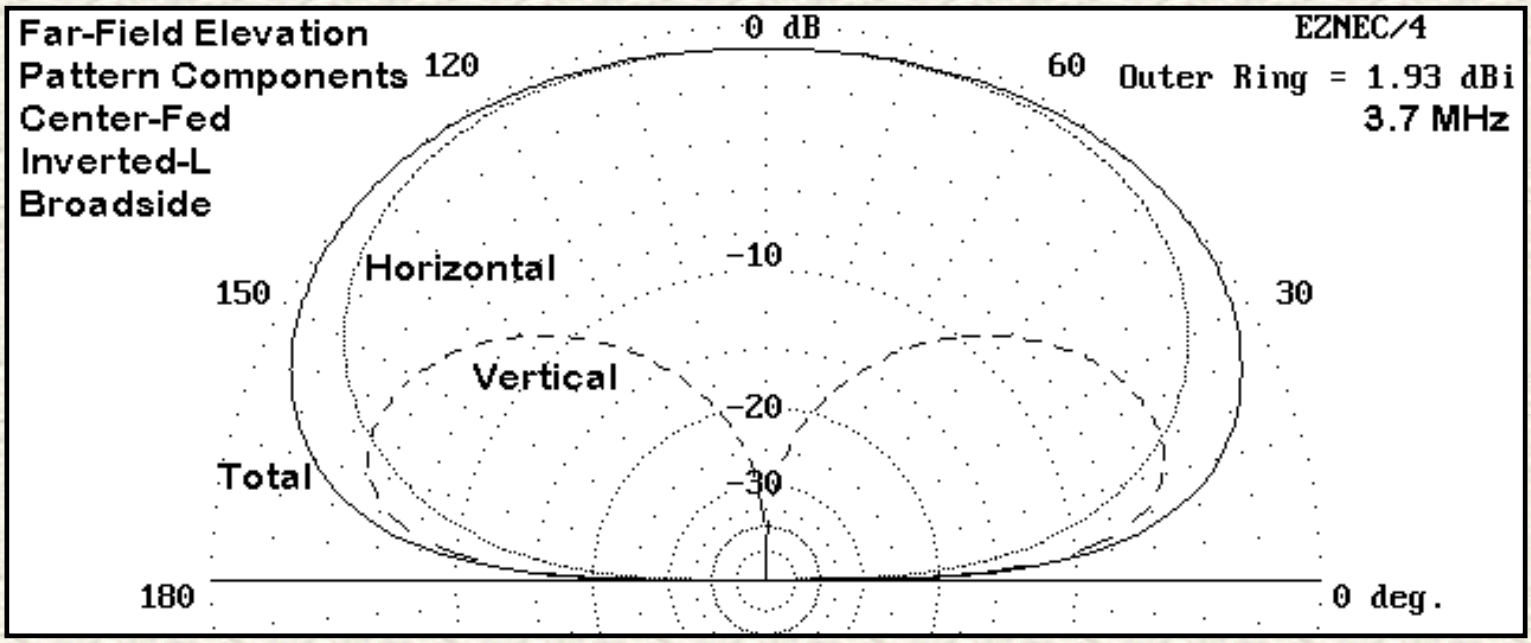
The 1/2 wl inverted-L which we shall examine differs from standard 1/4 wl inverted-Ls in 2 ways: First, it is longer, of course. Second, it is normally current fed at the center (although end- or voltage-feeding is always possible, even if not always convenient). Hence, it can be viewed as an inverted Vee tilted over by 45 degrees. Alternatively, it can be viewed as a 1-leg-ground-plane 1/4 wl vertical upside down.

If the upside-down vertical had a second leg going in exactly the opposite direction, the result would be--to a large degree--cancellation of the horizontally polarized radiation. Let's call this antenna the T.

Both the L and the T differ from the standard 1/4 wl ground plane vertical by being complete antennas--dipoles as it were. Hence, neither requires a ground plane beneath them. For some situations, this fact can simplify construction. The figure below shows the structural differences among the three antennas for models set at 3.7 MHz. The L and T models were set at a top height of 70', with the vertical arm terminated 4.5' off the ground.

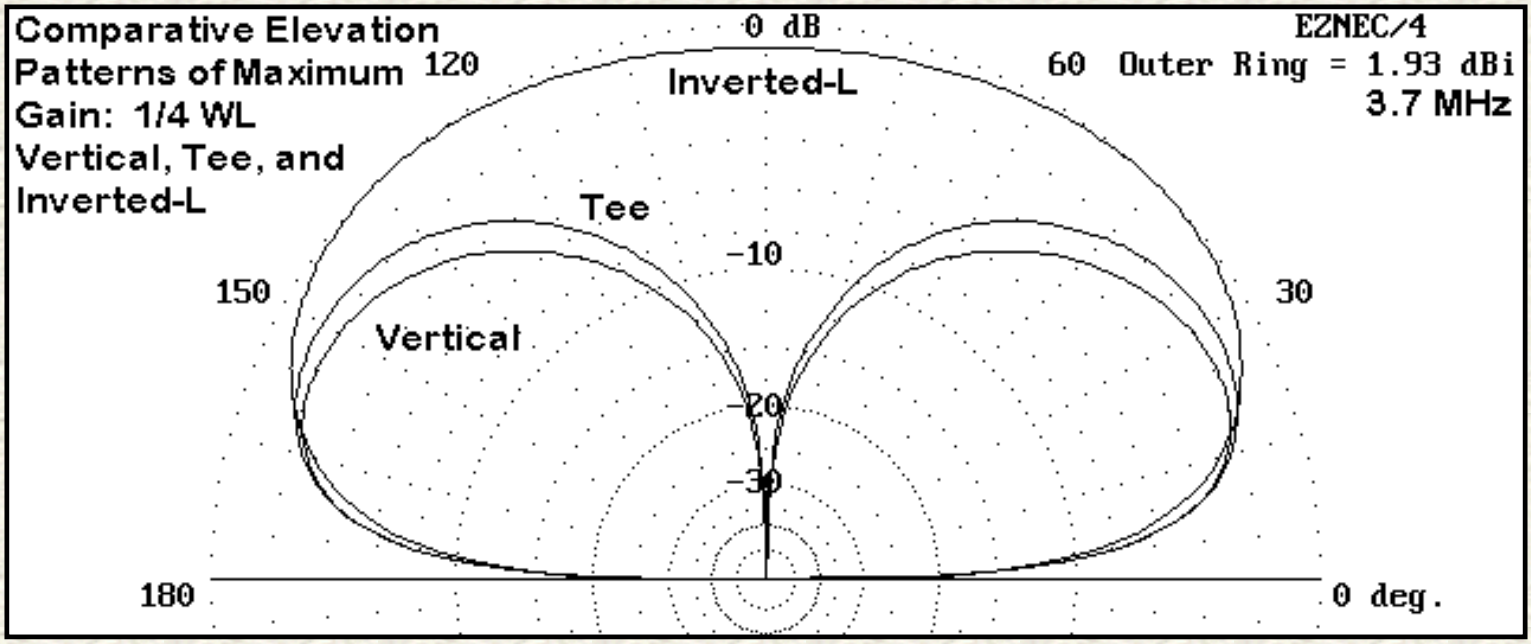


Each antenna was modeled using #14 copper wire and average ground throughout. Note that the inverted-L and the T present challenges to the builder in terms of routing the parallel feedline to the top feedpoint. We shall do some comparisons, but first, let's become a bit more familiar with the inverted-L basic pattern.

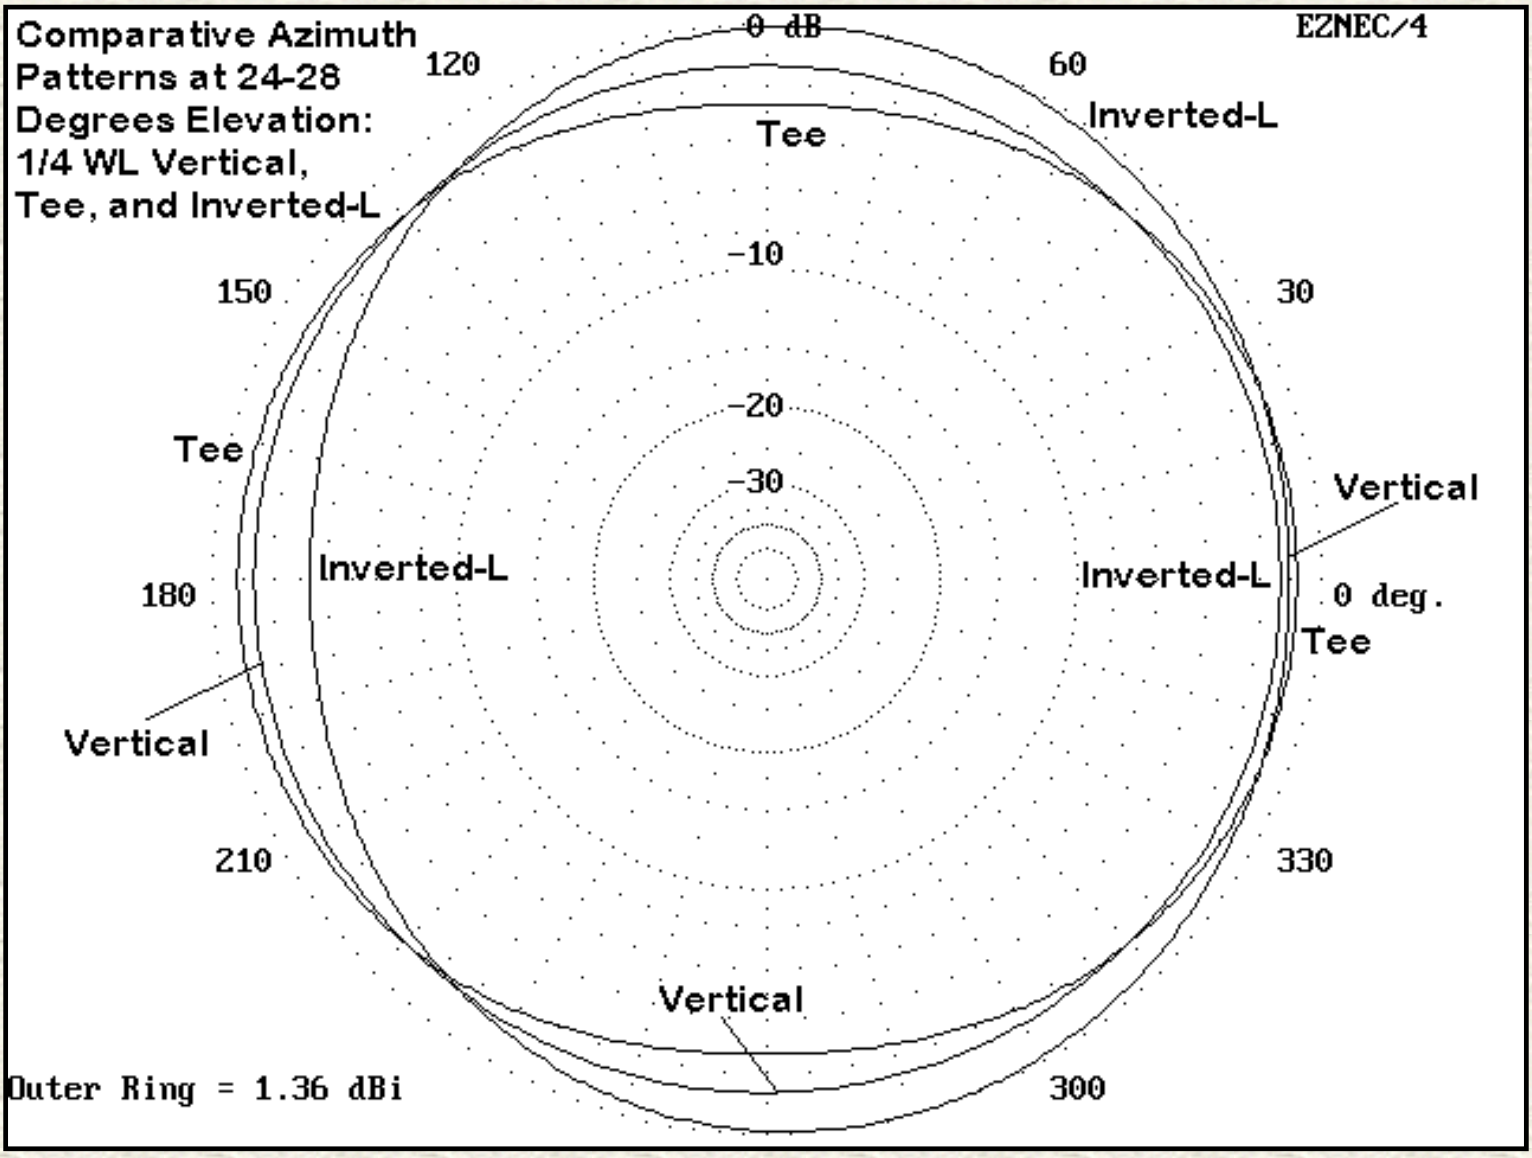


The elevation pattern above shows the vertical, horizontal, and total field components of the inverted-L radiation pattern taken broadside to the horizontal arm of the antenna, where radiation is strongest. In the plane off the ends of the horizontal arm, horizontally polarized radiation is somewhat weaker, but the vertically polarized radiation remains at full strength, with some pattern bending away from the horizontal arm.

A fair comparison might be made among elevation patterns for the L, T, and vertical. Since the total pattern of the L is a broad oval, let's take the strongest direction also of the T, which happens to be off the ends of the horizontal arms. The vertical is truly omnidirectional, so let's set at least 20 radials beneath it.



The comparative pattern above shows the rough equality of the T and the ground-plane-vertical patterns under the specified conditions. Surprisingly, the inverted-L comes close to both antennas in low angle radiation. It also has stronger high angle radiation--without becoming a cloud burner--which is useful for shorter skip contacts. In other words, the inverted-L has potential as an all-purpose low-band antenna.



The azimuth patterns of the three antennas--taken at elevation angles between 24 and 28 degrees--show the slight oval of the T and the slightly more radical oval of the inverted-L. The L's azimuth pattern also shows the slight displacement in the direction away from the horizontal arm. However, these effects are small enough not to stand in the way of using the antenna for general operating purposes.

The Ground-Plane Question

In principle, as a complete 1/2 wl antenna, the inverted-L requires no ground plane. Likewise, the T should require none. In contrast, the 1/4 wl vertical requires a ground plane to complete the antenna. To test the relative need and utility of a ground plane, I modeled all three antennas with ground planes, first using 4 wires and then using 20 wires. I set each ground plane first at 1' below ground, then at the surface, and finally at 1' above ground. The vertical's source segment touches the ground, which gives erroneous results in NEC-4. Therefore, the surface ground plane for the vertical was set 0.1' above ground. The radial wires were the same length as the vertical radiators, which means slightly shorter radials for the vertical than for the L or T.

The following table summarizes results for the three antennas with 4 and 20 wire ground planes.

Antenna/GP level	Gain dBi	TO angle degrees	Source Impedance R +/- jX Ohms
4-radial tests			
Inverted-L			
No GP	1.93	44	66.1 + j 3.8
GP -1'	1.97	45	66.1 + j 4.5
GP 0'	1.96	44	66.0 + j 4.0

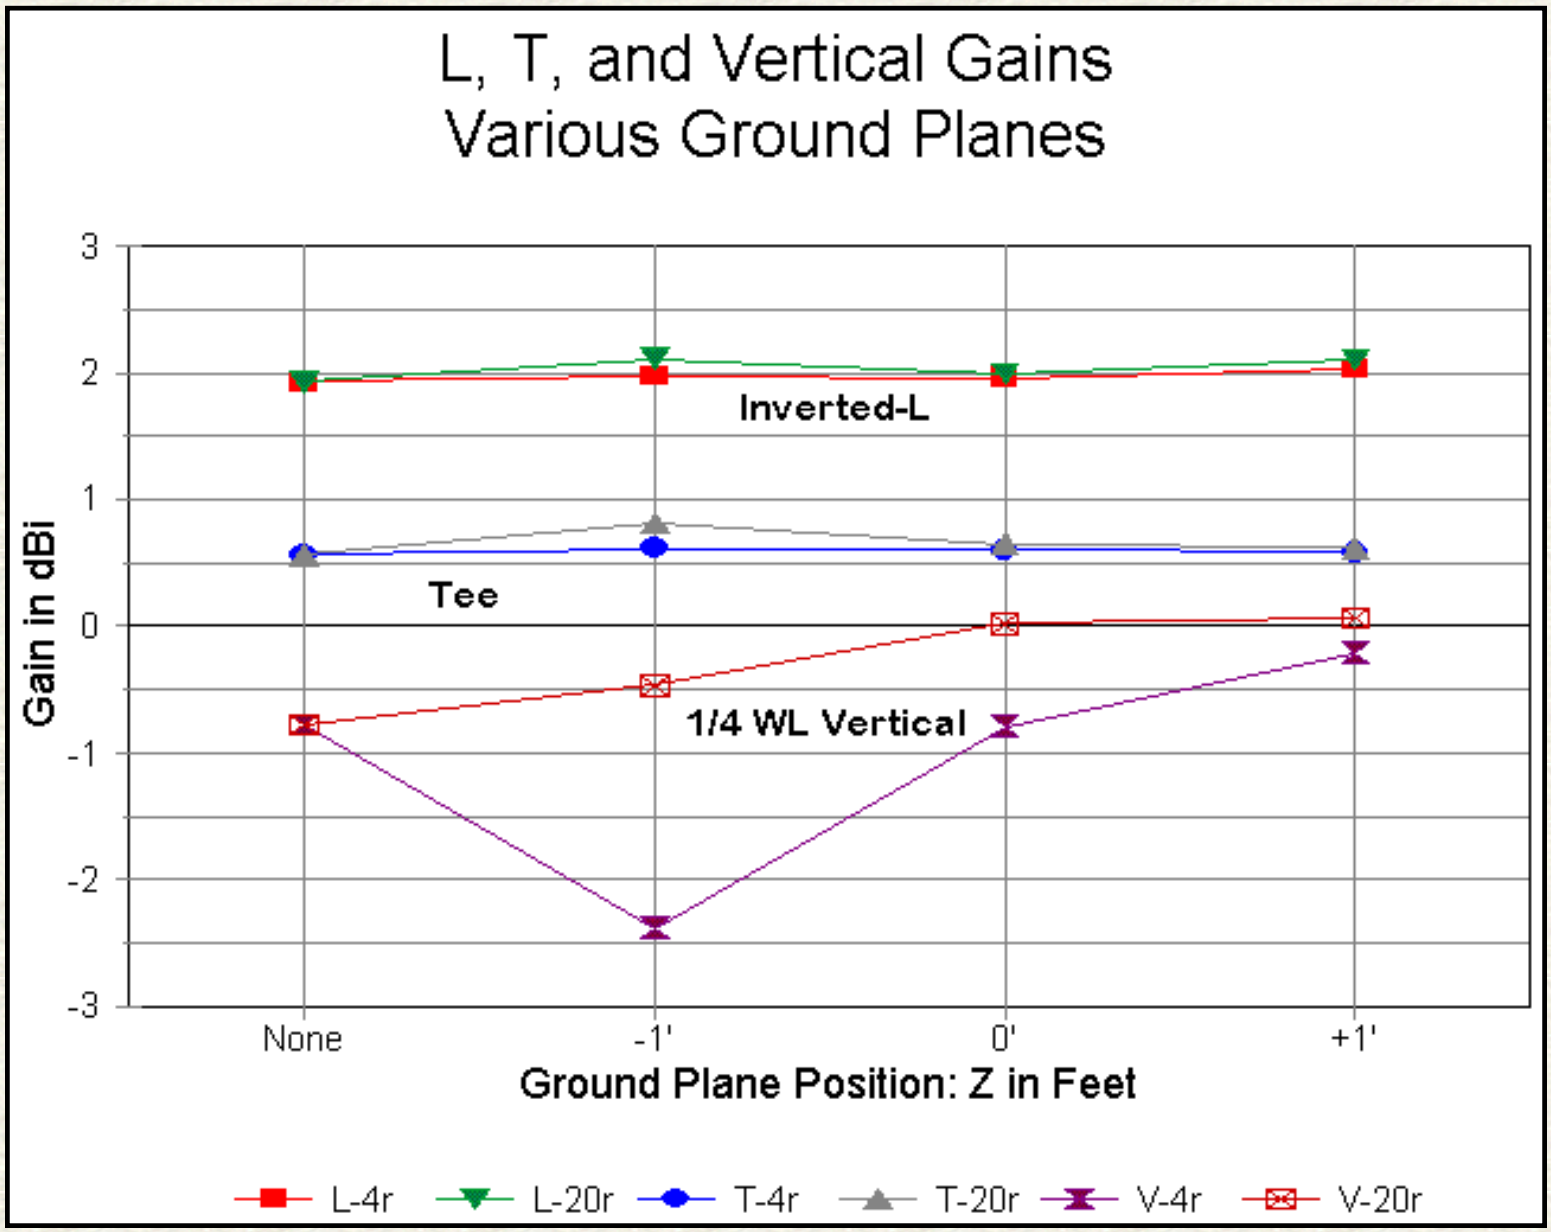
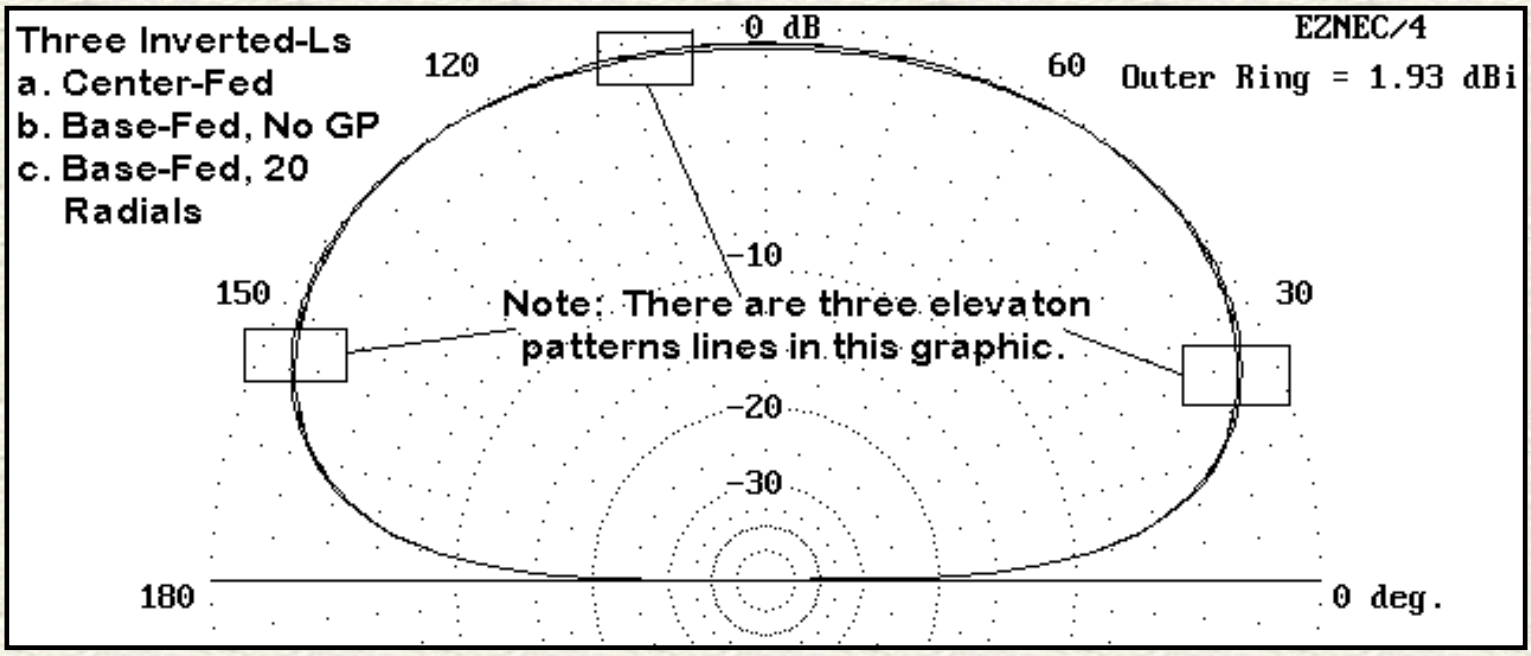
GP 0'	0.02	24	37.1 - j 3.9
GP +1'	0.06	24	36.8 - j14.6

Although the tables give the most data, comparisons are more difficult than with a graph.



The antenna gains are compared in the graph above. The line connections between points are not real connections, but only let the eye tell which data points go together. As is evident, NEC-4 modeling strongly suggests that the addition of a ground plane adds virtually nothing to antenna performance for the inverted-L and the T, both of which we have described as complete antennas. In contrast, the vertical is dependent upon the most extensive (up to 60-100 radials) that a builder can install. (The vertical antenna data point for "No Ground Plane" should be used for reference and does not represent accurate data relative to a real antenna.) I further modeled the vertical with 64 radials. At a depth of 1', the antenna gain increased to 0.19 dBi, while setting them 1' above ground yielded a gain of 0.02 dBi. Modeling has consistently suggested that for perfectly symmetrical ground planes above ground, more than 6-8 radials may be superfluous. This conclusion does not necessarily apply to ground planes that are not perfectly symmetrical.

An alternative to high-altitude center feeding of the inverted-L is to base feed it at the low end of the vertical. Models of this mode of feeding the antenna show patterns quite consistent with those for center feeding, with a source impedance in the neighborhood of 5000 Ohms. Once more, the addition of a ground plane does not aid antenna performance in any way, as the following elevation plot shows.



However, the absence of need for a ground plane should not be mistaken for an absence of a need for a good RF ground. In turn, we should not presume that the ground rod near the shack, which provides AC and DC power grounding for safety, also provides an adequate RF ground. Army tests established a couple of decades ago that a good RF ground needs periodic short (<2') rods connected by a perimeter wire or strap that essentially surrounds the entire station location.

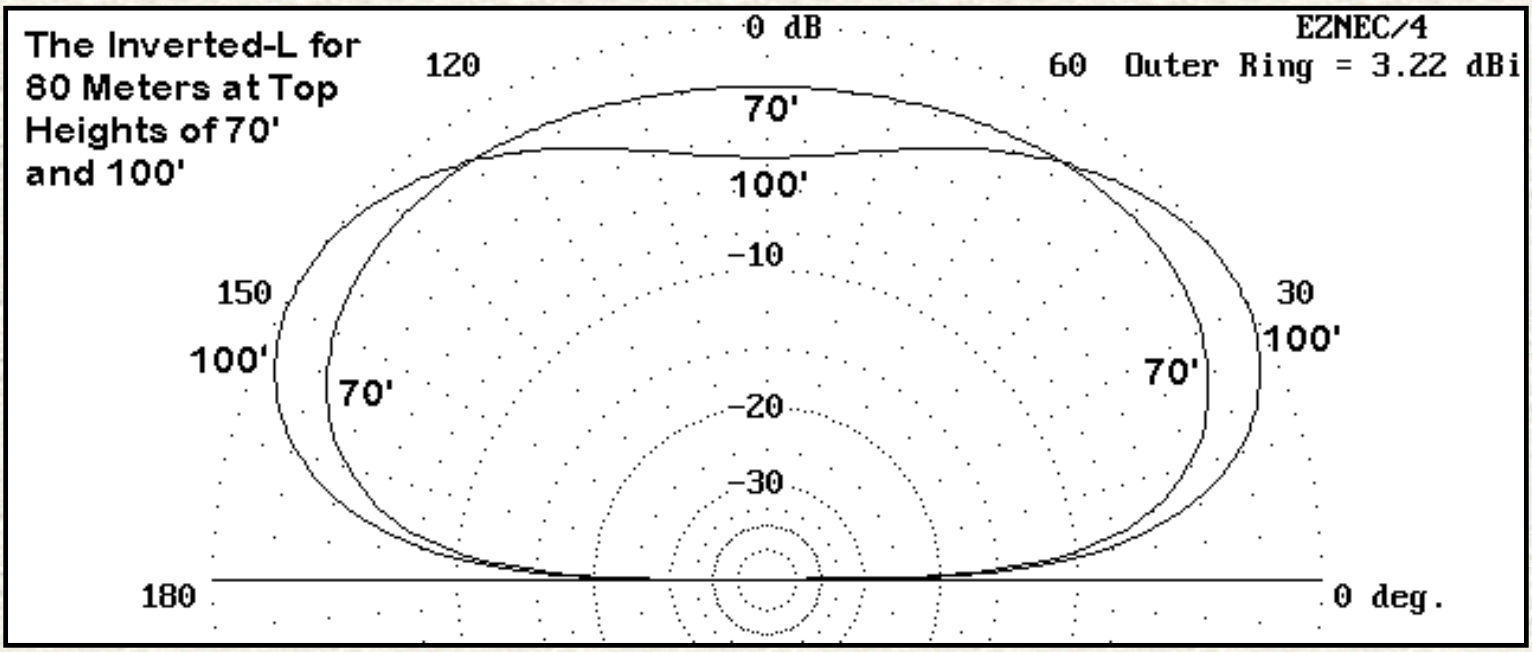
Installation Variations

Knowing that not everyone tempted to use the inverted-L will have all of the space needed, I checked some variants that represent typical construction compromises or changes. Since the antenna will be fed with parallel transmission line, matching is not a major problem. However, changes of gain and elevation angle may indicate that some variations are better than others.

1. Height: elevating the inverted-L is a route to slightly more gain and a lower take-off angle broadside to the horizontal arm. Here is a table of values modeled with top heights at every 5' from 70 to 100 feet up.

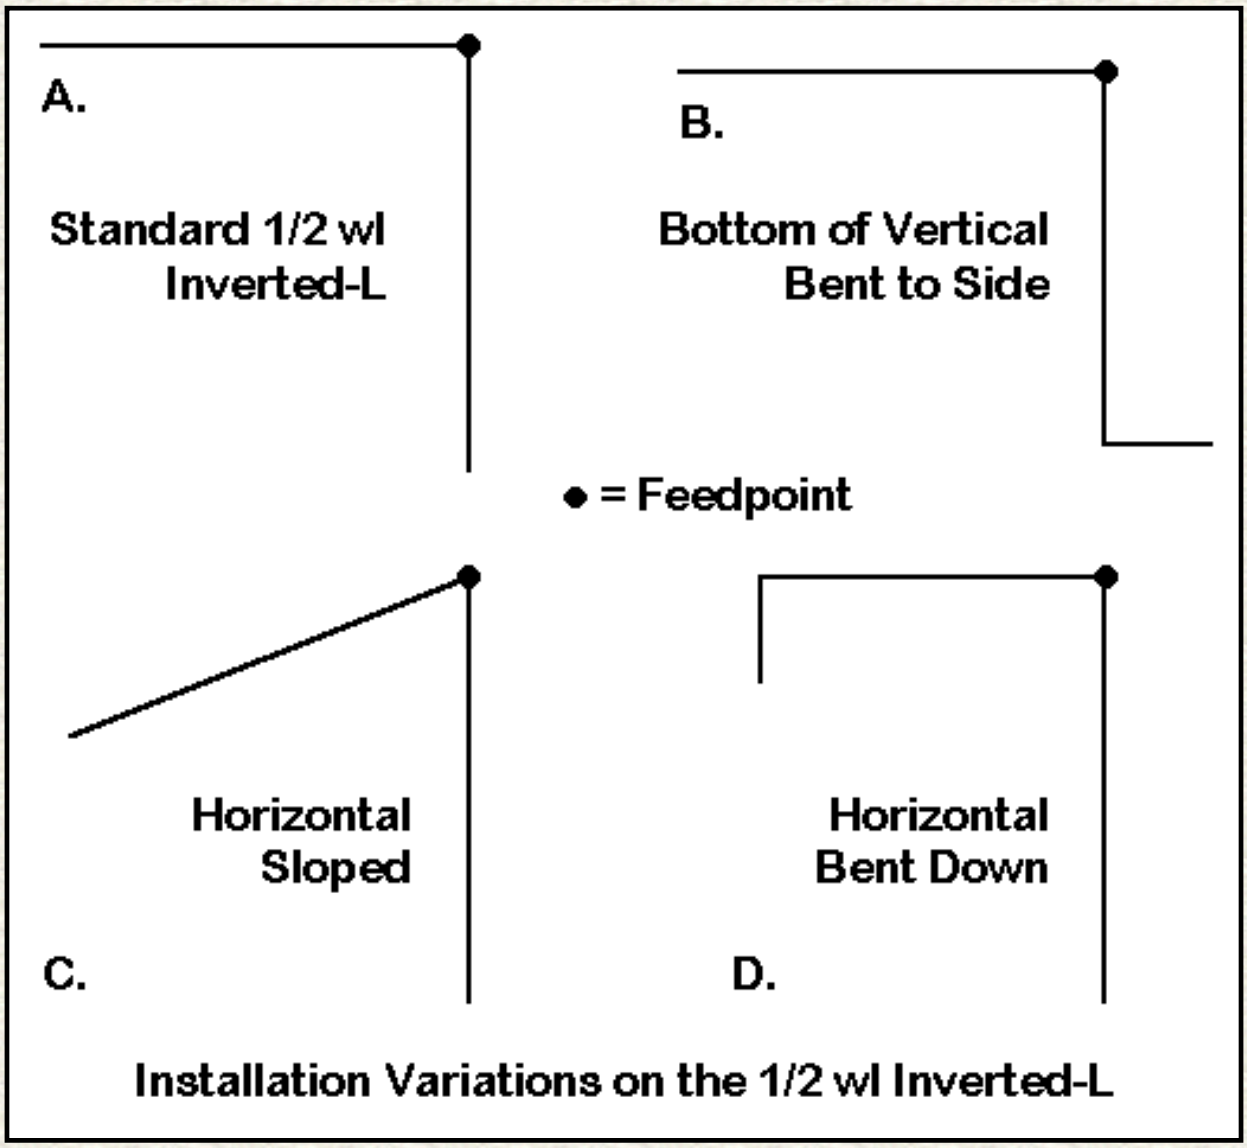
Top Ht. feet	Bottom Ht. feet	Gain dBi	TO Angle degrees	Feed Impedance R +/- jX Ohms
70	4.5	1.93	44	66.1 + j 3.8
85	9.5	2.20	42	62.8 - j 4.2
80	14.5	2.43	41	60.1 - j 9.3
85	19.5	2.63	38	57.6 - j12.8
90	24.5	2.83	37	55.3 - j15.4
95	29.5	3.02	34	53.0 - j17.2
100	34.5	3.22	33	50.9 - j18.5

Nothing drastic happens between any two levels, but the trends are clear. Gain increases and take-off angle decreases. The antenna plays shorter, the higher we go. However, unless one plans to use a monoband coax feed system, the precise dimensions are not at all critical.



The elevation patterns in the figure compare the antenna at 70' and at 100' and add visual confirmation of the conclusion drawn from the table.

2. Sloping and Bending: The more normal problem for home installation is too little vertical or horizontal space. As the figure below shows, there are a number of installation "tricks" we might use. The question at hand is how much each will hurt performance.



Installation Variations on the 1/2 wl Inverted-L

Bending the vertical at the bottom: The first way to save vertical space or to protect family members from the high voltage at the antenna element end is to bend the lower end of the vertical to the side. The upper horizontal arm remains 65.5' long. The overall length of the vertical is also 65.5', but part is now vertical and part horizontal. I tested three scenarios, listed in the table below:

Max. Ht feet	Vert. Wire feet	Low Hor. feet	Gain dBi	TO Angle degrees	Feed Impedance R +/- jX Ohms
70	60	5.5	2.04	45	64.2 - j 4.4
70	55	10.5	2.22	47	61.8 - j11.3
65	55	10.5	1.92	49	64.8 - j 2.7

The chief effect of the bend is to raise the high angle radiation strength a small bit and to raise the elevation angle of maximum radiation. The latter figure indicates a slight loss in the lowest angle radiation, which one would anticipate from shortening the vertical length. None of these small changes in dimension affect the usableness of the antenna.

Sloping the horizontal arm down: One might wish to use the antenna where there is only one truly tall support and the support for the far end of the horizontal arm is lower. The result is a sloping horizontal arm. Using a peak height of 70' and keeping the dimensions of each wire at 65.5', I tested 2 scenarios, representing two degrees of slope, against the

standard installation.

Max. Vert Ht feet	Hor. End Ht feet	Gain dBi	TO Angle degrees	Feed Impedance R +/- jX Ohms
70	70 (no slope)	1.93	44	66.1 + j 3.8
70	60	2.26	51	58.6 + j 8.4
70	50	2.66	58	52.4 + j32.0

Gain increases are at high angles of radiation, with some loss of low angle radiation strength. Although a true horizontal is perhaps the best compromise for maximum low and high angle performance, the patterns with a modest slope to the horizontal arm do not make the antenna unusable by any means.

Bending the horizontal arm far end down: If horizontal space is limited, a common practice is to bend (or dangle) the outer ends of a dipole downward. since the region is the high voltage and low current portion of the antenna, the radiation pattern is least affected by modifying the geometry. Again, I compared 2 scenarios to the full length horizontal arm configuration.

Max. Ht feet	Hor. Arm Lth feet	Bent Length feet	Gain dBi	TO Angle degrees	Feed Impedance R +/- jX Ohms
70	65.5	0.0	1.93	44	66.1 + j 3.8
70	55.5	10.0	1.82	45	62.7 - j 5.9
70	45.5	20.0	1.62	43	54.6 - j12.2

Low angle radiation remains essentially constant, since the vertical arm has not been altered. Further shortening of the horizontal arm would show a gradual further reduction in maximum gain and in the take-off angle. Higher-angle radiation is decreased, although the antenna remains eminently usable.

Like many wire antennas, the inverted-L will tolerate moderate alterations of geometry to fit the space available and still yield good, if not peak, performance.

Multi-Band Use of the Inverted-L

One disadvantage of the 135' horizontal doublet when used on the upper HF bands is that the pattern breaks into a collection of fairly narrow lobes with deep nulls between them. Since the nulls change position from band- to-band, the user is often surprised to discover that signals from certain directions are weaker than expected.

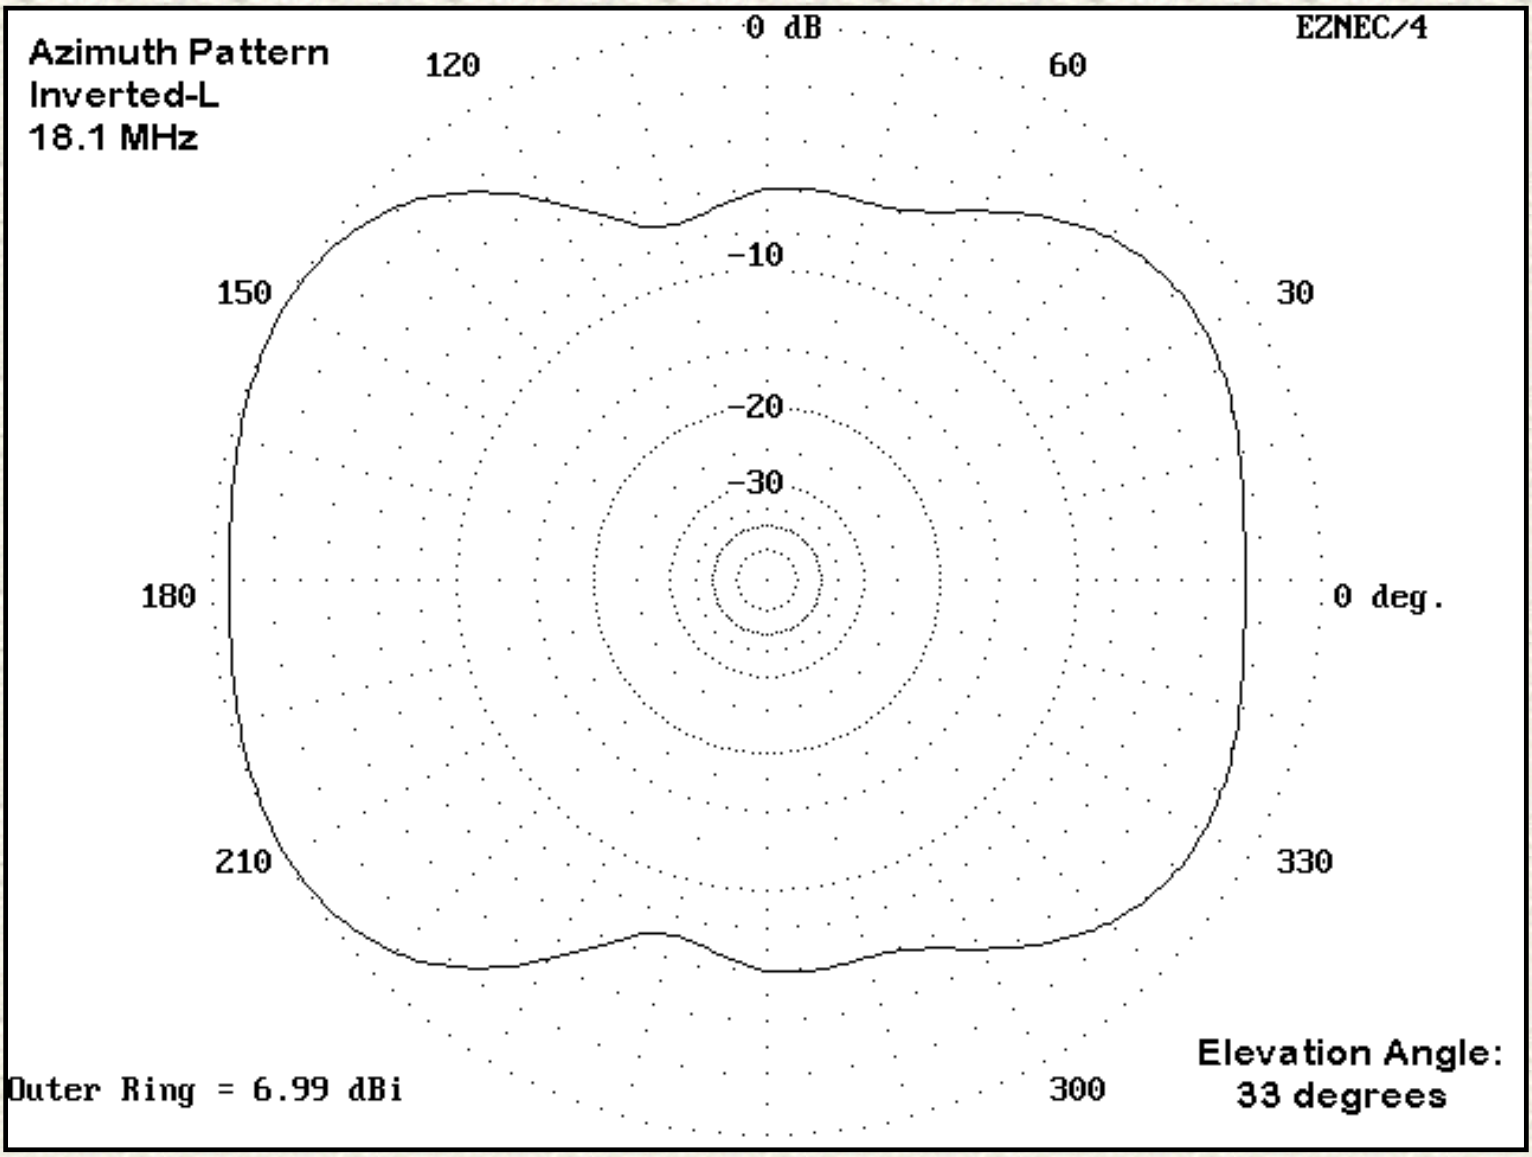
The inverted-L, when fed with parallel transmission line and an antenna tuner, is not wholly exempt from this phenomenon. However, since one arm is fully vertical, the nulls tend to be much shallower. At the same time, gain peaks are less pronounced.

The following table provides a rough guide on what to expect from each of the amateur HF bands:

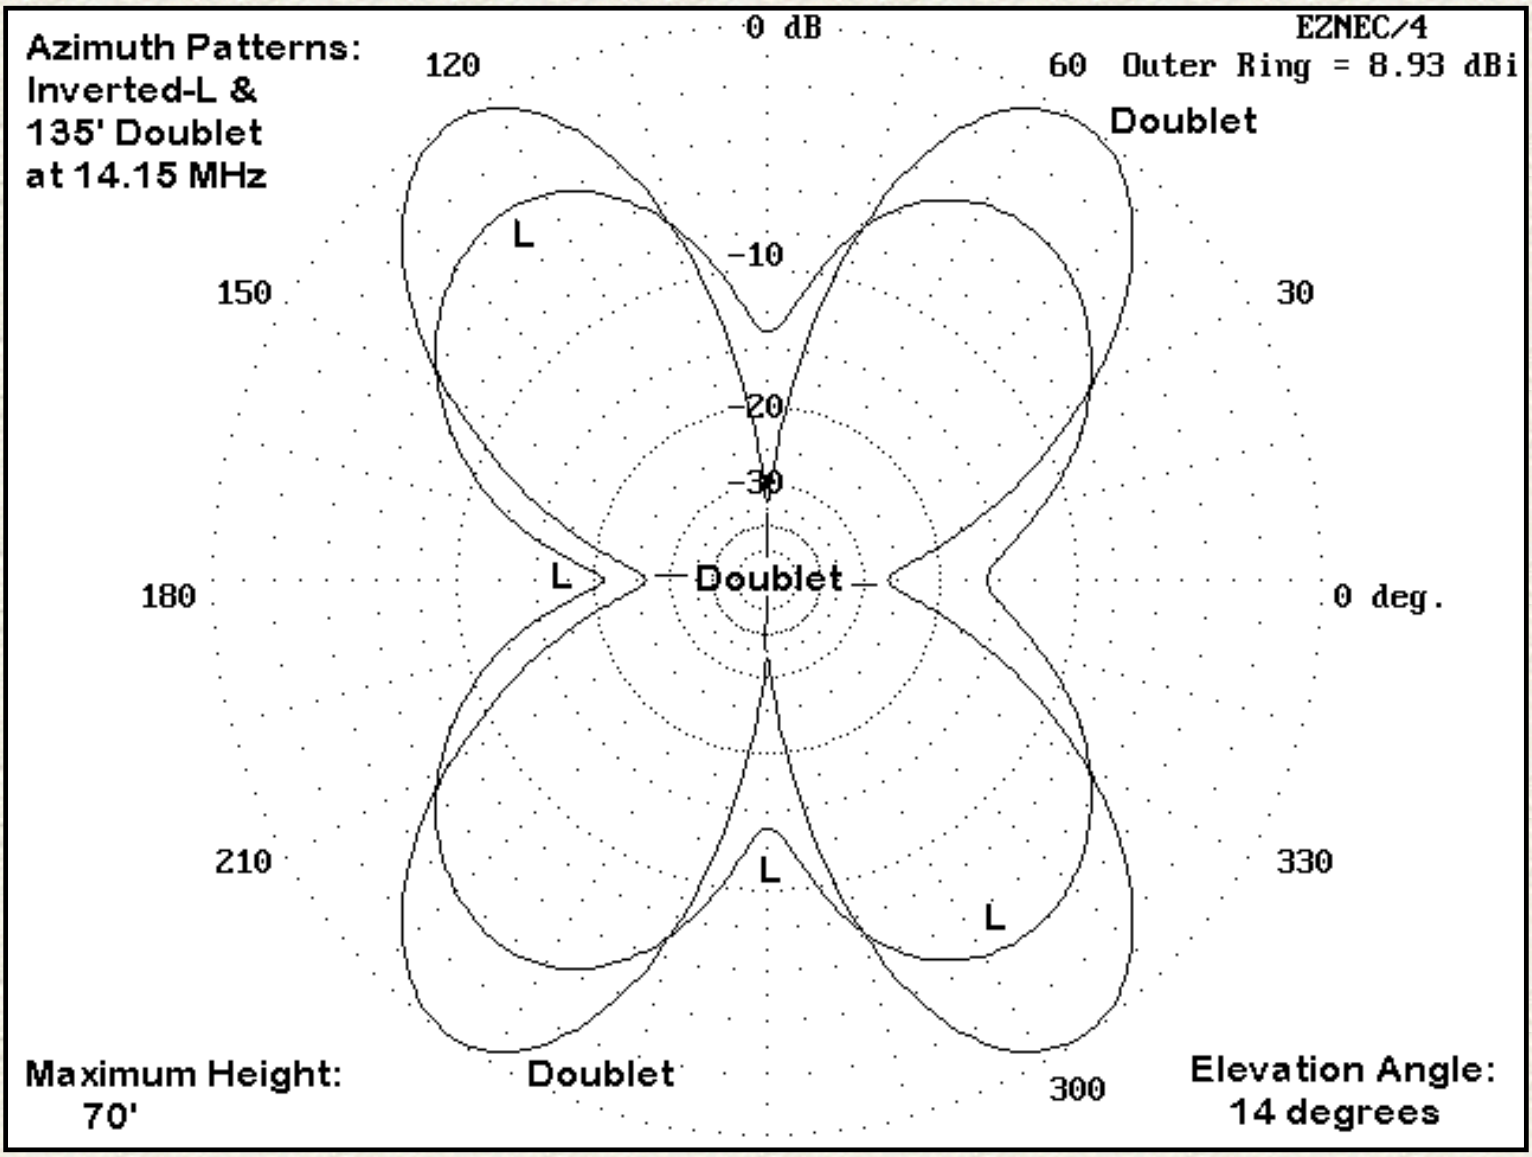
Frequency MHz	Gain dBi	To angle degrees	Feed Impedance R +/- jX Ohms	Pattern Shape (approximate)
3.7	1.93	44	66 + j 4	Broadside oval
7.1	4.09	26	6500 + j 300	Broadside oval
10.1	4.04	20	150 - j 500	Square

14.1	5.38	14	2000 + j2300	4 lobes
18.1	6.99	33	165 - j 255	Square
21.2	6.74	9	750 + j1400	6 lobes
24.9	6.63	8	210 - j 520	6 lobes
28.5	7.55	7	575 + j1000	8 lobes

Even harmonics of the antenna's fundamental frequency show high impedances, in some cases with a high reactive component. The WARC bands show more moderate impedances at the antenna feedpoint. Use of 450-Ohm or 600-Ohm parallel feedline is recommended in order to provide reasonable values of impedance at the antenna tuner terminals. As with all such antennas, if a tuner seems unable to effect a match on a given band, adding a short section of feedline between the existing line and the tuner output terminals will often correct the situation.



The annotation "square" to describe the azimuth pattern is illustrated by the 18.1 MHz pattern. On this band, the strongest signal occurs at the second elevation lobe. There is a usable but less strong lobe at about 16 degrees elevation. Note the absence of sharp nulls and lobes.



Even where lobes and nulls do occur, both are much less pronounced than they are with a standard doublet. The figure shows the differences for the 20-meter band. Doublet nulls exceed -25 dB relative to the lobes, whereas inverted-L nulls are under -10 dB relative to the lobes, which are also broader than those of the doublet. Of course, peak gain of the lobes is about 4 dB less than for the doublet lobes. For some types of operation, but certainly not for all, the absence of strong nulls can be more advantageous than a few extra dB of gain in very specific directions.

The 100' Center-Fed Inverted-L

Many hams who cannot erect a full 135' long inverted-L can often manage a 100' version of the antenna. This length would require 50' of horizontal run and about 55' of height to place the vertical section at least 5' off the ground. As we have seen, higher installations will yield better results, but the present values will provide a kind of worst-case scenario for modeling that antenna. Since the sketches for this shortened version of the inverted-L, which is about 70% full size at 80 meters, would be the same as those for longer versions, we can jump directly to a table of values for multi-band use of the antenna.

Frequency MHz	Gain dBi	To angle degrees	Feed Impedance R +/- jX Ohms	Pattern Shape (approximate)
3.7	1.32	51	30 + j 425	Broadside oval

7.1	3.13	31	305 + j1010	Broadside oval
10.1	4.95	24	2150 - j3100	Broadside oval
14.1	4.64	19	120 - j 185	Square
18.1	5.51	34	965 + j1785	4-Leaf clover
21.2	5.00	12	475 - j1300	4-Leaf clover
24.9	6.07	10	160 + j 95	6 lobes
28.5	7.03	9	1775 + j1990	6 lobes

As one might expect, the shorter antenna breaks into multiple lobes more slowly with increases in frequency. Moreover, the pattern of high and low feedpoint impedances differs greatly from the pattern for the 135' version. Given the lower top height, the elevation angles of maximum radiation are somewhat higher, especially on the lowest bands of operation. (Note that the band on which an unexpected high angle of maximum radiation occurs for both versions also shows a lobe of nearly the same strength at a lower angle--just about 20 degrees lower. Hence, useful radiation occurs on that band--in this case 17 meters.) Shorter antennas--down to about 90' overall wire length can be built and used on 80 meters. Below about 90' overall wire length, the antenna becomes essentially a 40-meter-and-up inverted-L.

Conclusion

The center-fed inverted-L has the potential to be a quite satisfactory all-band wire antenna suited to certain environments. The length can be almost anything about 3/8 wl or longer for the lowest frequency of intended operation. Although the overall gain will be lower for each band than the gain of a horizontal doublet using the same overall wire length, the elevation angle of maximum radiation for the L will be lower than for a doublet with the same top height.

There is little evidence, despite the vertical position of one arm of the antenna, that the inverted-L would benefit from a ground plane beneath the antenna. The actual low-angle gain of the inverted-L will, however, vary with the quality of the soil in the region of reflection at a distance from the vertical arm. All patterns were taken over average soil, and soils that are either poor or better than average will tend to show a higher gain and lower take-off angle, at least on the fundamental frequency.

The electrical lineage of the center-fed inverted-L is from the dipole by way of the inverted-Vee. For the amateur yard that is short on horizontal space but long on tall supports, the inverted-L may be the antenna of choice as an all-band wire--whether used as the primary station antenna or as the back- up for more complex arrangements.

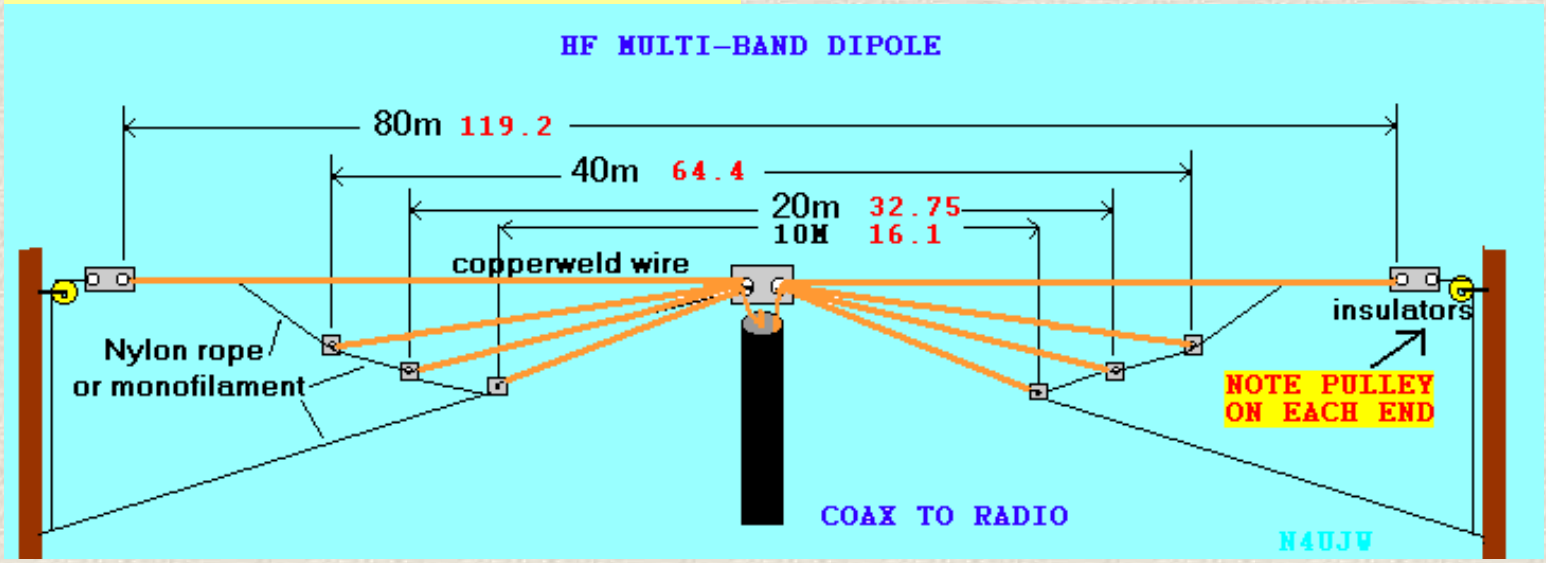
BUILD THIS MULTIBAND FAN DIPOLE FOR ALL BAND HF EXCITEMENT



Here is a simple and easy to build multi band horizontal fan dipole that can be constructed for all band operation from 160 meters up thru 6 meters or even higher.
In the drawing above, it is shown for just four bands, 80 thru 10. One separate dipole for each band needed. However you can build it to suit your own preferences by using the standard formula for a dipole:
468/freq mhz = total length for each band. Use the formula for your desired center frequency.

Each dipole length above in RED is in feet and tenths of a foot for the center of the General portion of each band and is derived from the above formula and should be cut a little longer for swr trimming. USE #12 TO #14 GAUGE COPPERWELD WIRE IF POSSIBLE or use what you have on hand.

Start with your lowest (in frequency) band of operation as the main (top) support for the entire setup. Cut it per the formula and a little longer. Try to use a wire size that will support the other dipoles. This is the main support for all the other dipoles and must carry their weight.
Cut a dipole for each band of operation.
Cut each full length in half....example: for the 10 meter length from the formula you get 16.1 feet for the total length. Cut it in half equaling approx 8 feet per side. Make sure you cut each length about a foot or more longer for swr trimming and attaching to center and end insulators!
If you are building the four band dipole above, you should have 8 lengths of wire scattered all over your work area.
WARNING!
DON'T DO IT IN YOUR LIVING ROOM, THE XYL WILL NOT BE VERY HAPPY WITH YOU AND AFTER SHE GETS FINISHED WITH THE QRM,,,, ALL YOUR ANTENNA BUILDING WILL HAVE TO BE DONE FROM THE DOG'S HAM SHACK! HI!
It is assumed that you have your end support poles, trees, center and end insulators, pulleys all ready to go before you start working on the actual dipoles.

A very important part of this design is the installation of the pulleys (in yellow on drawing) on each end attached to each side support.
They are added to this design due to the swr trimming process and make it very easy to pull the entire antenna up and down while making the swr adjustments. Mount a suitable size pulley on each end attached to your pole, trees, etc for the diameter of cord or rope used to support the system.
Start your antenna trimming with the top dipole.... attach your coax to the center insulator leaving several inches of the center conductor and shield exposed. Each half of each dipole will be connected to the coax center pigtail and the shield separately. In other words,

connect one side of the dipole to the center conductor and the other side to the shield.
Attach the other end of each half of the longest wire to the support cord and run thru the pulley on each end and pull the dipole up into the air between the end supports. Check swr.
Trim as needed with low power for lowest swr possible, lower with pulleys, attach the next highest band dipole electrically to the same point as the first dipole,, raise it to operating height, check swr,,lower for trimming, up and down, up and down.....due the same for all other dipoles for each higher band of operation.
When you are finished with the highest band of operation, pull the entire system up with the pulleys and tie of at the bottom securely.
Make certain that the coax center conductor is attached to one half of each dipole and the shield to the other half. All dipole ends at center insulator are connected together.
This may not be very clear to the new antenna builder so please see the drawing below for the center insulator arrangement.

The white areas in the drawing above are mechanical supports, clamps, wire ties or whatever your genius can come up with to support the main (top wire) and the weight of the coax.
Remember, all the weight of this antenna system is supported by the top wire.
The connections should be soldered and all should be sealed including coax end from water, ice, snow etc.
Use a 1:1 balun like the "Ugly Balun" project page on this site close to the center before coax goes to your rig.

For best performance get it as high as possible and remember that since this is a dipole arrangement, it will be somewhat bi-directional towards and away from you as viewed in the drawing. (BROADSIDE)
Remember that all elements will interact with each other in the tuning process and the final setup must be secured so the angle or distance between each dipole does not change when blowing in the wind, etc
The angle or distance between each dipole is not critical but the final spacing must be maintained!
It will take lots of work (trial and error) in getting each dipole to the lowest SWR. Just keep TRYING.
It should also be noted that the antenna can be used in an inverted v fashion but remember the spacing should be secure in the final operating posistion. Tune it as in all the above instructions.
You may use a tuner with this antenna un-trimmed to save a lot of work!
EXPERIMENT! EXPERIMENT! EXPERIMENT!

MULTIBAND ONE ELEMENT VEE BEAM

BY LA0HV

PETER OF NORWAY

A Six Band One Element Beam!

20 meters thru 6...cool!

Hi N4UJW.
Thanks for a GREAT web site !!!!!!!!
"I sent this email to Darrell, have a look, I think you will like it!"

Vy 73 LA0HV, Peter

YES PETER, WE DID LIKE IT!.....HERE IT IS FOR ALL HAMS TO BUILD...ENJOY!!

THE ANTENNA!

"First of all THANKS for the great web site of the "ONE ELEMENT V-BEAM FOR 15 METERS from Darrell, KB4XJ!

It really turned my antenna farm upside down! And what a relief.
My wife loves me again!
It reduced the antenna farm from several Quads and 3 element junior beams for several bands into the latest one element design.
A 6 band one element horizontal V-beam covering 20, 17, 15, 12, 10 and 6 meters!
Giving from 2.1 dBd (thats over a dipole) on 20 meters to 10.8 dbd on 6 meters."

Design is simple:

Take a Double Extended Zepp design for 6 meters using 1/2 inch or larger element material such as EMT, copper or aluminum. Copper is heavy! DO NOT USE WIRE (design freq. 51.110 MHz - "downunder DX window")
Each element will be 12.33 ft per side.. Feeder must be 400-600 Ohm ladderwire for at least 2.64 ft. (See Design calculator below)
Mount it in a 90 degree angle just like the "KB4XJ" Horizontal V-beam shape.
(I have not experimented with any other angles)
Now connect a 4 ft 400 Ohm ladderwire.

Connect a 4:1 CURRENT balun at the end of the ladderline (balun design must cover 6 meters)
Connect a remote tuning unit directly to the balun (ATU must cover 6 meters)
for example, the LDG RT11 ATU. A GREAT TUNER!
(Click here for info. The LDG ELECTRONICS RT11 ATU). Click back here when done.
The ATU is not a good solution for "normal" beams, because you cant tune all the other elements so easy.
But this is a ONE element beam so it WORKS GREAT!
Connecting a tuner directly at the feedpoint (the balun) will give a TRUE MATCH, not just a happy transmitter.
(Dont use a "by the rig" tuner, it won't do well).

Look at the dimensions and GAIN of this antenna:

On 20m: One element + wire is 1/4 wave. Gain: 2.1 dBd. Fb > 18 dB
On 17m: Almost a 1/2 wave dipole. Gain: 2.8
On 15m: 1/2 wave dipole. Gain: 3.3 dBd
On 12m: A little longer: 4.0 dBd
On 10m: The antenna is a little out of band but the Balun and RT11 tuner does the job. Gain: 5.8 dBd
On 6m: EDZ v-beam. Gain: 10.8 dBd. Fb > 25 dB

ALL WITH ONE ELEMENT !!!!!!

Now isn't that cool!

Vy 73 LA0HV, Peter
Horizontal V-Beam Diagram

LA0HV EXPANDS ON A GREAT DESIGN!
THE BELOW INSTRUCTIONS WERE TAKEN FROM VARIOUS EMAILS FROM PETER, LA0HV with added comments by the original designer of the
ONE ELEMENT VEE BEAM
Darrell, KB4XJ
Some contents edited for clarity.....excuse any spelling errors...Engish is not his native language!

Here is the basic theory:

**The triDouble dipole has two elements of 3/4 wavelength each.
It has resonance at the design freq but the impedence is high (500 Ohm) and the reactance/inductance value changes dramaticly when you change frequency.**

**To compensate for this you shorten the element length a bit and add openwire, 400-600 Ohm (not critical). This will decrease impedance to 200 Ohm at the design frequency.
This is why I use a 4:1 Current balun (must be a current balun).
This is the Extended Double Zepp, EDZ design parameters:**

**Length of each element: 0.64 x l
Minimum length of ladderwire: 0.137 x l**

**Now the great side effect is, that the antenna will work as good as, or better than a dipole at any frequency higher than the frequency that match a 1/4 wavelength at one of the elements.
Now using an open wire feeder, it will also work at the lowest freq and up, corresponding to a 1/4 wavelength, when you add the element length to the wire length. But now of course, gain will decrease because the ladder wire will be a part of the antenna.
Now the EDZ will be easily matched with a remote ATU that can handle rapidly changing reactance/inductance values. A remote ATU that can handle swr of 1:10 will do the work easily.**

Back to the V-beam design:

**The EDZ-V-beam with design freq at 51.110 MHZ will work with very high forward gain at the design freq, and as a normal "KB4XJ" V-beam at the 15 meter band (look at the element length).
Using open wire feed, minimum 4 ft
(longer is ok, but remember it is a part of the antenna at frequencies under 21 MHz), will give an easy match from 14 MHz and up.**

Conclusion: The trick is to use openwire, a 4:1 balun and a Remote ATU like the LDG RT11 TUNER connected directly to the balun.

**Vy 73, Peter
LA0HV**

THE LATEST INFORMATION

EMAILs RECEIVED AS OF (11-12-02) from Peter LA0HV and Darrell KB4XJ

Hi Darrell & Don.

I just finished the last experiment of the year. It's snowing heavily now in Norway, 1 ft per hour! Minus 10 deg Celcius .... Brrrr

Last experiment revealed something very interesting about the current in the elements of the V-Beam:

I made the KB4XJ 15m V-Beam design using thin wire, same length and angle.
This happend: Field strength measurement now showed a major backloop and a decrease of forward gain (almost no front to back). You can say that the Beam effect almost disappered.
I then took 1.25" kopper (copper) tubes, same length and angle, and all of a sudden I got a V-beam again. Backloop gone, forward gain increased to almost 6 dB !!!!!!!!!!

So .. conclusions from a freezing cold, windy Norwegian Hill-top is:

A "fat" element is turning the design from a resonant V-wire antenna into a Aperiodic (stable current) element V-Beam. The thick elements are doing the same job as a terminator in a Rhombic design . WOOOW !!!!!

Freezing smiles from LA0HV.

Re: Developing a 6 band Single element horisontal V Beam

Hi Peter,
The Field Strength Meter and getting readings.
I checked across the back side of the V beam and showed a field strength reading of a .1. At the sides of the front ends power rose .5 and just inside the ends power rose to a 1. In the near center power rose 2. and in the dead center it was a 3. In just the field strength reading I was figuring around 28 db difference between front to back. In the tests I made I was using 10 watts of power. The antenna performed very good 2 years ago when I first truly tested it on field day 2001. Field day 2002 was not as good, problems with generator, blowing rain. Anyway back to the Horizontal V, in my early study on long wire antennas it was noted that power was related to one wire and that when a wire had a twin, the power doubled. Further study of log periodic dipoles (when a log dipole is bent forward it will have an added gain of 2.5 db., it was also found the beginning horizontal V was a 1/4 wave. Now in my

experience I found that induction between the elements changes the resonant frequency and lowers the frequency of a dipole and as a result you have to add 2 inches per side to make up for the induction factor. In your 90 degrees configuration, the higher you go in frequency the broader the front lobe should be, in that a horizontal V at 90 degrees at 1/4 wave on design, at longer wavelengths the V angle can be narrowed down, but the antenna does work and I wonder why it was never truly correctly reported, not having the works of Dr John Klause at hand. I spent 4 months researching the horizontal V antenna, and I spent over a month refining the center mount and have the antenna and mount down to a lean 7 pounds! Darrell KB4XJ

Subject: SV: Developing a 6 band Single element horisontal V Beam

Hi Darrell.

The pointing right up idea of yours is also greate. I once did that experiment with a 2 element for 80 meter. For a long time I irritated me that the G5RV did'nt preform wel. I found out that when you are using a Inverted V type antenna over a sandy or rocky soil, it dosent work (I live on a rocky hill). The ground is absorbing the E-field. The reason why the Inverted v type antennas like the G5RV works for most people, I think, is because the Earth with a good ground-mirror soil works as a FireBack reflector.
So I took a 80meter dipole and mounted a reflector between the dipole and ground, the "beam" pointing directly in thy sky. The effect was thremendous! Within a 1000 miles range nobody understood how my signal could "hit" them with such a ekstreme powerfull strength. It was a 80 meter contest winner antenna. I think that it also is a good DX antenna, the only problem is that stations within 1000 miles is "bending" your S-meter, so you really need ekstremly strong filters to be able to work in the DX-window.
Back to your V-beam: I dont understand how it is possible to actually get a good FB-ratio on the V-beam. I did some fieldstrength readings and I am still suprised!!! It's so cool! Now talking about "cool" winther is closing in on me here in Norway so I have to wait until april for more eksperiments.
Havent got any RTTY at the moment, but wil get some equipment during the winter, I wil look for you on 15 then.

Vy 73 de LA0HV, Peter

Til: Peter Grün
Emne: Re: Developing a 6 band Single element horisontal V Beam

Hi Peter, Did you do any Field Strength readings yet? That is what shocked me with the orginal design of the horizontal V design on 15 meters. The very high increase in forward field strength in the antenna and the decrease to the rear, could hear 360 degrees but could see a noticeable increase on the S-Meter when you rotated to the right direction. It really nice that the antenna can be rotated with a cheap TV rotator, I'll have to try your modified version. I was thinking of trying another experiment but haven't had the time to do it yet, I was thinking of pointing the V straight up and using the sky to bounce off of or launching at a 30 or 40 degree and up, of the two experiments I think the second may be of a better. In the First your pulling the signal straight down out of the sky and shooting them back up and scattering, in the second your pulling signals down in a direction and shooting back in the same direction. The First pointed up has the advantage of making your antenna appear to be say 75 miles up with nearly omni coverage. The Second pointed off with a 30 or 40 degree rise should provide longer distance. This is what I think will happen, the extended double zepp is basically a 3/4 wave antenna shorted to 5/8 wave with a 1/8 wave of ladder line, I have one but haven't tried it in the V configuration yet. I have time constraints and have to go off and work, I started my own business in refrigeration repair and also work with a solar pool heating contractor and I have to get going to work, we have a 40 panel system to put back on a building and we spent 6 hours yesterday just putting back up 4 pieces of pipe, and it looks like another 2 days on the job. If you operate rtty, I operate around 21.278 Mhz, current project is connecting my new radio a Patcom PC 9000 to my Pakrat 232 TNC and then to a old laptop for some portable rtty with the One Element Beam with Solar Power. Have yet to get the charge controller for the solar panel, I'am using a string of silicon diodes to drop the voltage to 13.8 volts DC. Got to Go good by for now, hope we can exchange information later. Darrell KB4XJ 73's

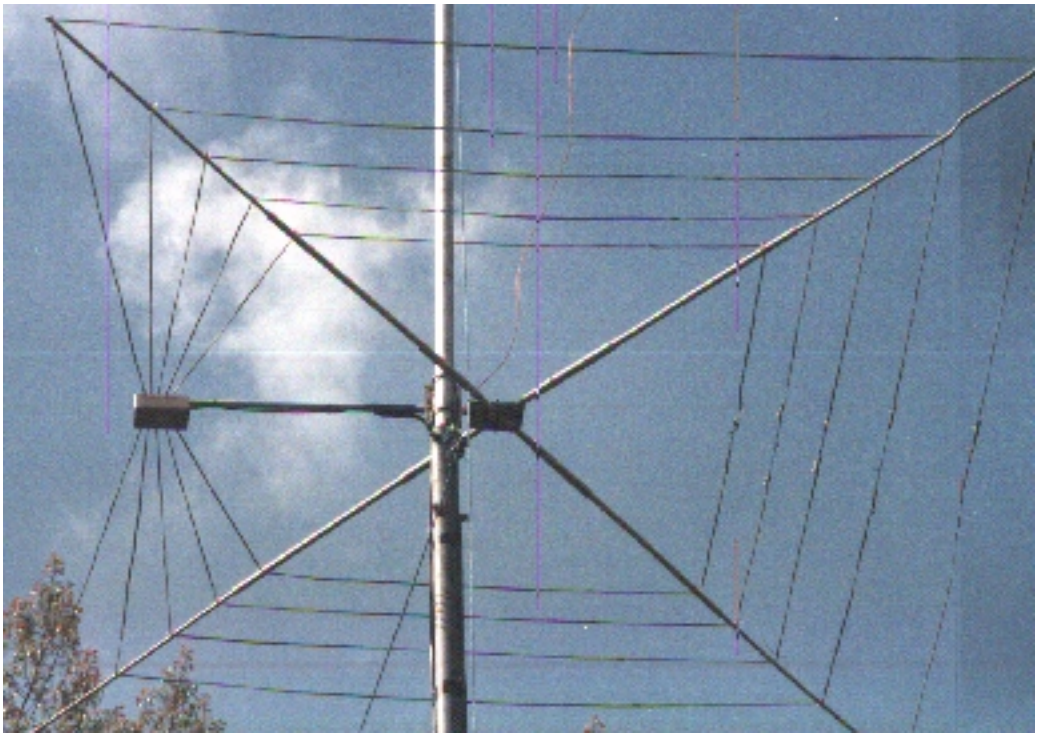
The Cobwebb HF Antenna



The G3TPW Cobwebb antenna covers five bands, 14 - 28 mhz, including the WARC bands. It is made by SRW Commuications Ltd (Steve Webb), Astrid House, Swinton, Malton, N. Yorkshire YO17 0SY (tel: 01653 697513).

It is strongly made using fibre glass rods and comes pretuned, but is easily adjusted to one's own frequency of preferrence if required.

It consists of five nested dipole balun fed and mounted horizontally. Rotation is not required. Fed with 50 ohm coax. Can be used indoors in a loft as it only measures eight feet across and is very light to handle.

I use one here ar G3YCC mounted on a pole at the bottom of my garden, see photograph. Note, in my case the pole passes through the centre of the Cobwebb, but it works very well and I have had a QSO on SSB - rare for me! - with VK on 15m through contest QRM.

Although I have no commercial connection with Steve, a professional aerial designer, I have heard him speak on antennas at our local club and can recommend the Cobwebb, particularly for those with restricted space. I have a friend who uses one in his loft, which enables him to get onto 5 bands, which otherwise he could not do, owing to available space outside.

YANKEE CLIPPER CONTEST CLUB

Double-L Antenna For 80/160

Don Toman, K2KQ
toman@ibm.net

A popular misconception about vertical antennas for the low bands is that they must have elaborate ground systems. Here's a vertical antenna for 80 and 160, fed with a single feed line that is simple, effective, and requires no ground system. You won't beat the 4-squares, but you will hold your own against a grounded quarter wave with ridiculous amounts of copper in the ground.

Rather than get into the theory of why this antenna works, I will simply describe it here and let results speak for themselves. If there's a demand, I'll do a follow-up article on the relevant theory.

The antenna is a center-fed half-wave vertical with about 70 feet of vertical length with the remainder of the top and bottom of the antenna bent horizontal and parallel to each other. The antenna looks like a squared-off letter "C" fed in the middle of the vertical part.

Thus, the 160-meter antenna is a 270-foot dipole fed in the center with the bottom antenna wire bent parallel to the ground about 10 feet off the ground and the top at 80 feet off the ground. The horizontal parts are 100 feet long and parallel to each other.

The 80-meter antenna is a 130-foot dipole, fed in the center with 70 feet vertical and 30 feet horizontal 10 feet off the ground and 80 feet off the ground.

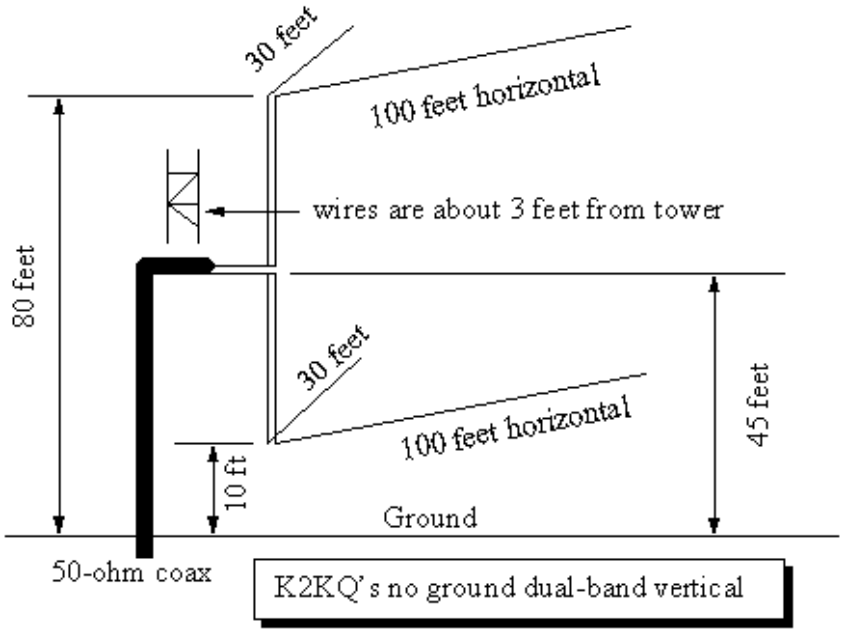
Think of it as an inverted L fed against an L. The two Ls are balanced with respect to each other and because the currents in the horizontal sections are out of phase, the antenna has a minimum of horizontal radiation.

The 80 meter and 160 meter antennas are separate, fed from a common coaxial feed line.

In my case, the 80-meter and 160-meter horizontal sections are about 30 degrees apart. The 160 horizontal wires run east while the 80 wires run east-northeast.

On both bands, the bulk of the current flows symmetrically in the center of the antenna, with the current peak about 45 feet off the ground at the feed point. On 80, the current loop peak is about 0.16 wavelengths above ground and on 160, the current loop is about 0.08 wavelength above ground.

The accompanying figure illustrates the antenna.



You can adjust the resonance of the antenna by adjusting the lengths of lower horizontal sections. The small asymmetry doesn't bother anything. The center impedance of mine at resonance is very close to 50 ohms on 160 and close to 70 ohms on 80. The 160 antenna presents high impedance at 80 meters and the 80-meter antenna looks like a parallel capacitor across the 50-ohm 160 antenna. The 160 antenna covers 1800-1860 with under 2:1 SWR. I needed to take about 2 feet off the horizontal section to get mine resonant at 1830. If 80-meter current flows in the 160 antenna, it tends to flatten the current loop in the vertical section.

The 80 meter antenna is resonant at 3750 with the 130-foot length shown. The VSWR is under 2:1 over the DX part of the 'phone band. It needs to have some length added to cover the CW portion. I haven't tried to bring it to resonance in the CW band, but have chosen to feed it through a tuner.

I originally had this antenna hung from trees. This year I put up an 80-foot Rohn-25G with three sets of guys. I hung the wires from ropes attached to the tower so they are separated from it by about 3 feet. The coaxial feed line comes off perpendicular to the antenna and is then taped to the tower. The center conductor goes to the top and the shield goes to the lower part. Before the coax turns on to the tower, I've wrapped some 30 feet of it into a coil. I expected to see a lot of interaction, but the tower and guys seem well off resonance at the operating frequencies and I didn't see any to worry about.

The first QSO on 80 was VK6LK, long path on SSB at sunset on September 12. I've worked a few ZSs, HF0POL, LU, and the usual Europeans. On 160, the first QSO was KP4SN on September 15. In the couple of weeks since hanging it from the tower, I've worked ZS6UT, TU2MA, TL5A, VK6VZ, VK6LK, VK3ZL and NL7Z and the usual horde of Europeans on 160 with no fuss. I run about 800 watts out from a Ten-Tec Centurion.

Last January, I had about 200,000 points with 750 QSOs in the CQ WW CW 160 contest using the predecessor hung from trees.

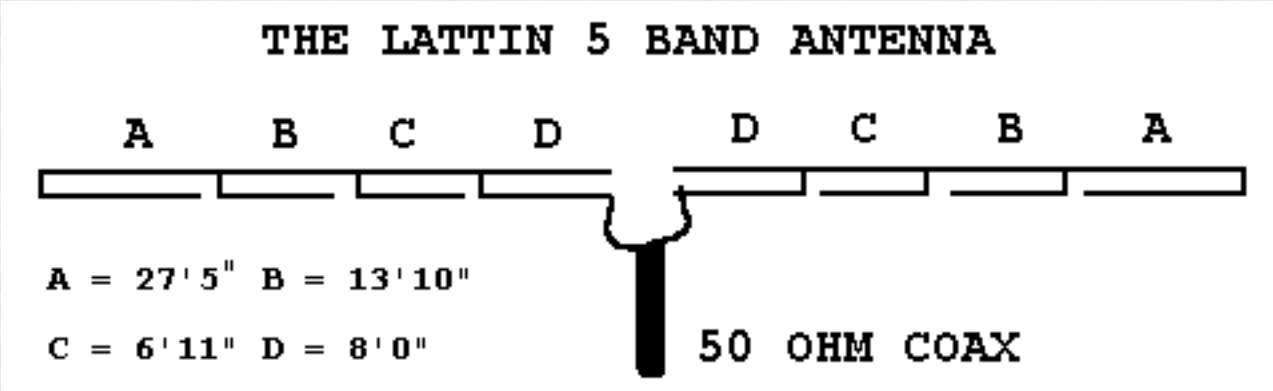
THE LATTIN 5 BAND ANTENNA

(DESIGNED BY W4JRW)



THE LATTIN 5 BAND ANTENNA (FOR 80, 40, 20, 15 AND 10 METRES)

The antenna was named for **W4JRW** who invented it and holds a patent on the basic principle and uses quarter wave stubs, which act as insulators at the frequency for which they are cut. For example, the 6'11" stub (quarter wave times the velocity factor 0.8 of the feed line used) blocks RF for 28 mhz from reaching the rest of the antenna.

In the example shown in the diagram, tubular foam filled 300 ohm feed line was used, which has a VF of 0.8. Other feedlines may be used, for example, slotted ribbon and the length of the stubs worked out using the correct velocity factor

BUILDING THE LATTIN ANTENNA

This will require some forethought and planning. Avoid cutting the continuous top wire, which supports the whole system. I wonder if it might be an idea to use a suitable polypropylene line to support the wire, which may be subject to breaks, especially at the solder points?

A suitable centre piece may be constructed and constructors may want to include a balun at the centre of this balanced antenna, which is fed with unbalanced line (coax).

If you do have a go at this, please let me know - I have always wanted to make one and never as yet got round to it!

A version of the Lattin could be designed for all bands, including the WARC bands - get snipping!

Frank, G3YCC.

Trapped Antennas

ARRL Technical Information Service page · TIS Menu page

Additional information on this subject and related topics can be found in back issues of *QST* and the following:

The ARRL Antenna Book

The ARRL has an extensive catalog of books and materials related to Amateur Radio.

Articles

Note: Some of the following articles are in Adobe Portable Document Format (PDF) files. To view and print these files, you'll need a copy of Adobe's Acrobat Reader program. (Version 3.0 or later required). More information here.

- Coaxial cable Antenna Traps (1,318,022 bytes, PDF file) MEMBERS ONLY
  QST May 1981, pp. 15-17
  Both the coil and capacitor of a parallel-resonant antenna trap can be made from the same length of coaxial cable. Sound intriguing? Here's how.
- Build a Space-Efficient dipole Antenna for 40, 80, and 160 Meters (570,975 bytes, PDF file)
  QST July 1992, pp. 35-36
  A new trap design, using only RG-58 and PVC pipe, yields better space efficiency than conventional coaxial traps.
- Two New Multiband Trap Dipoles (785,934 bytes, PDF file) MEMBERS ONLY
  QST August 1994, pp. 26-29
  W8NX details a new coax trap design used in two multiband antennas; one covering 80, 40, 20, 15, and 10 meters, and the other covering 80, 40, 17, and 12 meters.

A TRI-BAND 2 ELEMENT PORTABLE YAGI

After operating QRP during the 1996 ARRL Sweepstakes Contest I decided that the next time I entered a QRP contest it was going to be with an antenna that had gain over the dipole antennas I was using! Operating from a temporary location, a tower and tri-band yagi constructed of aluminum tubing was not an option. After much thought and a lot of reading, I decided to build a tri-band 2 element yagi using wire elenments. The results of this experiment are contained in an article published in the November 2001 issue of QST. A PDF file of the article as well as the EZNEC antenna files is available at the following links.

Portable 3-Band Yagi Article
EZNEC zip file at QST

ADDITIONAL NOTES:

Assembly

When you are ready to assemble the array, attach the 20 meter reflector and the driven elements first and then hang the array between two supports, (trees etc.) at about 5 feet above the ground. Pull it tight so that the array is fairly flat. It won't stay flat because the driven elements are heavier than the 20 meter reflector so support one end of the 2 x 2 end supports on a rung of a step ladder or box so that the array lies horizontal. Add the 10 and 15 meter reflectors next using a little less tension than the 20 reflector. Next attach the feed line. The last step is to adjust the V slings as mentioned below so that the antenna is balanced in the horizontal plane. All adjustment for lowest SWR, if needed, must be done with the antenna raised to its typical operating position. Do not attempt to adjust any of the element lengths or the hair-pin match for lower SWR while the array is close to the ground. Check the SWR on each band with the antenna at a height of at least 25 feet before attempting any adjustments.

V Slings

There are two V slings, one on each end. The secret is that they are not equilateral in shape. The combined weight of the driven elements and feed line is heavier than the reflectors. If the length of the sides of the V sling are equal, the array will turn with the 2 x 2 end supports positioned vertically. Increasing the tension on the side of the V that is attached to the end where the driven elements are attached causes the whole array to turn toward the horizontal plane. Do this by shortening the length of the side of the V that is attached to the driven elements. It is quite easy to adjust in the field. Once the V sling is adjusted, the array stays balanced. You can change direction 180 degrees by pulling on the the feed-line. If you pull it hard enough, the whole array will begin to turn-flip over. Stop it from turning too far by holding on to the feed line once the array has swung over to face the opposite direction.

Balun

It is not clear what to do with the coil of coax at the feed point in Fig. 1. This is meant to be a choke balun to choke off any RF from flowing along the outside of the coax shield. It is best to let the coax feed line drop straight down from the centre insulator, attach it to the centre of the hair-pin shorting bar with a plastic tie or string and then make the balun by coiling up the coax 6 to 8 turns with a diameter of 4 inches or so just below this point. The centre of the shorting bar is neutral potential so there is no problem mechanically attaching the feed line to it for support.

Biography:

I obtained my ham radio licence in 1959 at the age of 16 and was assigned the call VE7BGE. (My first Ham Station) After high school I obtained my 2nd Class Commercial Radio Licence at Room 19 in the City of Vancouver, BC. Upon graduating from Room 19, I obtained work as a commercial radio operator and weather observer at Alert BC off the west coast of Vancouver Island at a Loran Station. I was later transferred to Smithers BC, then served for one year at Alert NWT. After returning from the arctic, I was transfered to Terrace BC and finally to a Canadian weather ship named, The Stonetown, stationed off the West Coast of British Columbia. In 1967 I decided to return to school and enrolled in general sciences at the the University of British Columbia, (UBC). While at UBC I was a active member of the university ham club called HAMSOC. (Hamsoc FD 1967), (1986 HAMSOC Reunion), (1992 HAMSOC Reunion), (1995 HAMSOC Reunion). During my second year at university I met my future wife, Gaye. We were married in 1969. We have one daughter and two sons. Our daughter and youngest son are married and we are blessed with two grandchildren. In 1979 I was issued a two letter call, VE7CA.

I have been working in the commercial real estate industry for the last 30 years and have no plans to retire. Here I am in front of my operating desk looking for you on my homebrew HBR2000!

I continue to be active operating mostly CW, chasing DX, looking for new grids on 6 meters and entering contests under the QRP category. I have a strong interest in antennas and have published 4 articles on antenna designs that I have developed. Homebrewing is something I really enjoy as well and lately I have been absorbed in building a high performance HF transceiver. See the above menu for further details regarding my antenna articles and homebrew projects.

Antennas:
160/80 trap dipole, switchable to Vertical T antenna.
Triband Dipole at 35 feet.
Portable 2 Element Wire Tri-band Yagi, See QST November 2001
Portable 2 Element 6 meter Quad
Portable 3 Element 6 meter Yagi
Cross Polarized 144 and 430 Mhz Hi-Gain yagis.

Ham Gear and Test Equipment:
Homebrew 160-10 Meter High Performance Transceiver HBR2000
Homebrew 6 meter CW/DSB 10 Watt DC Transceiver
Modified Norcal Sierra QRP CW Transceiver 40-10 meters
Homebrew 40 Meter Optimized QRP CW Transceiver based on W7EL design in August 1980 QST
Homebrew 160-10 Antenna Tuner

Kenwood TS-940s HF Tranceiver (FOR SALE)
Yaesu FT-726R VHF/VHF Transceiver
Homebrew 6 Meter 70 Watt Solid State Amplifier
Heathkit SB220 Linear
Homebrew Spectrum Analyzer based on W7ZOI/K7TAU design, August 1998 QST
Homebrew Personal Network Analyzer based on design by Steve Hageman, see Jan/Feb 1998 QST
Homebrew Power Meter by W7ZOI/W7PUA, June 2001 QST and K3NHI additional features May/June 2002 QEX
HP8640B signal generator. See July/Aug 2004 QEX if your gen. has no output power.

My Favorite Multi-Band Antenna

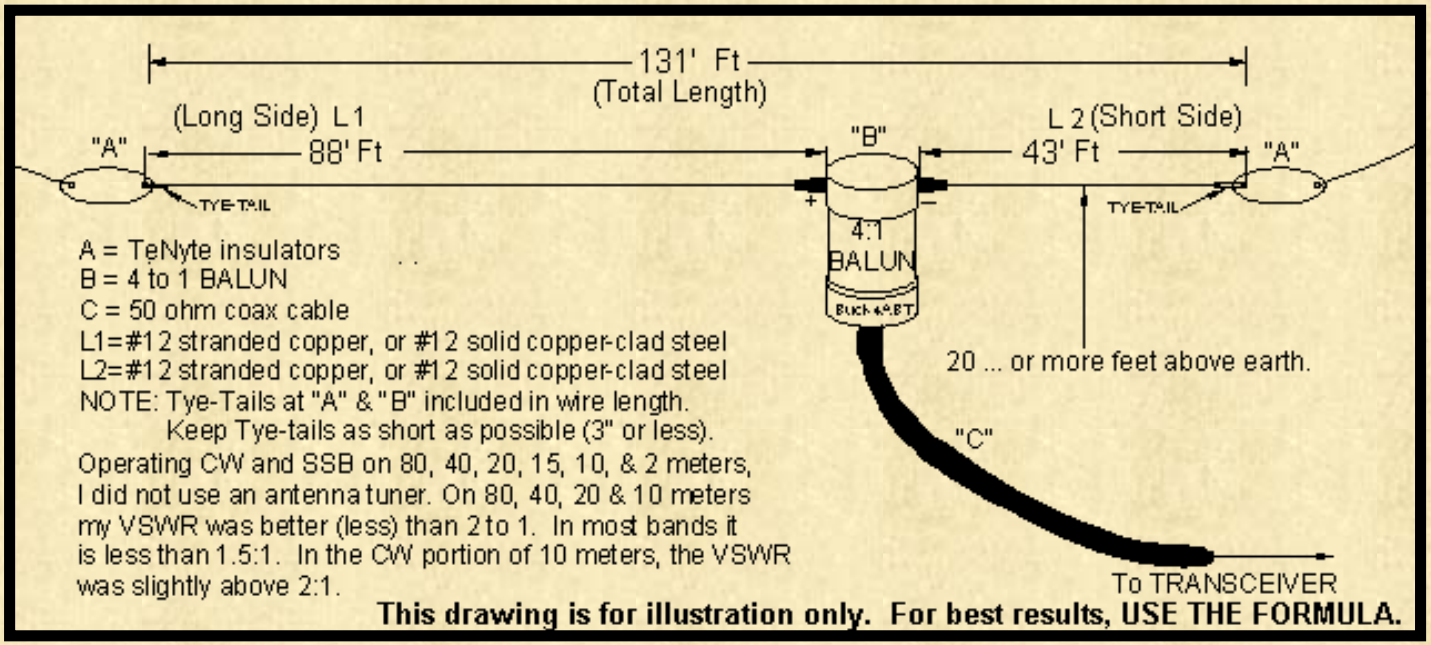
The "WINDOM"

By G. E. "Buck" Rogers Sr; K4ABT

In September of 1949, I was tired of climbing poles and trees to move, remove, add, or change my single-band HF antenna's. In those younger years of my HAM radio hobby, I had used single band dipoles and doublets for almost every HF Amateur band. I had tried long-wires, doublets, dipoles, and Zepps, but again, operation was restricted to single band operation, maybe two bands at most.

I had heard of the "Windom" and read a few articles about the Windom, but most of my thoughts were ... ho-hum.. just another dipole fed a bit off-center. Then one evening at a meeting of the GARC in the old "Sea Scouts" club house near the Coosa River in Gadsden, Alabama; I heard some of my "elmers" Gilbert Watson (SK) W4PAC, Gale Caudle (then W4CFB), Jack Kennamer (SK) W4YPC, Bob Bynum W4USM, Austin (Vic) Vickery, Walter Damkohler (SK) W4EBO, W4CWF, Ed Elkins (SK) W4CDI, Homer Dupree (SK) W4OZK, Jim Runyan, Homer O'Dell, Robert Martin, ... and others discussing the Windom *all-band HF antenna*. It was when Jack (W4YPC), mentioned ***using one (Windom) antenna, on the all HF bands*** *that my ears went directional!*

That last phrase caught my undivided attention. "most all HF bands, ...etc"
What ! *A multi-band HF antenna ?* Surely I had been blessed.



To think that I could put up a Windom, and no longer have to climb the poles and trees to hang another (single band) HF antenna was great news to me. To be able to use it without an antenna tuner was icing-on-the-cake. For a kid without extra funds, an antenna tuner was a luxury that I could *not* afford. Even my transmitter was a single 807 rig I homebrewed on an old *Atwater-Kent* radio chassis, my grand-father had given me.

In those days, a BALUN was unheard of. My Elmer's described, a means of connecting the coax to the off-center fed antenna using a nine (9) turn coil of the coax feed-line at the feed point. This coil of feedline coax formed a "de-coupling" loop. The de-coupling loop provided a crude means of matching the feed coax to the antenna, and at the same time, it would reduce the "re-radiation" (RF currents) along the outside (shield) of the feeder coax.

Today we have toroid cores and BALUN devices that provide a more efficient means of coupling RF energy to the antenna (reducing the VSWR, "standing-waves"), while performing better impedance matching. In the drawing shown above, I've drawn the exact dimensions of the Windom I built in 1949. The only differences in my Windom of 1949 and today are:

1) the material the insulators are made of, and
2) I've substituted a 4 to 1 BALUN for the 9 turn, 8 inch diameter, decoupling loop.
AN UPDATE:
Since writing this article a few decades ago for a major HAM radio magazine, I've received tons of mail (and eMail) asking for more information, especially with regards to a 160 meter version; Here then is "the rest of the story."

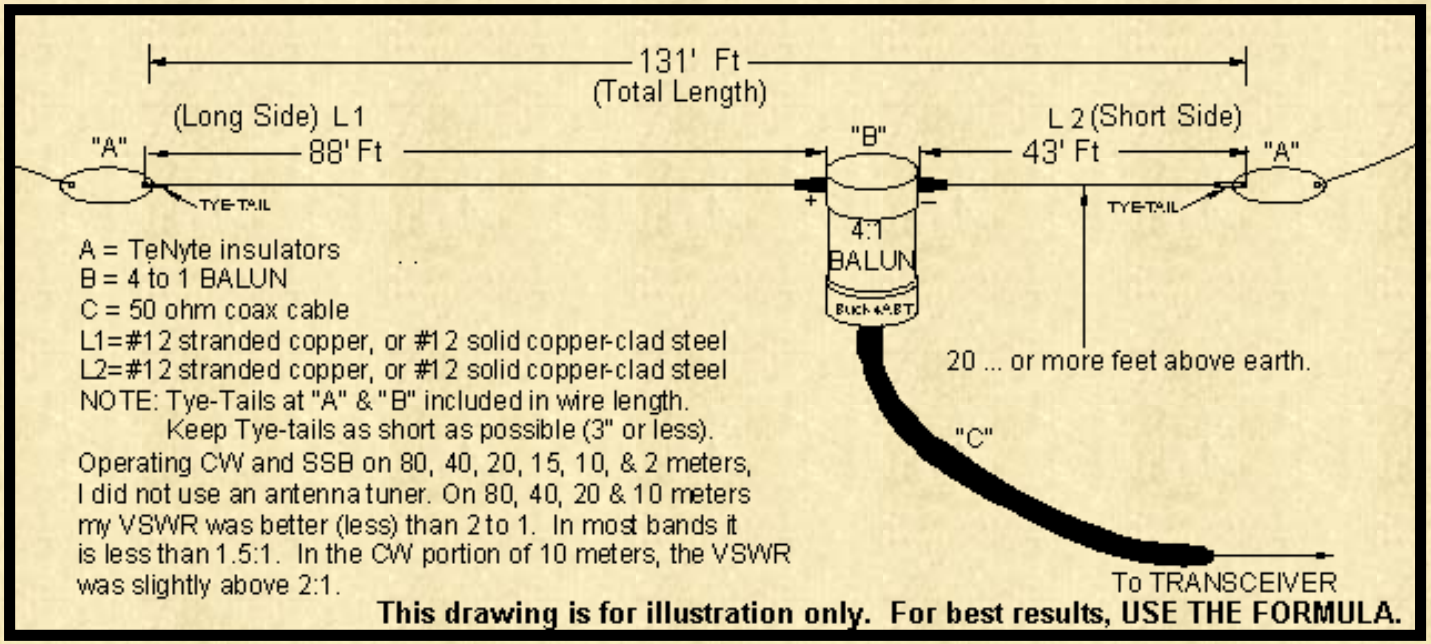
First of all, we'll address the formula, and how to determine the length(s) of each section, using the same old formula that I used in 1949.

Long side.... = 468, divided by the frequency, then multiply by **.**64 (= Feet)

Short side.... = 468, divided by the frequency, then multiply by **.**36 (= Feet)

THUS; for 160 thru 10 Mtrs.....
Long Section; 468/1.8 MHz = 260 x .64 = 166.4 feet.
Short Section; 468/1.8 MHz = 260 x .36 = 93.6 feet.

For 75 thru 10 meters do similar math to arrive at/near the dimensions shown in the drawing below, but for best results, use the formula.

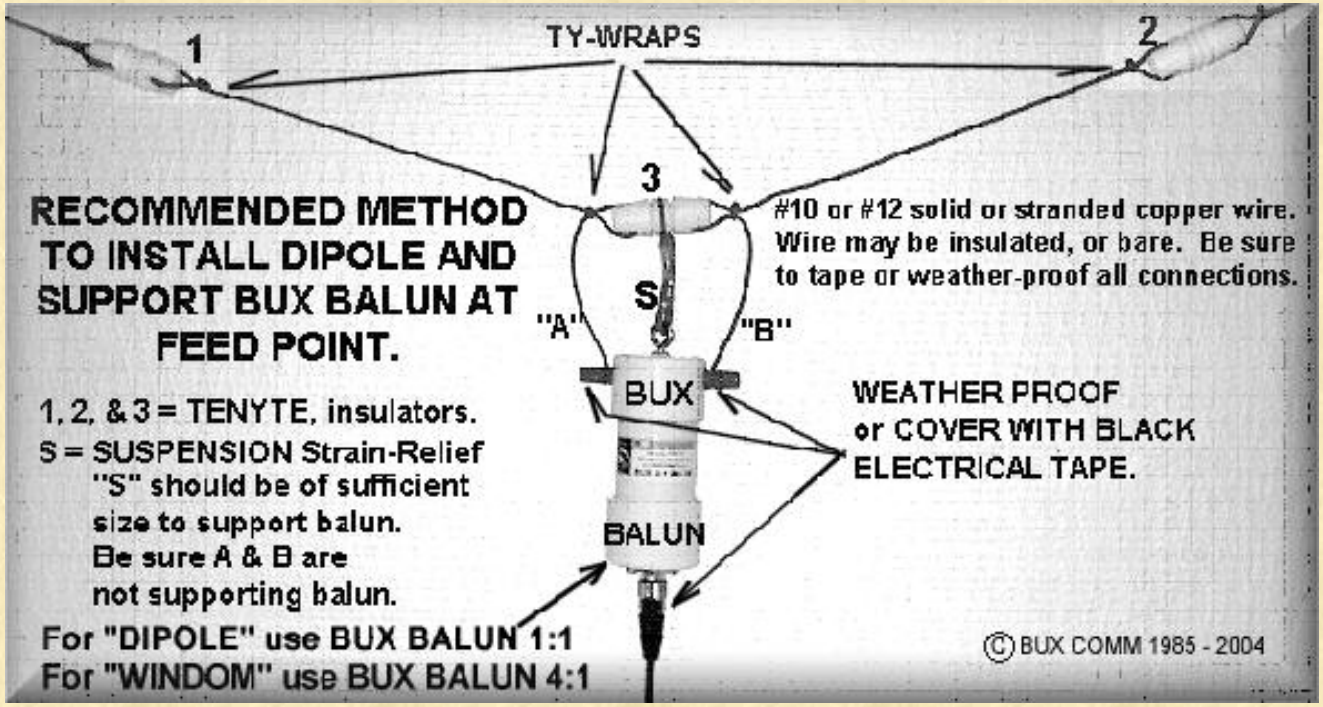


The Windom can be installed as an inverted VEE, or as a sloper, ***but in no case,*** should the angle be less than 90 degrees against itself. *To use an angle that folds against the pattern of the opposite end of the Windom, would change the impedance of the feed-point, change the multi-band features, and most important, destroy the radiation characteristics of the antenna.*

In other words, install the Windom as you would any other dipole, while using a common sense approach. The fact that we are feeding
this Windom using *coax,* and a single balun, gives us the ability to construct it as an inverted VEE or at a "real estate saving (angle)" without destroying the features and performance of the Windom.

This is *not* true with those antennas fed with ladder-lines and those that have several impedance transitions built into the feeders

of the "*basic" Windom..... There's more to come, so read on!*



ANTENNA INSULATORS

Weatherproof, (TENYTE) insulators. Perfect for your DIPOLE or Windom antenna.

For the apartment dweller, you can now hang the 20 meter doublet in the attic. I've QSO'd with stations all over the world with the 33 ft dipole in my garage attic. One insulator at the center, and one each end.

It's great for other HF WINDOM and single-band dipole antennas. Dielectric strength is comparable to the old ceramic insulators, without susceptibility to cracking or breakage under impact or extreme temperature changes.

Package of 3, $2.99 ANTINSL3 Order Now

Package of 10, TeNyte Insulators $8.99, ANTINSLX10 Order Now

Now it's time for me to P O the wire and cable vendors, and the proponents of Windom's with too many feed-line transitions. Twin Lead, Ladder-line, Window Line..... etc.. is an over-kill.. The trade-off is not...; I repeat; NOT... worth the pain and upkeep to replace it every year or two.

And trust me... It is NOT a problem of the ladder-line insulation quality or properties that I'm speaking of. I speak from experience; Wind will destroy ladder/twin-lead line. Even the robust type will succumb to the wind element in time.

IF; you decide to use ladder line, make one turn (twist) to each 20 to 24 inches of line to decrease the wind resistance presented by the "flat" line..... even if it is "window-slotted" type ladder-line. By adding the one twist per 20 inches, it may last longer than three years.

COAX does NOT present a high degree of wind resistance, and it'll last much longer.

Having *been there, done that*, and heard similar horror stories from others; another question arises regarding parallel line currents that come with the use of so-called balanced (twin-lead) feed-lines. To add injury to the ladder-line proposition, the balanced line may also assume the properties of a *single wire feeder (yuk)*.

Some purveyors of the Windom that use ladder-line transitions, must use two impedance matchers (or BALUNS) with their (knock-off) Windom. One is to transition the coax outside the HAM shack *(heaven forbid, we use ladder-line inside the shack... RF "feedback" in everything)*, to the ladder line, then another at the Windom (antenna) feed-point to choke off parallel current from the ladder-line.

Since the feed point of this antenna has been found to be near 220 to 260 ohms, *the use of a 4:1 BALUN to join our coax to the antenna,* emerges as a compromising solution.

Let's not lose sight of the most important advantage of using this antenna; and that is: It provides us with a powerful, multi-band antenna, and a minimum of feedline components.

Now for the "perfectionists" among us, if you want to smooth out the hills and valleys on some of the bands, add your antenna tuner to the system, and the Windom becomes very flat across the bands. When I say "flat," we are talking about reducing the VSWR to a minimum, to produce a good forward power, transfer of RF energy to the Windom.

We're having fun already... with the Real WINDOM antenna

The "Windom Antenna" was described by Loren G. Windom in QST magazine, September 1929. Pages 19 through 22. It is named after its inventor/designer.

Loren Windom, W8GZ, was first to reveal the antenna to the radio amateur community by describing the antenna in the September 1929 issue of QST. It was by Windom's name that the antenna became known. The Windom antenna is an off-center fed dipole with an unbalanced coax feedline.

In 1937, the Windom was first described as a compromise multiband antenna. The antenna can be employed on 80, 40, 20 and 10m with considerable, though acceptable levels of VSWR. What became perhaps the most popular multiband Windom design of all, was the German-made Fritzel FD4 antenna, described by the late Dr. Fritz Spillner1, DJ2KY, in 1971. It had the same dimensions as the multiband Windom antenna, but fitted with a 200Ω (4:1) balun in its feedpoint and fed with coax.

Today, many radio amateurs are using multiband Windom antennas with more than satisfactory results. It would not be without reason that Windom antennas are being employed during IARU HF World Championships! and most of all, by "high-stake-contests." ***Perhaps many young hams ignore the multiband Windom antenna because of its sheer simplicity and may be thinking it is too good to be true.*** *The complexity of feeding other dipoles and doublets, the losses in dipoles with traps and the esoteric marketing of some other antennas seem to appeal to them more.*

CLICK HERE: and read more about the evolution of the WINDOM, to ZEPP, to VHF J-POLE.

BUX BALUNs should be installed at the antenna feed point, or where the coax or feed-line attaches to the above ground antenna. BUX BALUNs are used to connect balanced antennas to unbalanced transmission lines, such as coax cable. Their primary purpose is to prevent antenna (RF) currents from flowing down the outside of the cable. Another function of the BUX BALUN41 is to match the impedance of an unbalanced coax to the balanced feed point of a balanced input antenna(s). BUX BALUNS may also be used as “line isolators” anywhere along the cable to prevent the destructive influence of induced RF currents (VSWR).

BUX 1:1 BALUNs are current BALUNs. They consist of several large, number 73, ferrite type 44 cores. ***BUX BALUN11*** operate from 3.5 to 72 MHz and allow use of RF power to the rated capacity of the BALUN.

BUX 4:1 BALUNs are voltage BALUNs. They consist of a large, number 41, ferrite dough-nut bobbin. ***BUX BALUN41*** operate from 3.5 to 55 MHz and allow use of RF power to the rated capacity of the BALUN.

During this month, when you purchase either of our BUX BALUNs, we will include 3 (Tenyte™), insulators FREE. A $2.99 value. *Be sure too mention this offer in*

the "Comments" space on the order form check-out page!

At BUX COMM, *We don't cut corners!

The components used in the manufacture of our BALUNs are from top quality components, beginning with the Silver Plate SO239 connectors and center insulator is made of teflon™(E.I Dupont). The wire we use to wind the ferrite donut is heavy-duty, silver flashed wire, with teflon™ insulation that will handle RF voltages above 5000 volts, and temperatures above 2000 degrees. The binding posts are heavy-duty, tempered brass, with end holes and side-thru holes to accommodate either type loop-thru connection. A double-shoulder brass capture nut is used to add a secure bite and improve antenna wire electrical connections. With our BUX UN UN (ONION), the coax is Belden™ and the PL259 connectors are Amphenol™.

4:1 Balun, BUXBALUN 41 $19.95 Order Now

o 50 ohm, SO-239 unbalanced input
o Balanced output
o 1.6 to 50 MHz
o Toroid (Voltage) design
o Heavy Duty, Lightweight construction
o Sealed against moisture

1:1 Balun, BUXBALUN 11 $19.95 Order Now

o 50 ohm, SO-239 unbalanced input
o Balanced output
o 1.6 to 50 MHz
o Toroid (Current) design
o Heavy Duty, Lightweight construction
o Sealed against moisture

BUX UN UN *De-Coupling transformer, similar to above,* but has *SO-239 (female) input* connector and *output connector is 1 ft Mini 8 cable with PL-259 (male).*

BUX ONION $19.95 Order Now

4:1, *1.5kw* Balun, BUX BALUN 41HD $27.95 Add To Cart

Toroid design, wound with teflon covered, silver plated wire.* Heavy-Duty, construction.

1:1, *1.5kw* Balun, BUX BALUN 11HD $27.95 Add To Cart

Toroid design, wound with teflon covered, silver plated wire.* Heavy-Duty, construction.

BUX ONION Decoupling Transformer

BUX UN UN De-Coupling transformer, has SO-239 (female)input connector and output connector is 1 ft Mini 8 cable with PL-259 (male).

BUX ONION is and UNbalanced to UNbalance (UN-UN) *decoupling transformer* designed to be used specifically with **the DBLSPCL antenna.**

High RF currents traveling along the coax feed-line shield can cause high VSWR. This decoupling transformer prevents RF currents from traveling down the outer shield of the coax.

The input connector is an SO239 (female) and the output connector is a PL259 (male), which mates the connector of the "DBLSPCL" RV/Apartment dweller antenna shown above.

BUX ONION $19.95 Order Now

WHY USE A 4:1 BALUN

Krusty Olde Kurt is now going to repeat himself. Why? Because the same question keeps coming up over and over. And he wants everyone to get it right.

"I'm feeding my dipole with 600-ohm line. At the station end I need a balun to convert to 50-ohm coax. I need a 12:1 balun, right?"
Wrong! *A **4:1 balun** would be better.*

Why is that? If your dipole is up, let's say, 35 feet then on 80 meters it will probably have a resistance at resonance of about 40 ohms. The actual resistance depends on the height above ground in wavelengths.

If the dipole is 40 Ohms then what do you see at the transmitter end of your 600 ohm line? If the line is a half-wave long (120 ft on 80 Meters) you'll see 40 ohms. Remember, a half-wave line repeats what it sees at the other end. But if it is a quarter-wave long you'll see 8500 Ohms! At other line lengths you'll see impedances somewhere between these two extremes.

So you are not going to see 600 ohms at the end of your 600-ohm line. That only happens if you have a 600-ohm antenna hooked onto it. With such a variation in impedance at the trans-mitter end of the line there is no one balun transformer that will match it. Most of the time the impedance will be above the 50 Ohms of your coax so a high impedance balun would be desirable. Unfortunately high imped-ance baluns don't work well when not matched.

Experience has shown that ***4:1 baluns work best*** in this service. They are more rugged and will take bad mismatches especially if they are wound on an iron powder core. So stop searching for that 12:1 balun. **Use a 4:l BALUN and your system will work just fine.**

You can read Kurt N. Sterba "AERIALS" column in **World Radio Magazine.**

BUX MOBALUN

When you hear those strong HF mobile signals, here's one reason they stand out from the rest.
By installing the BUX MoBalun near the input to your antenna, you deliver more RF energy to the antenna. At the same time, the BUX MoBalun prevents RF from traveling back along the shield (high SWR) of your coax. High power rating, Low-permeability toroid, with Internal composition fiber-glass to prevent vibration during mobile operation. For input and output connectors, we use only the best Silver plated, Teflon insulated, SO239 connectors. 700 watts PEP. *Our **MoBALUN** is also ideal for marine antenna installations*.

6m Vertical Antenna

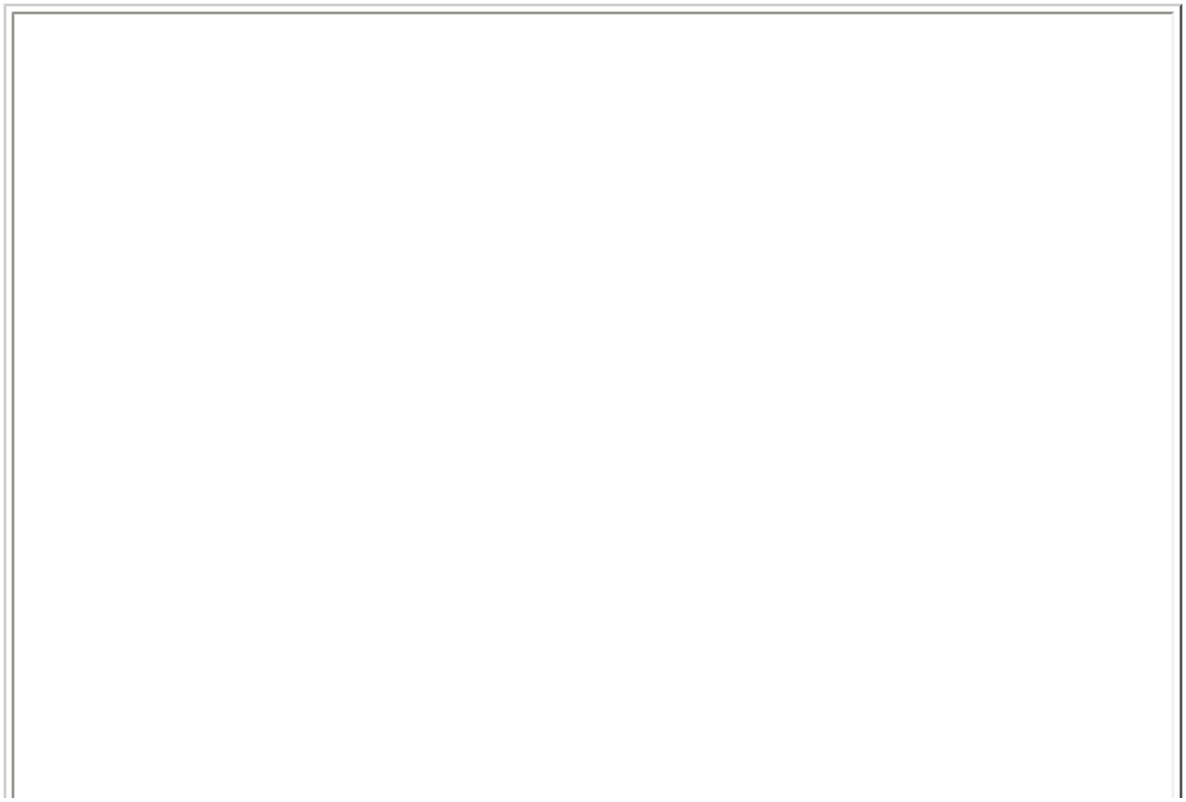
By Mike, G3JVL

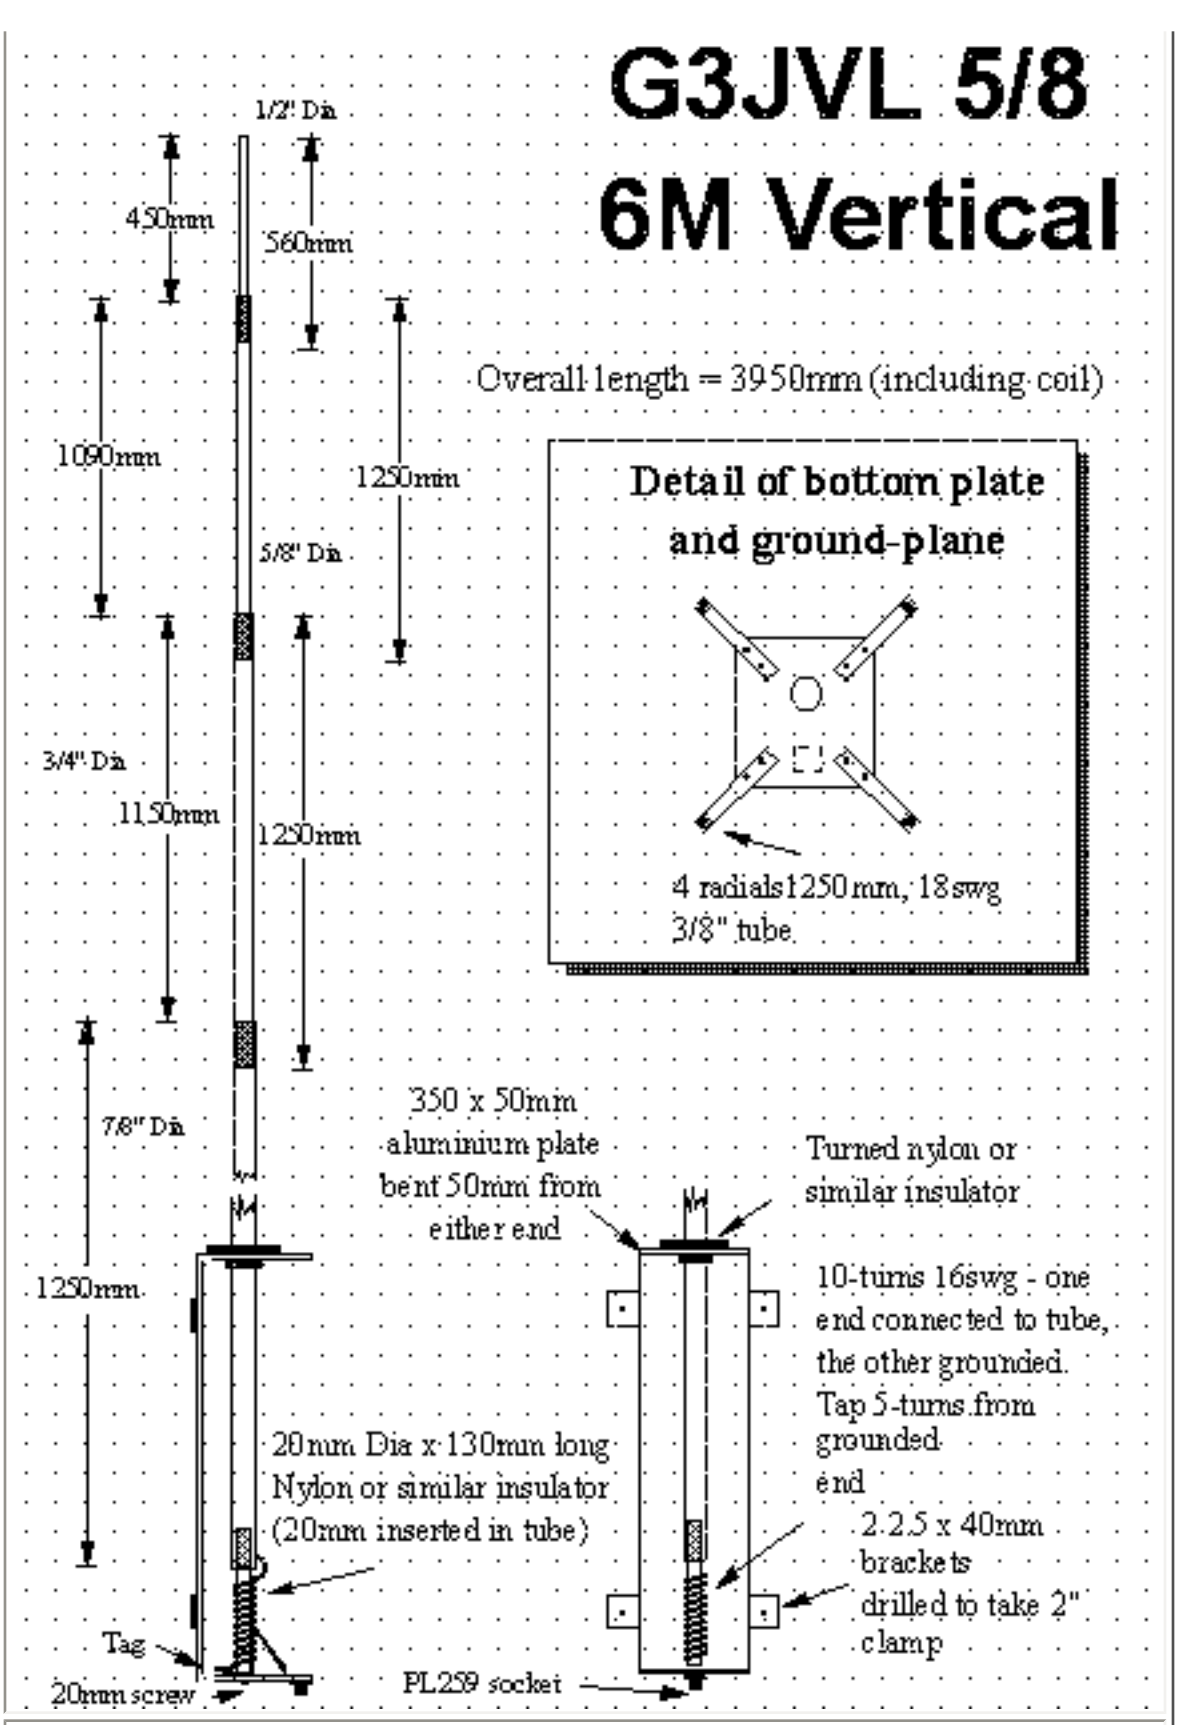
The G3JVL 6M ground plane vertical is a compact antenna that is ideal for portable operations. It packs away into a small bag only 1.3 metres long which is an ideal size for hand-baggage on aircraft.

Although a little engineering work is required, it well within the abilities of the home workshop and all you newly licensed amateurs!

The vertical itself is constructed out of four overlapping sections of aluminium tube whose sizes are given in the diagram opposite. The four tubes are meant to telescope so wall thickness should be chosen to achieve this. In practice, 16swg or 1.6mm might be OK but 18swg or 1.2mm will easily fit. The lengths are held in place by three stainless steel self-tapping screws.

The vertical is bottom-loaded with a coil wound on an insulated former (nylon or similar material - it is not too critical at 50MHz). - the former is 130mm long with the top 20mm turned so it can be inserted into the bottom section of the vertical. The loading coil consists of ten turns of 16swg (1.6mm) diameter copper wire with one end connected to the bottom section of the vertical with a machine screw and the other end connected to the ground plate. A tap at 5-turns is connected to the input PL-259 socket.





The construction of the 6m vertical antenna

The four ground plane elements are Constructed from 1250mm long, 9.5mm (3/8") diameter aluminium tube. These are mounted to the base plate by the use of eight

stainless steel machine screws. This arrangement allows easy disassembly.

The vertical itself is supported by a piece of 350mm by 50mm x 4mm aluminium plate bent into a 'U' shape. The bottom section of the vertical is insulated by a turned piece of nylon or similar tubing. If you do not have access to a lathe any other insulating arrangement should suffice so long as it is robust.

The overall length of the vertical is 3950mm including the loading coil. The top section should be trimmed to set the centre frequency. If the VSWR at resonance is not close to 1:1 then alter the position of the tap on the loading coil (remember, changing this will alter the resonance of the antenna!).

Once completed give the whole assembly several coats of varnish to keep out the weather.

HF designs.

Several sites on the web carry very good information about antenna designing. One of the most interesting sites I've found is that of W4RNL, have a look t them. In the past i made a 5 band yagi, covering 20 to 10 meter band, with a boom length of 40-50-60ft. This design was published in QEX a while ago. It has been reproduced successfully

by several hams around the world. This killer antenna was in use for our OT9E OT0E

Contest station. We managed to win 3 times in a row the ARRL roundup as multi single.

Contents.

A multiband yagi antenna

Design en construction ON4ANT-ON4GG

As most of us know, the monoband yagi is by far the best antenna choice. The majority of hams have unfortunately no room to put up several towers for all the different monobanders. The average ham chooses a trapped multi-band yagi. This antenna type allows him to be active on a number of bands, but it has some drawbacks as well: loss of swr bandwidth, antennagain and F/B ratio. Over the past years a number of commercial interlaced designs have been available. These designs often put 2 bands on a same boom.

These interlaced yagis often give a good result and can be an excellent replacement for the trapped yagis.

(The W4RNL web site carries an interesting article about these interlaced yagis).

Struggling to get a number of bands with good swr bandwidth and gain on a single boom made me decide to develop the antenna described here. The basic principle is to put a number of mono band yagis on the same boom, one in front of the other. The first conclusion is that the boom length increases rapidly, especially if one wants to cover 20 to 10 meters.The boom length was limited to 15 meters with an option to shorten the boom to 12.8 meters. This should allow most of us to reproduce the design. Those having plenty of room can go for the long design 18.3m (60ft) boom. The antenna covers the 20 to 10-meter bands.

The design has been done with the help of AO*, YO*, EZNEC/4*, STRESS*, and YAGI DESIGN*.

The electrical design can be found in part 1.

It gives full details about element lengths and spacing. The feedpoint impedance, free space gain and swr bandwidths are also given. Two modified designs are described as well.

Part 2 gives mechanical details, including the tapering detail, wind survival and total wind load.

Part 3 gives a table with the gamma match details

Part 4 gives you a table with gain figures from the most common available mono band yagis. These designs have been verified with the same software as used for designing this antenna. Trapped yagis have not been taken into account as these show less gain than their mono band counterparts and usually these trapped yagis have unrealistic gain figure claims.

-

Part 1.

The basic calculation has been done for an antenna in free-space and all values are in dBi. We don't take into account the influence of the earth ground gain, and the reference antenna is an isotropic radiator. (0 dBd = 2.15 dBi). If one takes into account the ground gain (as most manufacturers do) the gain figures will be 4-5 dB higher.

However this in influenced by the antenna height.

The setup above real ground will change the radiation pattern.

The table gives the element length for a constant diameter (20mm) and the element spacing.

Element Length	Description	Position (m)
5.45	Reflector 20	00.00
5.2	Driver 20	02.00
4.9	Director 20	03.60
4.15	Reflector 17 & dir 20	05.25
4.02	Driver 17	06.20
3.8	Reflector 15 & dir 17	07.20

3.395	Driver 15	08.40
3.02	Director 15 & ref 12	09.50
2.91	Driver 12	10.30
2.78	Reflector 10 & dir 12	11.60
2.55	Driver 10	12.45
2.355	Director 10	13.40
2.265	Director 10	15.00

What is to expect from this antenna?

Gain is comparable to a 3-4-element monobander, with excellent swr bandwidth and F/B.

-

Antenna specifications.

_

Frequency Gain (dBi) Impedance F/B SWR

14.000 8.1 33.0-j4.1 26.8 1.26

14.175 8.2 30.9+j3.0 29.1 1.00

14.350 8.3 26.0+j12.2 25.9 1.44

18.068 8.1 20.9-j3.6 21.5 1.10

18.118 8.6 22.3-j2.3 22.3 1.00

18.168 8.6 23.5-j1.2 23.2 1.07

21.000 8.4 32.4-j7.8 21.1 1.27

21.200 8.5 34.2+j0.5 21.0 1.00

21.400 8.6 35.7+j8.1 20.9 1.25

```
24.880 8.5 10.7-j3.6 30.6 1.19

24.940 8.5 10.8-j1.7 30.6 1.00

24.990 8.5 10.8+j0.1 28.0 1.19

28.000 7.9 26.0-j7.2 29.7 1.47

28.350 8.1 26.9+j3.1 25.7 1.00

28.700 8.2 27.6+j13.9 22.6 1.48
```

This design has an almost constant gain over the 5 bands.

The swr bandwidth is excellent over the entire range with exception of 10 meters;

here it is limited to 28.8 MHz. Of course this swr is in reference to the matching frequency.

I'm sure that things still can be improved, but this may have a negative influence on swr bandwidth and/or F/B. Another disadvantage of getting the last .5 dB out of the design makes it more critical and less tolerant for small dimension errors (element lengths and spacing).

If you really want more gain, go for the longer design on the 18m boom. You will get the same bandwidth and F/B (or even better) with higher gains.

Variant 1.

A 15-meter boom too big for you? Perhaps this 12.8m antenna is the solution.

There will be one element less on 20m. The gain will drop to about 7 dBi, which is still good.

Element length (m) Description Position (m)

5.45 Reflector 20 0.00

5.2 Driver 20 2.00

4.15 Reflector 17 and director 20 3.05

18.118 8.3 21

21.200 8.7 23

24.940 9.6 38

28.350 10.0 29

This design made it at my home QTH.

The calculated specification seem to be corresponding really well with the on air performance.

Initial testing show an advantage as compared to a very large commercial multi band yagi.

The design is very broadband and allows different kinds of matching.

_

Part 2.

_

Feeding the antenna.

The driven elements are all resonated in band.

The actual impedance of the antenna is high enough to allow different kind of feeding.

Personally I use a gamma match; the elements don't need to be spliced up in this case.

Element mounting.

One can choose isolated or non-isolated element mounting. The boom influence on the element length is minimal.

The use of isolated element can be a disadvantage is you want to use your tower as a toploaded vertical on 160m. (* ON4UN).

The boom element plate measures 200x100mm. If you wish to mount the elements non-isolated you can calculate the

influence of the boom on the element lengths with **YAGI DESIGN***.

The calculated influence is only a few millimeters for the 20m element. As this design is not critical, one can use the isolated element lengths.

Element tapering.

Each element has to be as strong as possible for a minimal windload and weight so we use tapering.

Most of the available antenna design software programs allow calculating the taper. Only a few allow calculating the element strength.

Initially I used **STRESS***, this software is used by the former Telex/Hygain company.

Afterwards I used a Belgian product, **YAGI-DESIGN*** by ON4UN. This package can calculate in all circumstances the taper of an

element that complies with a wind survival. This for the lowest possible weight and windload. The element sag is also calculated.

The calculated minimal wind survival is 160km/h, (100mph). The antenna is mounted on an 80ft tower on top of a 300ft hill here.

Parameters: EIA-222-C pressure 30lb/sq ft at 86mph.

Shape factor .666

No ice-load

Aluminum 6061-T6 (yield strength 35000)

The table gives us element diameter, wall thickness, length, half element weight and length. The elements will be adjusted with the tip end.

Some of these elements are telescopic on the inside. All of the 20m element consist of 3 diameters.

–

Element 1-2-3

```
1700x28x1.5 3000x25x2.5 2750x19x1.5
```

Insert 250x19x1.9

The wind load of this half element is 0.13m². The weight of this half element is 2.6kg

Element sag is 20.5cm. The tip will be adjusted.

Tip lenght ! (100mm overlap)

Isolated Non-isolated

Element 10-11-12-13

750x25x2.5 **x19x1.5

The wind load of this half element is 0.059m². The weight of this half element is 1.1kg

Element sag is 3.5cm. The tip will be adjusted

Total element length ! (100mm overlap)

Element 10 : 2845mm

Element 11 : 2583mm

Element 12 : 2364mm

Element 13 : 2264mm

-

Wind load and weight of elements.

44.55 kg and a 2.20 m² windload.

If you choose the variant 1 you will have 0.26m² less wind load and will gain about 5.2 kg.

The actual weight of the antenna is function of the choosen boom diameter, the mounting plates and all related hardware.

My antenna uses a 4 inch boom and the weight is around 60 kg.

Part 3.

The Gamma match for the 18.3 m version

	A(mm)	B(mm)	C(pF)	D(mm)	D(mm)
14.175	1067	120	180	28	4
18.118	562	120	150	25	4
21.200	735	100	100	25	4
24.930	867	100	100	25	4
28.400	361	100	81*	25	4

* (3x27pf parallel)

The Gamma match for the 15 m version

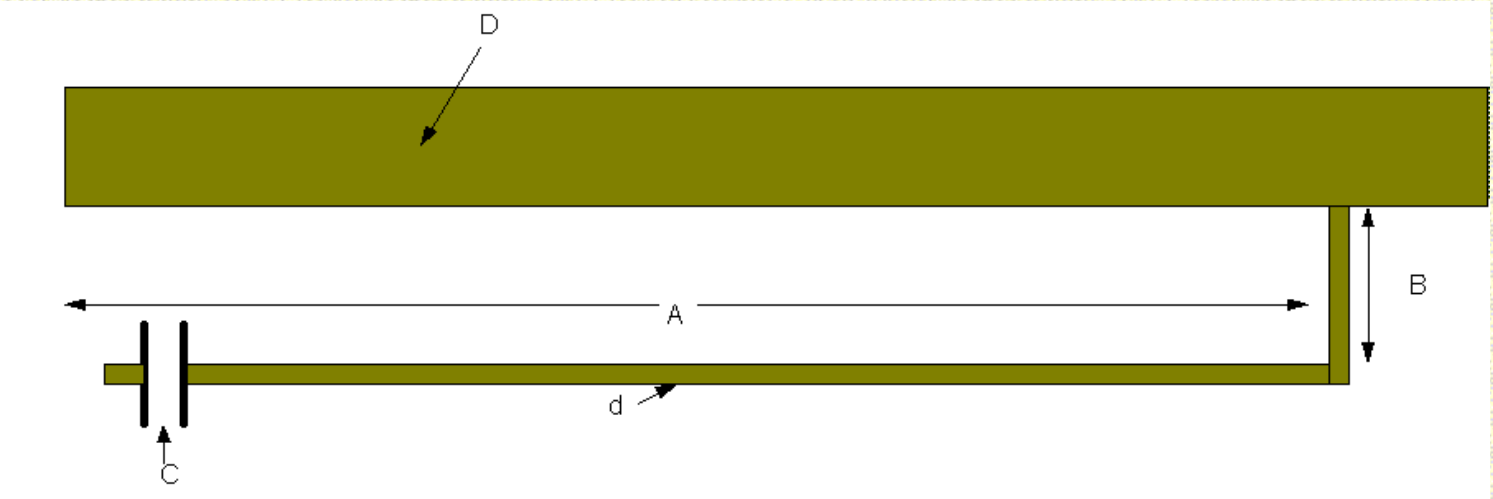
	A(mm)	B(mm)	C(pF)	D(mm)	D(mm)
14.175	950	120	180	28	4
18.118	602	120	180	25	4
21.200	631	110	100	25	4
24.930	522	80	270	25	**3**

28.400	496	100	100	25	4

[The Gamma match for the 12.8 m version]

	A(mm)	B(mm)	C(pF)	D(mm)	D(mm)
14.175	880	120	154	28	4
18.118	598	120	200	25	4
21.200	629	100	111	25	4
24.930	279	100	190	25	**3**
28.400	497	100	100	25	4

For an output power of 2000 watts one should get capacitors handling 300 volts and 6.3 amps current.



[The Hairpin match for the 18 m version]

	A(mm)	B(mm)	d(mm)	Shorten driven element
14.175	50	541	4	139mm
18.118	50	393	4	56mm
21.200	50	407	4	88mm
24.940	50	235	4	87mm
28.500	50	317	4	103mm

Part 4.

Is it all worth the trouble ? Looking at the actual cost, YES. The price should be below $800 (US) for the 60ft design.

The design is non-critical can can be easely reproduced. The gain is excellent and you will have a big signal on the bands.

However, an antenna this size requires a strong tower and big rotator. If you have the tower and rotator for it, its an excellent choice.

A comparison with some commercial mono band antennas gives you a idea about the performance of this antenna.

The values indicated are NOT those from the manufacturer, but those calculated with the design software used for this antenna.

Only this procedure gives an objective view on the gain, since all gains were computed in exactly the same way.

dbi

Type Gain SWR bandedge Description

310-08 7.17 1.31-1.46 3el 10m on 2.3m boom

103BA 7.51 1.53-2.01 3el 10m on 2.3m boom

420-26 8.60 1.28-1.37 4el 20m on 7.8m boom

20-4CD 8.54 1.78-2.20 4el 20m on 9.6m boom

510-20 9.75 1.49-1.53 5el 10m on 6.0m boom

KLM510 9.21 1.33-1.43 5el 10m on 6.1m boom

105CA 8.38 1.42-1.23 5el 10m on 7.2m boom

155CA 9.70 1.49-1.62 5el 15m on 7.7m boom

205CA 9.23 1.43-1.96 5el 20m on 10.4m boom

KLM520 9.43 1.66-1.25 5el 20m on 12.8m boom

Conclusion.

This design is a valuable alternative for a 4 element monoband yagi, taking into account the gain and swr bandwidth.

It is obvious that some improvements can be done, depending on your specific needs. Perhaps you need less bandwidth.

I tried to have a broadband yagi with gain figures close too or better than the common 4 element moband yagis.

The real gain, with associated radiation angle is given in next table.

14.150 13.55 dBi @ 12°

18.118 13.64 dBi @ 10°

21.200 13.74 dBi @ 8°

24.940 14.20 dBi @ 7°

28.400 13.77 dBi @ 6°

If you wish more info on this design, or want to share some of your antenna experiences, you can always email me ON4ANT@hotmail.com

AO and YO written by K6STI.

Comparison of this design made by W4RNL with EZNEC4 shows very similar results to those obtained with AO.

The W4RNL site contains lots of valuable antenna information and really is worthwhile visiting.

My sincere thanks to L.B. Cebik for the verification of this design and the information available on his website.

YAGI DESIGN was written by ON4UN and covers all mechanical issues of antennas. It's a DOS based program,

and is extremely easy to use. I wish to thank John for his help as well. Those wishing to obtain this program can

always contact John, ON4UN

STRESS Hygain/Telex.

Back to top

A 5 element yagi for 10 meters

(Wide band design)

Here is a very simple 5 element covering the entire 10 meter band (28.000-29.700) with a swr of less than 1.4 at the band edges. The elements are non tapered! Element diameter is 11 mm.

	Position (mm)	Half element (mm)
Reflector	0	2670
Driven	1014	2530
Director 1	1816	2400
Director 2	3775	2370
Director 3	6250	2250

Here is the overview of freespace gain compared to an isotropic source. SWR reference is 28.500 MHz.

Freq.	Gain(dBi)	F/B	Impedance	SWR
28.000	9.3	16.8	31.3-j9.0	1.35
28.500	9.5	21.1	37.4-j0.5	1.00

29.000	9.8	21.5	38.7+j7.8	1.25
29.700	9.8	23.0	28.6+j3.3	1.35

Seen the high impedance, several matching methods are possible.

What happens if we use 20mm elements?

Freq.	Gain(dBi)	F/B	Impedance	SWR
28.000	9.5	17.9	31.3-j6.1	1.26
28.500	9.8	22.3	34.1+j0.7	1.00
29.000	10.0	22.5	36.4+j9.2	1.28
29.700	9.5	25.3	10.2+j9.1	3.56

Bandwidth has been reduced!! So probably you will need to re-dimension the yagi.

Lets consider a boom-element plate of 100x200mm. On the version with the 20mm element..

We start of with a saddle height of 10mm, element is mounted 10mm above the plate with U bolts).

The equivalent element diameter for the part above the plate (a length of 100mm that is) has an

equivalent element diameter of 46.4 mm. So when modelling the yagi with the plate, one has to consider

The element as being tapered, a 100mm long 46mm element in the middle and the rest a

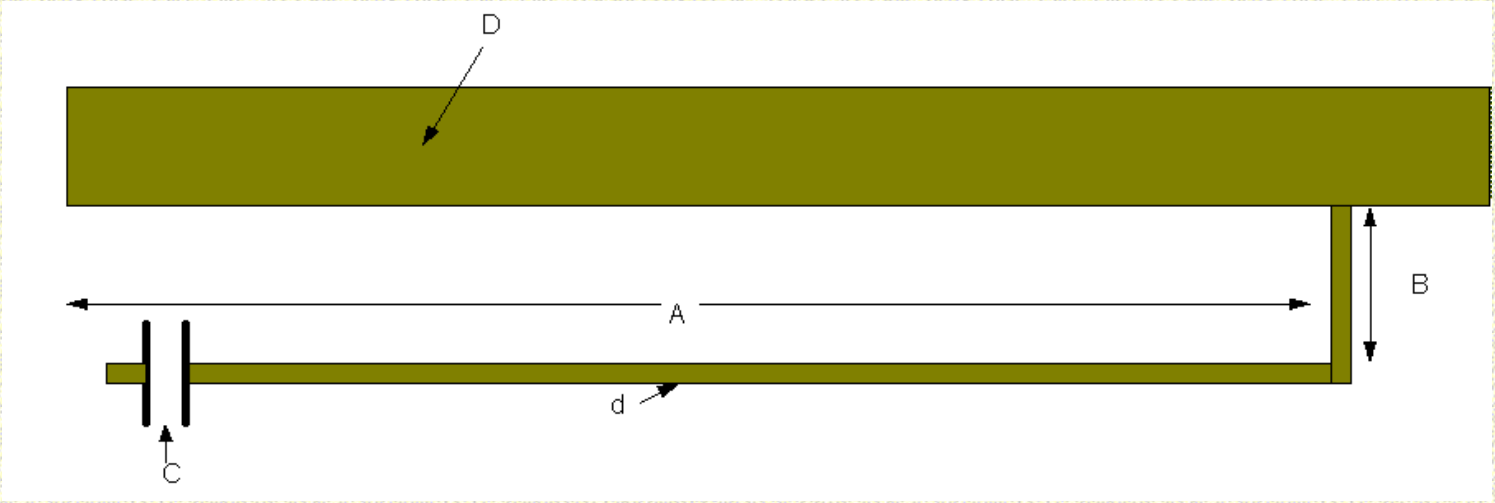
20mm element.

The boom diameter itself has no more influence on the equivalent element diameter. (if insulated)

Now we are going to verify the influence of the saddle height on the equivalent element diameter!

Saddle height	Equivalent element diameter
5mm	42.4mm
7mm	44.0mm
9mm	45.6mm
10mm	46.4mm

Gamma matching.



d = 4 mm

D = 20 mm

A = 420mm

C = 100 pf

B = 100 mm

Hairpin matching.

If a hairpin is used the driven element needs to be shortened by 10.5 cm !

A = 50 mm

B = 360 mm

D = 4 mm diameter

Back to top

A 5 element yagi for 10 meters

On a 6m boom. (standard length)

This economical design uses a standard 6 meter long square boom (50x50x1.5mm).

The boom-element plate is a 5mm thick 200x100mm plated bolted to the boom.

The elements are bolted to this plate. (no saddles)

Matching is achived with a hairpin, so the driven element is insolated from the plate.

A rubber water tube with an inner diameter of 20mm will do fine, and use 2 u bolts to fix this element. The element diameter is 20x1mm

	Position (mm)	Half element lenghts (mm)
Reflector	0000	2670
Driven	1000	2459*
Director 1	1750	2420
Director 2	3460	2380
Director 3	5950	2190

* the element is shortened to accomodate the hairpin (was 2530mm before)

	28.000	28.500	29.000	29.400
Gain	9.31	9.5	9.6	9.5
F/B	20.4	22.7	22.7	22.9
Imp.	26.9-j7.9	31.2+j1.0	36.5+j6.0	22.8-j0.8
SWR	1.34	1.07	1.3	1.3

A = 50 mm

B = 271 mm

D = 4 mm diameter

Back to top

A 9 element yagi on a 15m boom

(a 50 MHz yagi with 15.0 dBi gain)

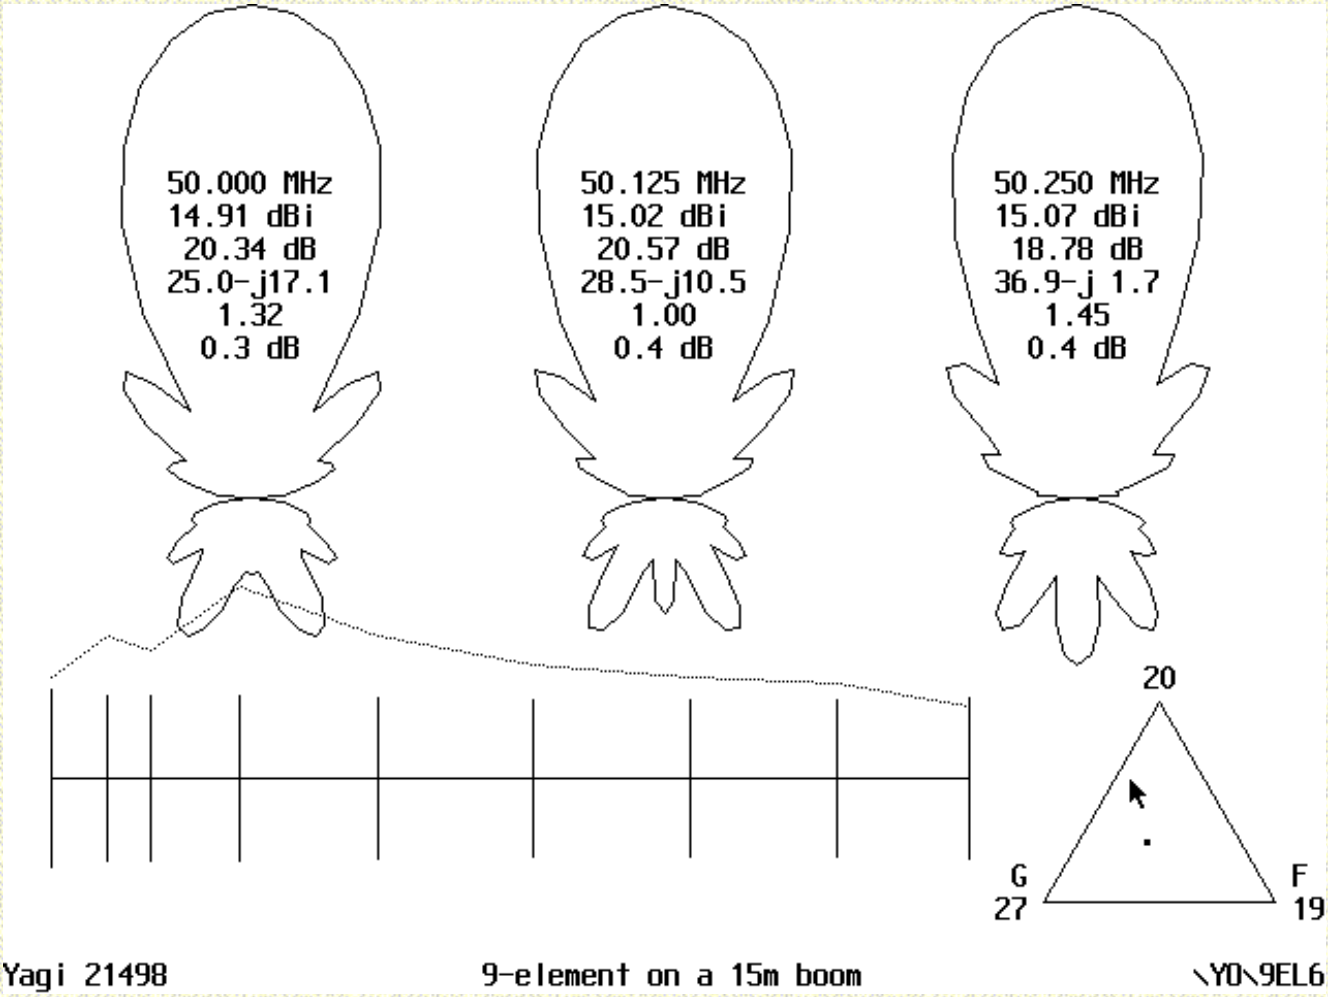
Having lots of space for antenna I started out with a design for a long yagi, 9 elements on a 15 meter boom.

I did not choose to go for a folded dipole, but rather stick to a minimum value for the feed impedance.

Table : Element length versus position. Element diameter is 12 mm.

Position (mm)	Length (mm)
0.0000	144.9851
91.5139	135.0005
163.0316	135.4751
163.0316	133.1443
531.7224	130.1802
780.1813	128.3098
1037.0823	127.7031
1273.9320	128.1430
1489.3116	130.1693

Table : Gain, F/B, SWR and impedance versus frequency.



A total gain of 15.0 dBi, this out performs the DL6WU designs by a few tenths of a dB.

It outperforms the commercial M2 design as well with 0.15dB.

(6M9KHW !, the older 9 element, a 2 WL, is 1 dB down)

The impedance remains reasonable and allows for different feed methods.

Back to top

A 9 element yagi on a 12m boom

(a 50 MHz yagi with 14.1 dBi gain)

If one wants a very simple feed like a folded dipole with a 4:1 coaxial balun, you can opt for for this design.

Lower gain (14.1dBi) but excellent match.

Table : Element position versus element length

Position(mm)	Half element length
0	**1450**
1400	**1420**
1966	**1368**
3170	**1350**
4700	**1320**
6450	**1320**
8510	**1318**
10640	**1298**
12840	**1298**

This very 'easy' design has a free space gain of 14.1 dBi. The element diameter is 12mm.

The values given in the table do not take into account the influence of the boom.

There are some formulas to calculate the influence of the boom on isolated elements going through it.

Have a look at http://www.dubus.org for valuable info on antenna designs for 6-2-70-

23.

Table : Gain, F/B, SWR and impedance versus frequency.

	50.000	50.150	50.300	50.450
Gain (dBi)	14.04	14.10	14.12	14.08
F/B (dB)	20.32	20.84	20.09	17.01
Impedance	43.6-j2.2	49.3+j0.5	57.9-j0.8	65.9-j11
SWR	1.16	1.01	1.16	1.28

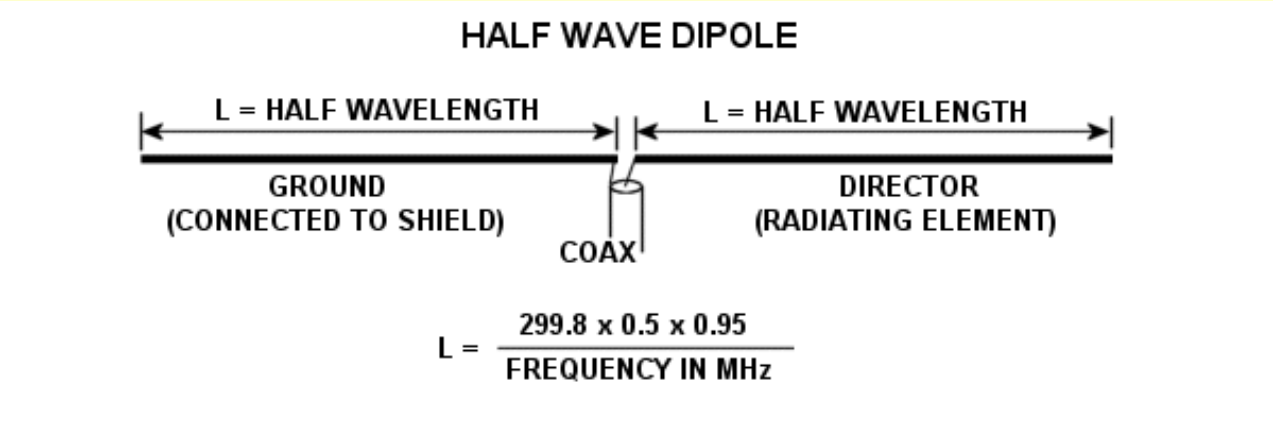
SIMPLE MADE DIPOLE FOR 6 METERS REVIEW BY JIM BAUDO



From: "Rune Austefjord" <rune.austefjord@hjemme.no>

To: "JIM BAUDO" <n0uqz@yahoo.com>

Subject: Re: Homemade 6m dipole

Date: Fri, 24 Jan 2003 17:40:22 +0100

My Quck Review Of My 6 Meter Dipole :

Made a simple dipole from 1.25mm diameter copper speaker wire.
Each of the two elements are (299.8x0.5x0.95)/frequency=142.5cm (for 51MHz).
These elements were soldered to the center and ground of a BNC female connector in this instance.
There were no baluns in use.
SWR was measured to approx. 1.1:1 max in the band 50MHz to 52MHz.
The antenna was hanged vertically in free air at least 2 feet away from any horizontal obstacles, and 4 feet above ground.
Transmitter power was varied from as low as 5W to as much as 100W, with little variation in the SWR.
Because there is little to none 6m activity in my area I didn't have the opportunity to test against other stations.
Overall impression of the antenna is good, easy to make, easy to make play, mobile as it could be coiled up and put in a pocket for transport, cheap and simple. Check out the graphic.

Hope this is what you wanted. Have made a 2m GP-antenna from an old umbrella as well.

THE 6 METER OMNI HALO

from
KB1DIG

April 28th, 2002, By Steve KB1DIG

Something a little more advanced. Always fun to try out new bands. This halo is made with a true Gamma Section this time and is fashioned from aluminum. Most of the parts are leftovers from old car projects. The 3/8" fuel line I used came from Summit Racing Equipment: #SUM-G2538, and a 25' section costs only about $20.00.

Some of the mods I came up with were:

Welded the elements to the aluminum plate with some of that "Alumalloy" stuff advertised on television. I drilled a small hole in one of the elements to allow condensation to evaporate.

Capped off the end of the gamma arm with a plug to keep the weather out.

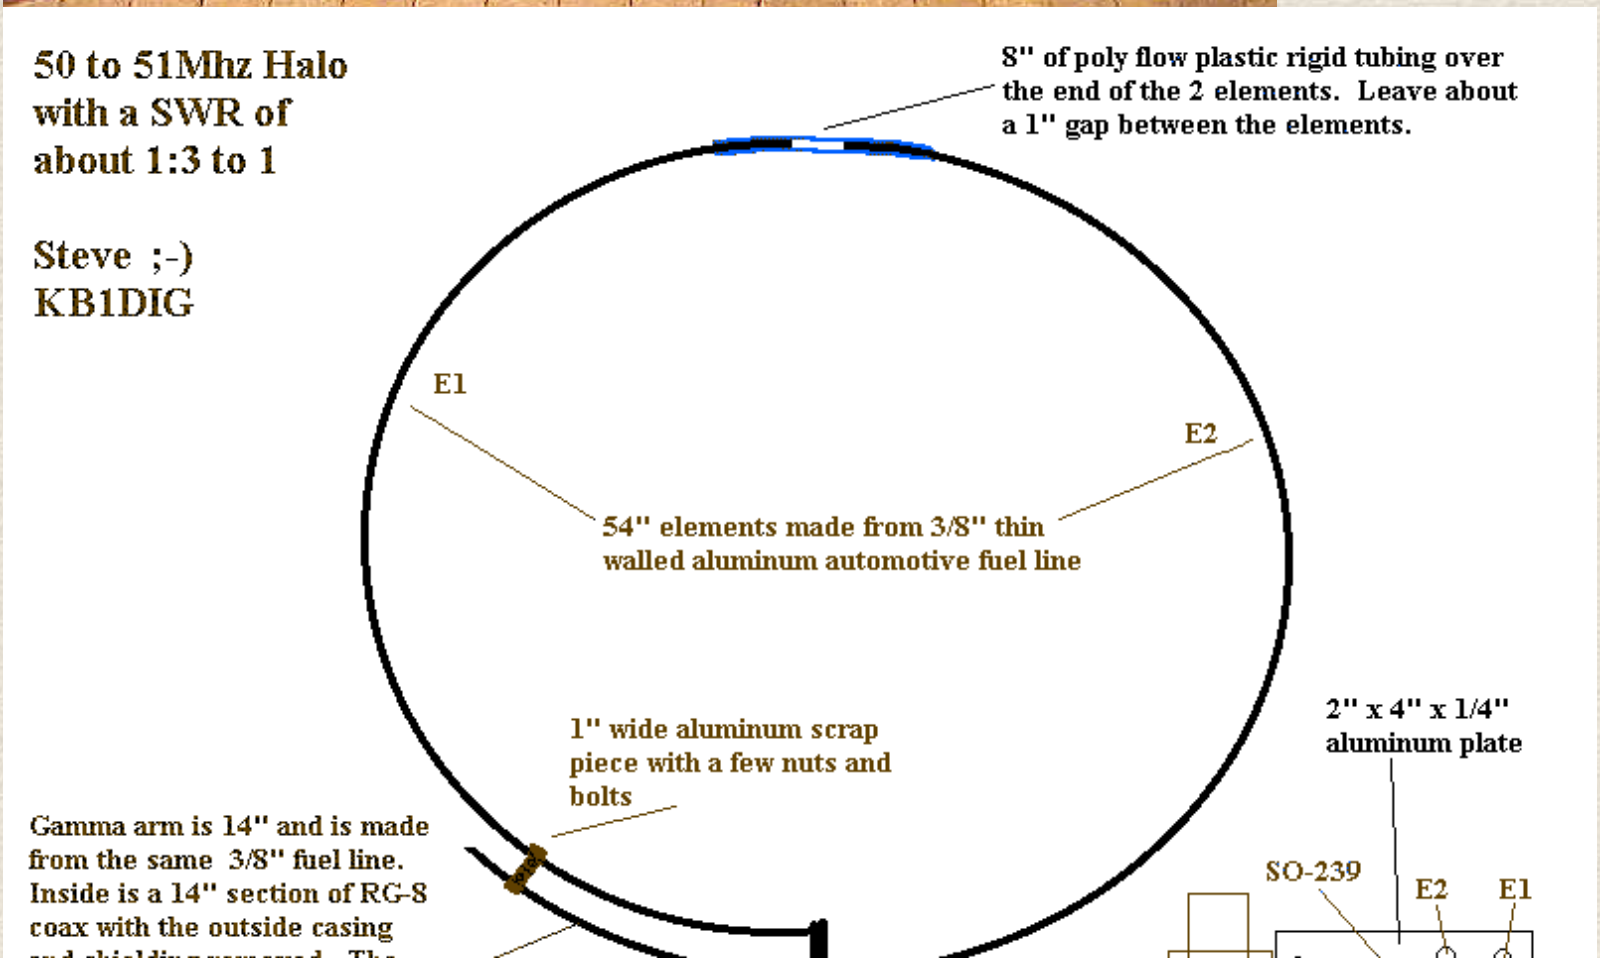
The plug was an automotive type used to block off a PCV line from a carburetor.

After mounting horizontally to a 10' mast I added a support system made from 2 thin 3' fiberglass rods and some wire-ties.

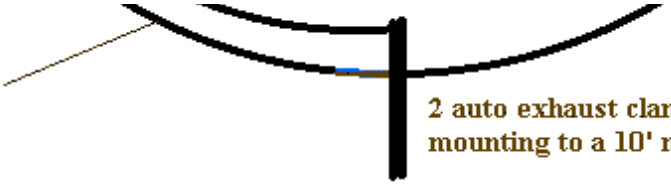
Also remember to hot-glue the wire-ties to the fiberglass rod and adjust for lowest swr as usual.

Works slick! CQ CQ DX!!!

HAM UNIVERSE



coax with the outside casing and shielding removed. The gap between the Gamma and E1 is about 1 1/2" or less.



2 auto exhaust clamps for mounting to a 10' mast

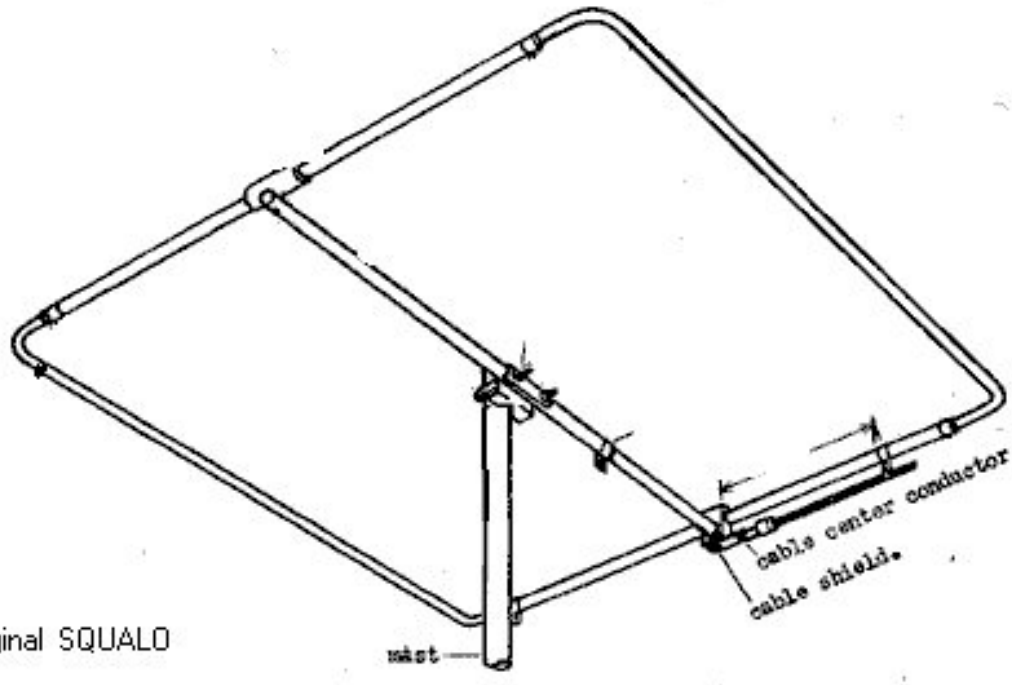
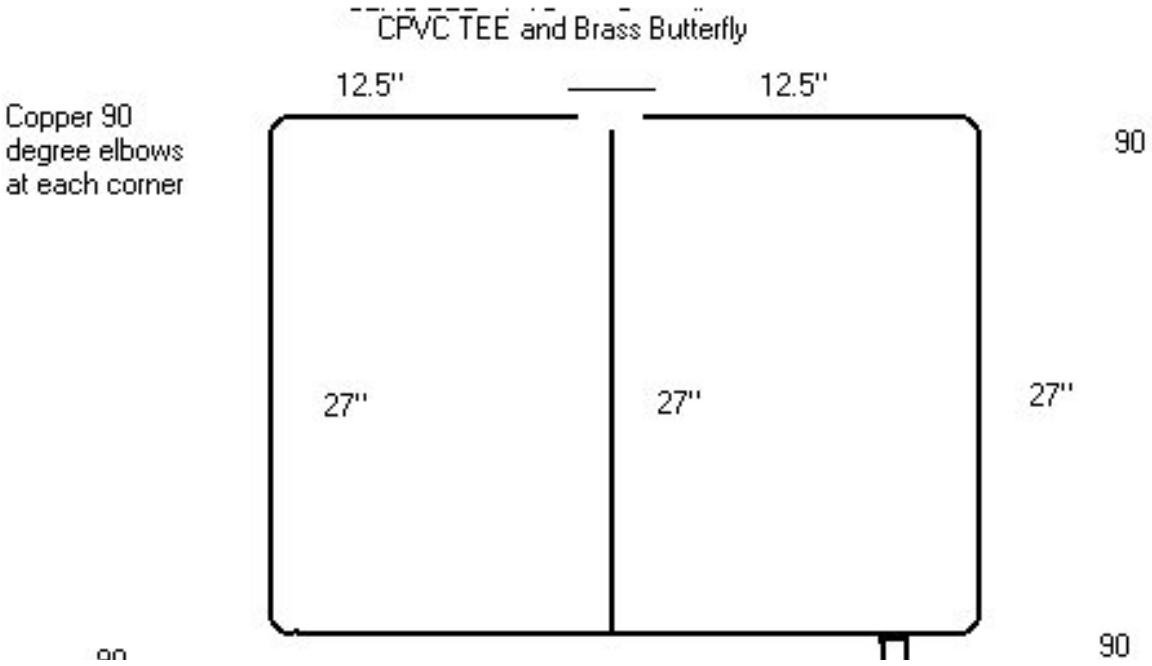
Antennas & More for HF antennas

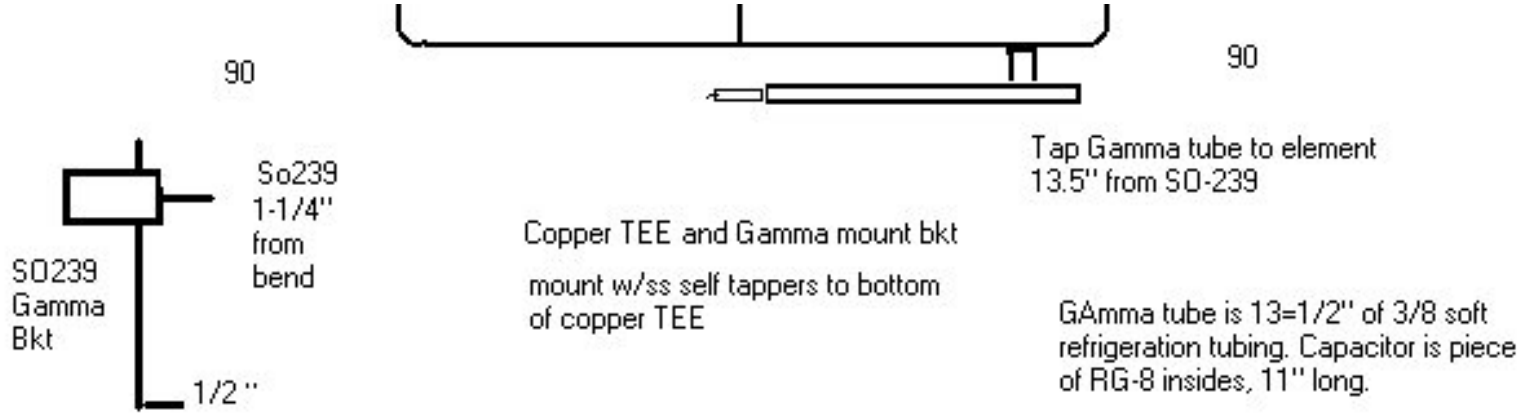
K0FF's 6 -meter SLOOP



Original SQUALO

Electrical Equivelent Circuit
of K0FF Copper Square for 6





Characteristics:

It is more or less omni-directional, and horizontally polarized. Copper is the best possible electrical conductor at normal temperatures, next to silver. Copper conducts better than gold! Antenna efficiency is the RADIATION RESISTANCE of the antenna, divided by the ELECTRICAL RESISTANCE. An antenna made from copper is 1.6 times more efficient than the same antenna made of aluminum.
It presents a high angle of takeoff when mounted low, and singly (great for Es), can handle 100W. Stack two or more for extra gain if needed.

It's just a dipole folded around on itself, and supported at the far (open) end with a plastic insulator. "Bent Dipole" might be a good term, as a "Folded Dipole" is quite antoher thing.

The Gamma Match:

A low VSWR may be obtained by adjusting the Gamma Match shorting bracket position, and also the length of the tubing and shorting bracket. The Gamma bracket "finds" the 50 Ohm point along the element, and connects that to the Coax connector via the Gamma tube. The additional length of tube adds inductance into the circuit, and this is canceled out by the series capacitance formed between the insulated Gamma wire and the inside of the Gamma tube.

Description:

The shape is a closed 28" square, with a mounting /support bar through the middle. This mounting bar is attached to a copper TEE at the drive end, and to a CPVC TEE at the other end. The CPVC TEE acts as support and end-insulator for the radiating element and provides a mounting point for the Butterfly.

A large (3/4") part is used, and adapted down to fit the water pipe, to increase its insulating qualities, as there is very high voltage at this point. A strip of brass or copper 1/2 by 3" is screwed

to the outside middle portion of the CPVC Tee, through a small center hole, and is rotated one way or the other as a resonance tuner (Butterfly). When the Butterfly is at right angles to the element, the frequency is the highest, when parallel, it's the lowest.

A Gamma match sets the impedance to 50 Ohms, and the Butterfly adjusts the center frequency. Center frequency is 50.00 to 50.800 with the exact dimensions shown. Typically the 2:1 SWR bandwidth exceeds 500 kHz.

Mounting:

A U bolt and saddle through the central tube provides a center mounting point. Another approach is to install a copper TEE in the center tube, with the open end down. In that open end solder a 1/2" brass rod which has been drilled and tapped for 3/8-24.

Side mounting on a tower can be achieved by using conduit clips to fix it to a horizontal mast.

In some climates where water is a problem, drill small weep holes in the bottom corners. A spray coat of Krylon Clear Enamel will keep the copper shiny. If used mobile, you may use a colored paint, the same shade as your vehicle.

Construction:

Material:

1/2" Copper waterpipe :

3 ea. 27 inch piece
4 ea. 12.5 inch piece
4 ea. Copper 90 Degree elbow
1 ea. Copper TEE

Other Copper or Brass :

1 ea. 13.5 inch piece 3/8 i.d. Copper refrigeration tubing (Gamma tube) *
1 ea. Brass plate 1/2" x 3" (Butterfly) *
1 ea. Brass plate: 1"x 2-1/4 in (to mount SO-239, Gamma rod) *
1 ea. Copper strip 3/8 x 4" to make Gamma tube bracket *

PVC :

1 ea. 3/4 CPVC TEE

3 ea. 3/4 to 1/2 CPVC reducer

Odds and Ends :

1 ea. 11" piece of RG8 insides (center conductor and insulation, Discard shield and outer plastic) *
1 ea. SO-239 coax connector (with tapped mounting holes and center pin) *
1 Lot Stainless Steel and Brass screws and Hardware *

Glue two of the 12.5" pipe sections into the CPVC reducers first, then glue the reducers into the opposite sides of the CPVC TEE. Lay the assembly on a flat surface with the center opening of the TEE facing the middle of the antenna. This is where the first 27" piece (mounting bar) goes in, via a reducer. On the outside edge of the CPVC TEE is where the butterfly attaches. For mobile or portable use, use 3 s.s. #6 screws through each of the CPVC TEE joints for added strength. The rest of the antenna solders together to form a square, using the 90 degree elbows at the corners. Drill small weep holes in the bottom corners of all four 90s to let accumulated water drain out.

The brass plate is bent to form an "L" 1-3/4" tall with a 1/2" lip. A 5/8" hole is provided 1-1/4 inch from the bend, and an SO-239 is attached . Two small holes are drilled in the lip and the plate is mounted to the copper TEE with s.s. #6 self taping screws. Attatch the center conductor of a 11" piece of RG8 insides to the center pin (center wire and plastic dielectric only- remove and discard shield and outer covering). This is accomplished by soldering or using a screw if the SO-239 has a threaded center pin *. Slip the other end of the RG8 insides into the 3/8"copper tube 10.5", and tap the copper tube to the radiating element 13-1/2" from the SO-239 center, with the Gamma tube bracket.

The tap on the Gamma sets the impedance presented to the feedline. Resonance (center frequency) is adjusted by turning the butterfly.

Mount 15 feet or more high, for home use, and wherever you can for mobile. An antenna like this can be mounted 3" to 6" above the roof of a vehicle using CPVC , PVC or acrylic spacers with suction cups.

Have fun on 6. Geo>K0FF

Don't Eat the Batteries" clause:

Recently my wife and I bought a new TV set, and in the instructions for the hand held remote control the warning said "Don't Eat the Batteries".

SO....

WARNING!!! **This is antenna is an electrical conductor. Contact with power lines can result in death or serious injury. Do not install this antenna, supporting mast or tower structure near any power lines, or where they could come into contact with power lines should the antenna or structure fall.**

A Long-wire Aerial for Six Metres

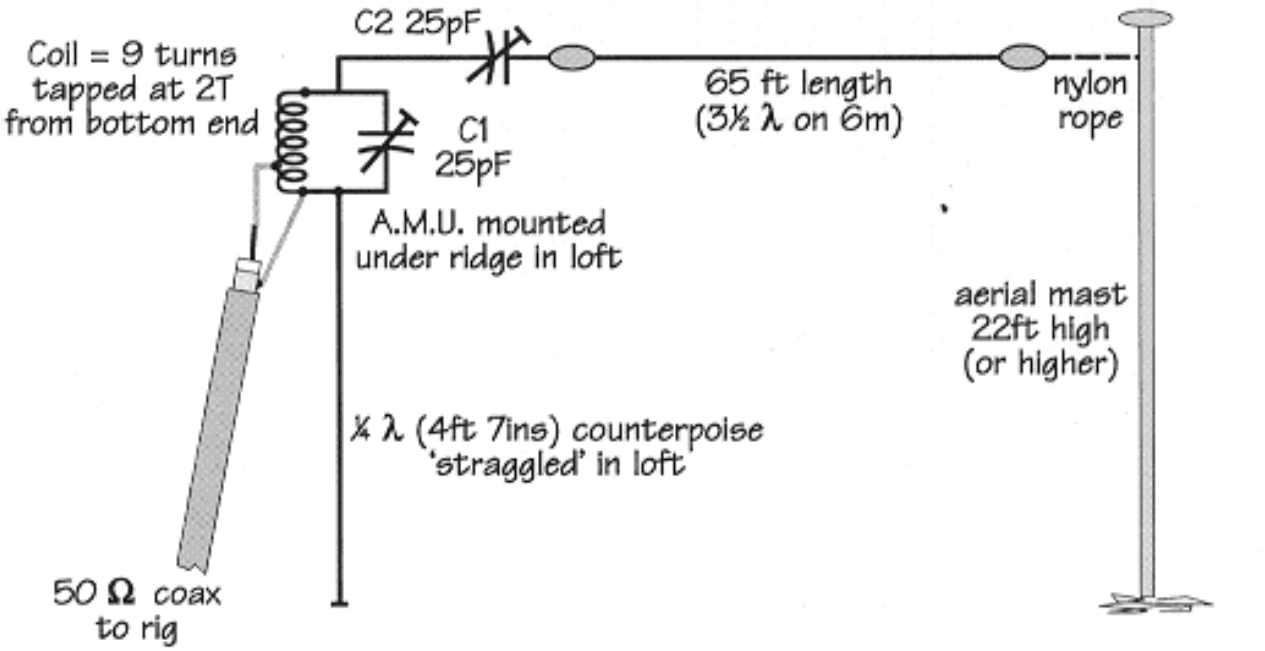
Brian D. Williams, GW0GHF

Issue, 56 February 1998

Having had the time to evaluate it, I find this aerial very useful for both semi-local and sporadic-E on six metres.

The antenna is about 65 feet of ordinary aerial wire, insulated at the far end. The near end connects to a matching unit situated in the loft of the house. The aerial wire enters the loft under a tile near the ridge of the roof of the house, through an insulating sleeve.

The



theoretical diagram.

The aerial is voltage-fed (high impedance) and the antenna matching unit (AMU) transforms this to match 50 ohm cable. The two trimmers are 'polycon' variables - these are OK up to 50 watts. For operation at higher powers, obviously more substantial trimmers, such as mica compression types, will be needed. Old radio receivers of the 1950 vintage or before are often a source of these types of trimmer. 'Cirkit' can supply them, but they are not cheap! The trimmers are likely to be the only 'expensive' parts required for this antenna, however.

The method of adjustment is to set C2 to half capacity and then adjust C1 for best noise on receive. Then feed in a carrier (or an audio tone on SSB) and adjust C1 for a low SWR reading. 1:1 is achievable at this QTH.

No problems with 'RF in the shack' have been encountered at 50 watts SSB. The counterpoise were effectively 'earths' the bottom end of the parallel-tuned circuit; it hangs from the AMU in the loft. It is 4ft 6in in length.

The AMU is constructed on a tobacco-tin lid. The coil is nine turns of 18 SWG copper wire taken from old coax cable. It is 3/8 inch in diameter, spaced over approximately ¾ inch.

Increasing C2 too much will prevent the tuned circuit from resonating at 50MHz. This, in turn, depends on the capacitance of the whole aerial wire to earth - but no problems were found and it was easy to get unity SWR. Shorting out C2 might be acceptable if a low-capacity system can be constructed, but this did not work at my QTH.

The wire gives a gain of 4 dB in four directions at 35 degrees to the run of the wire. There are also several smaller lobes which are useful. This is a good ‘listening’ antenna with gain that can be arranged in desired directions.

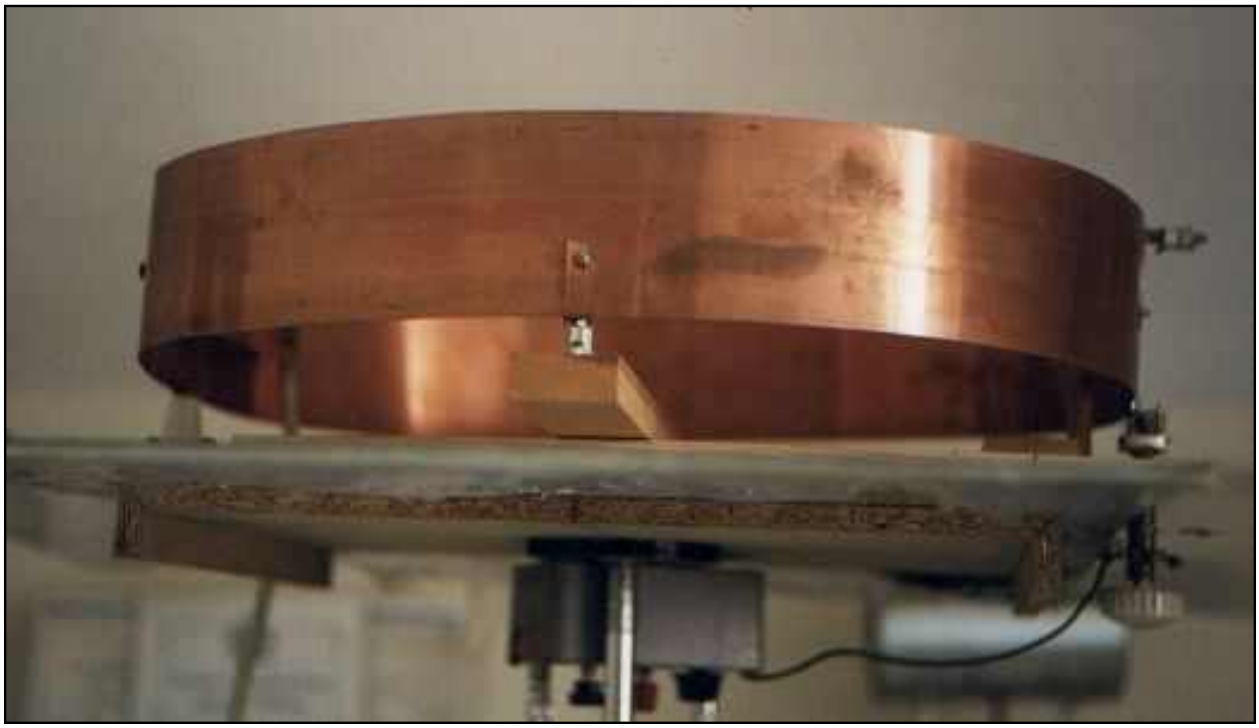
An Indoor Loop Antenna for 6m

Colen Harlow, G8BTK

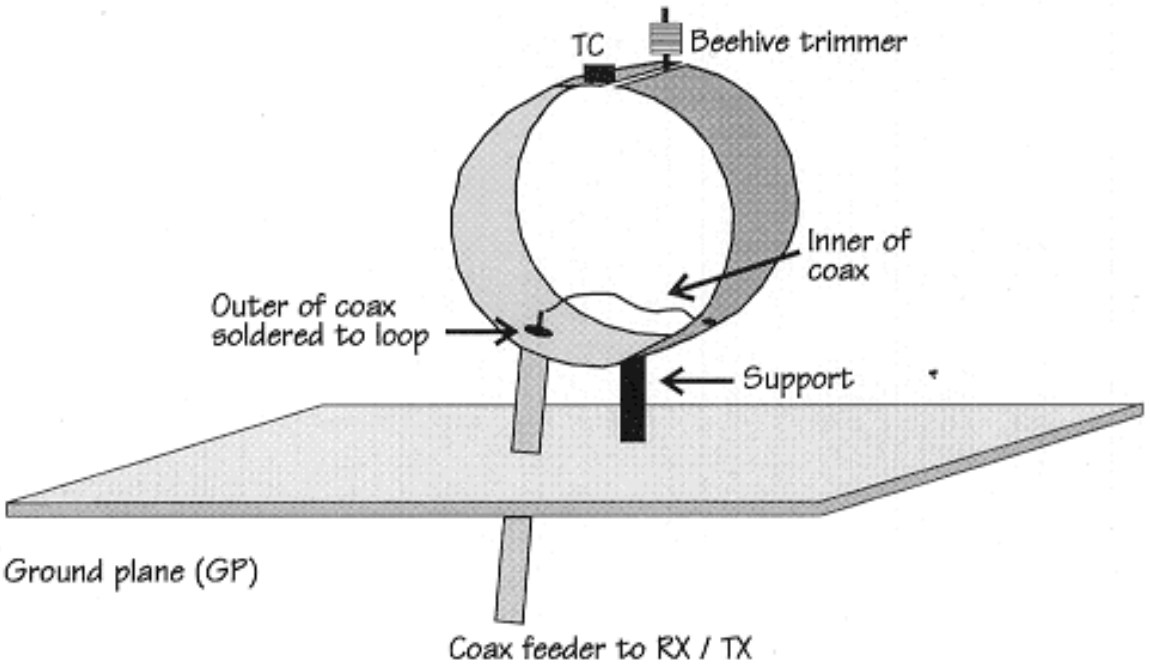
Issue, 56 February 1998



The 6m 20" high Loop.

I have worked 24 countries with my 20 inch loop. Living as I do in a flat with a complete ban on external antennas, I turned to the loop, having for many years experimented with this type of aerial in various forms. I now use them for six metres (20" diameter), four metres (10" diameter), two metres (6" diameter) and 70 centimetres (3" diameter).

G8BTK's

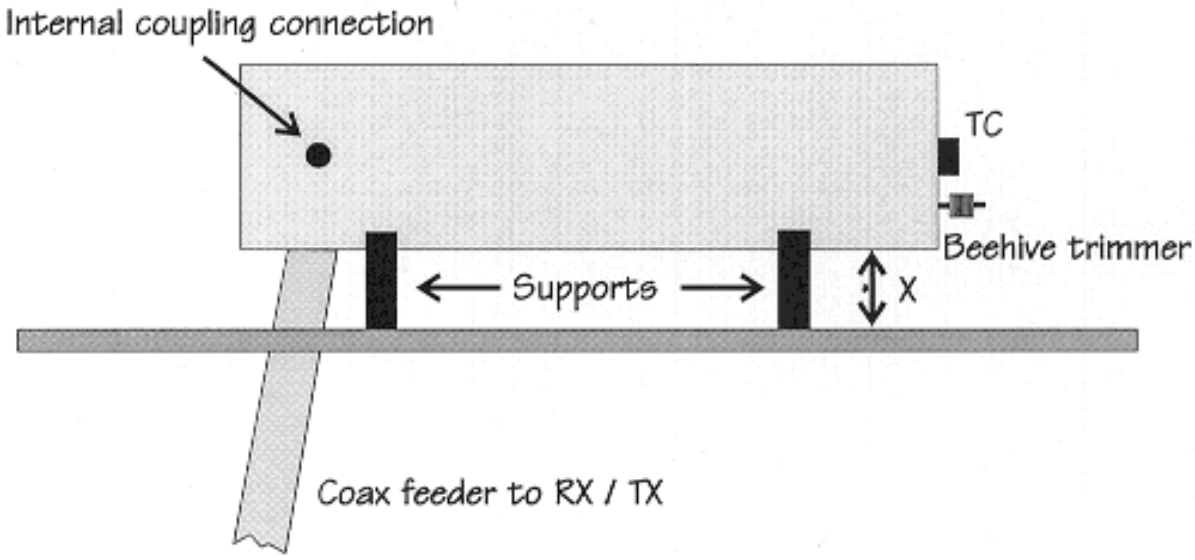


vertically polarised loop

The six metre loop (figures 2 and 3) consists of a four inch wide strip of copper formed into a ring, the ends of which are joined by a butterfly trimmer and beehive trimmer in parallel, for ease of adjustment of resonance. The loop is mounted above a ground plane of a three foot square aluminium sheet - hardboard covered with kitchen foil would do just as well. The loop is centrally positioned, about four inches from the ground plane.

The feed-point is taken at right angles from the opposite side to the capacitors. Good quality (ceramic, PTFE or similar) insulators should be used. The feeder coupling consists of a strip of copper or heavy-gauge wire as shown in the diagram.

The



horizontally polarised version of G8BTK's loop

The separation of the loop from the ground plane ('x' in the diagram of the horizontally polarised version) determines, to a great extent, the radiation angle, as does the size of the ground plane. With a three foot ground plane I have found between four and 12 inches to be the best.

6m Loop Coupling and feed

For six metres a resonated loop also works very well and the vertically polarised version exhibits a very pronounced null.

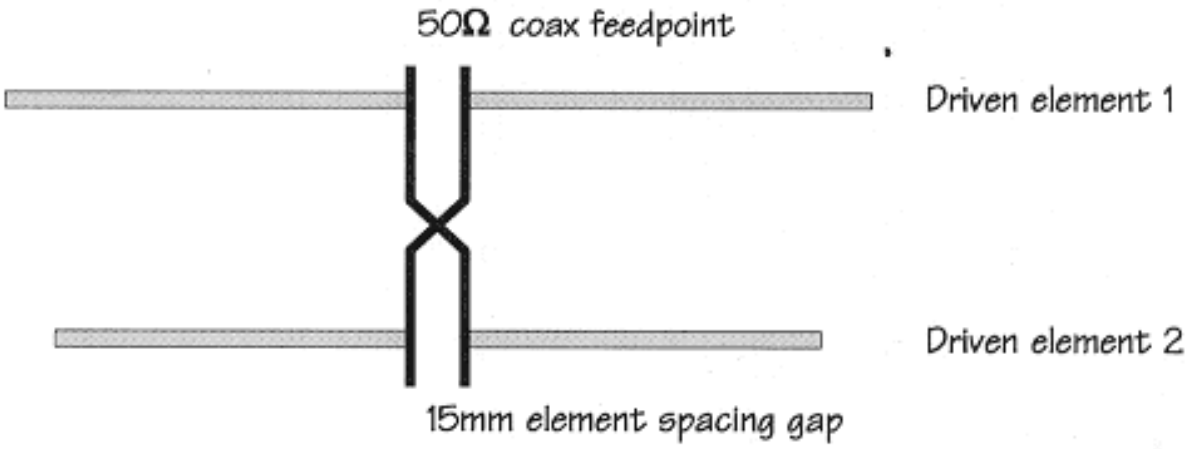
The ZR6YY Antenna for 6m

Maurius, ZR6YY

Issue, 56 February 1998

The



Driven elements of the ZR6YY antenna

Having received numerous requests to publish the design for the ZR6YY yagi I have now put the information out world wide in the hope that the design works for you.

Element Lengths	
reflector	320 cm
driven 1	296.5 cm
driven 2	274.5 cm
director 1	255 cm
director 2	254 cm
director 3	245 cm

Element Spacing	
The measurements are taken from the reflector element	
reflector	0
driven 1	78.5 cm
driven 2	120.8 cm
director 1	179.2 cm

director 2	267 cm
director 3	383 cm

Construction

All the elements are isolated from the boom. The two driven elements are fed direct and 180 degrees out of phase. Feed the antenna directly with 50 ohm coax no balun necessary. Driven element 1 and driven element 2 are made up of two pieces of aluminium each separated by a 15mm gap.

Technical note from Clive, G4FVP

The design shown has considerable experimental potential and should give a good forward gain on a short boom length of only 3.83 metres. The concept of the yagi is the two driven elements which act as an end-fire array. This should theoretically give a gain of 3dB but will in practice be less. Remember to reverse the feedline between the two driven elements to ensure they are 180 degrees out of phase.

Maurius does not specify the feeder between the two driven elements however a starting point would be to use an electrical half wave length of 300 ohm slotted ribbon feeder. To determine the electrical half wave multiply the free space length by the velocity factor of the cable in use. For 300 ohm slotted ribbon feeder this will be 150/f X 0.87. For 50.100MHz this is 2.60 metres.

Moxon Rectangles for 6 Meters

L. B. Cebik, W4RNL

I have had numerous requests over the last few years for the dimensions and construction plans for Moxon rectangles designed for the 6-meter band. The Moxon rectangle is a quite broad-band antenna, but it is not quite broad enough to cover the entire band. As well, the lower end of the band is the major arena for horizontal polarization using CW or SSB. The upper portion of the band sees most of the FM activity, with vertical polarization being standard.

Hence, for full band coverage--or for selected use of one or the other mode of activity--we really need 2 Moxons. The first will be a horizontally oriented beam designed for 50.5 MHz with coverage of the first MHz of the band. The second will be a vertically oriented version designed for 53 MHz, with coverage from 52 to 54 MHz. After looking at the characteristics of these two versions of the same basic design, we shall make a few construction suggestions. Finally, we shall show how to combine them into a single array--but with separate feedlines.

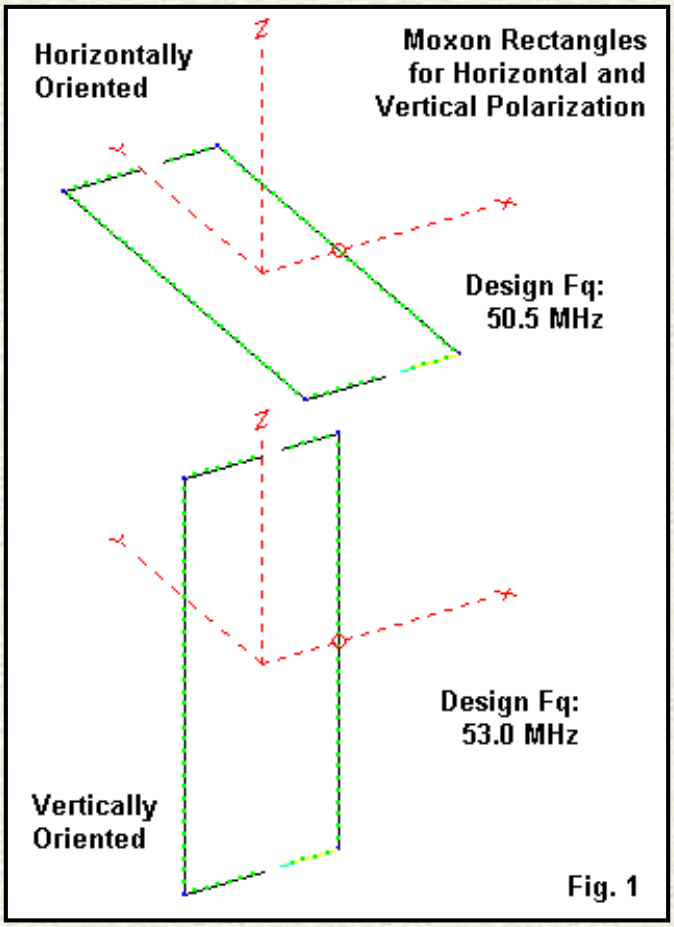

Fig. 1 shows the general outlines of the two types of Moxons. The Moxon is a driver-reflector type of parasitic array. Unlike standard Yagi designs that employ only the coupling between parallel lengths of element conductor, the Moxon folds back its elements to provide a second form of coupling. The coupling of the driver and reflector tails that face each other provides a second form of coupling, and the combination of the two gives us an array that we can design for very good front-to-back performance, about as much forward gain as a 2-element Yagi, and a 50-Ohm feedpoint impedance for direct connection of

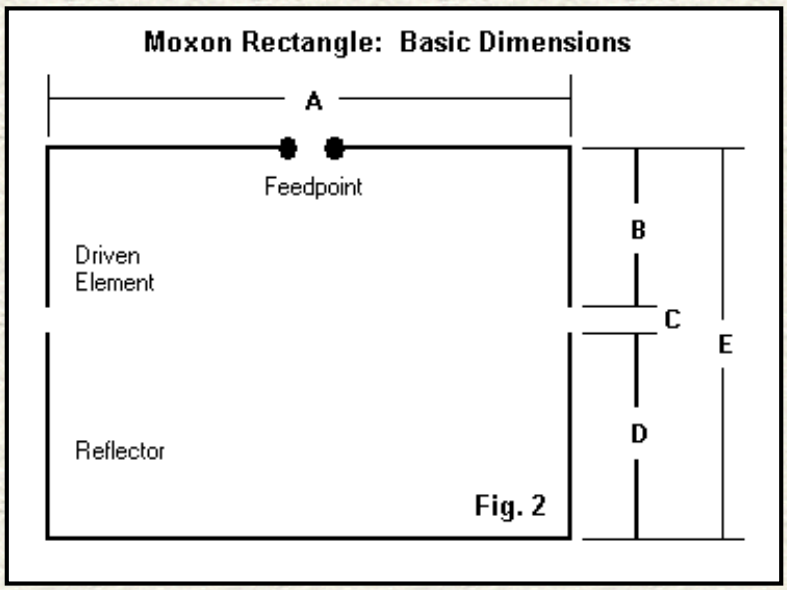
a standard coaxial cable feedline.



Since we need a way to refer to the parts of a Moxon when giving dimensions, **Fig. 2** supplies what has become a set of default designations. Dimension A is the total side-to-side dimension of the array. B is the driver tail or fold-back portion, and D is the reflector fold-forward portion or tail. C is the most critical dimension, the gap, and tends to vary as a direct function of the element diameter. E is simply the sum of B, C, and D, and gives us the total front-to-back dimension of the array.

All 6-meter Moxons will be about 7' wide or about 3.5' each side of the center line. The front-to-back dimension with be about 2.5', plus or minus a little. Hence, the Moxon makes a very compact array, suitable for enhancing repeater communications or for SSB operation in local nets.

In fact, the precise dimensions for a 50-Ohm Moxon for any frequency and element diameter have been developed into several computer programs, ranging from a GW Basic utility in the HAMCALC suite to a NEC-Win Plus model to a stand-alone Windows program developed by AC6LA and available for free download from his site (**http://www.qsl.net/ac6la**). Since all of them are based on the same modeling and regression analysis that I performed some time back, all will give the same dimensions for the same design frequency and element diameter.

Let's start our foray into 6-meter Moxons with the low-end horizontal version.

A Horizontal Moxon Rectangle for 50.5 MHz.

The materials that folks have access to will vary from region to region. Therefore, let's make a chart of dimensions. All of the dimensions will presume that we are using some form of aluminum tubing, ranging from 1.0" down to 0.25" in diameter. As we shall see in the construction section, aluminum tubing is an optimal choice for a 6-meter Moxon.

In the following table, all dimensions refer to **Fig. 2** and are in inches.

. . . . . .

Dimensions for a 50.5-MHz Moxon Rectangle

El. Dia.	A	B	C	D	E
1.0	83.61	10.40	4.58	16.22	31.20
0.875	83.68	10.53	4.46	16.21	31.20
0.75	83.76	10.69	4.32	16.19	31.20
0.625	83.86	10.86	4.16	16.18	31.20

0.5	83.97	11.07	3.97	16.15	31.19
0.375	84.12	11.32	3.74	16.12	31.19
0.25	84.31	11.65	3.44	16.08	31.18

. . . . . .

Note that the dimensions change only a small amount from one tube diameter to the next. Moreover, the front-to-back dimension (E) changes almost not at all. However, the differences are important to centering the performance curve of the Moxon on the design frequency, which then has consequences for performance at the band edges. So using the dimensions that apply to the element diameter that you will use does have significance.

Let's set the antenna 25' above ground, which is just over 1.34 wavelengths up. The forward gain will be about 11.4 dBi at 50.5 MHz, with a 180-degree front-to-back ratio of about 30 dB and a 78-degree beamwidth between -3-dB points. The feedpoint impedance of 50 Ohms, plus or minus 1 to 2 Ohms reactance.

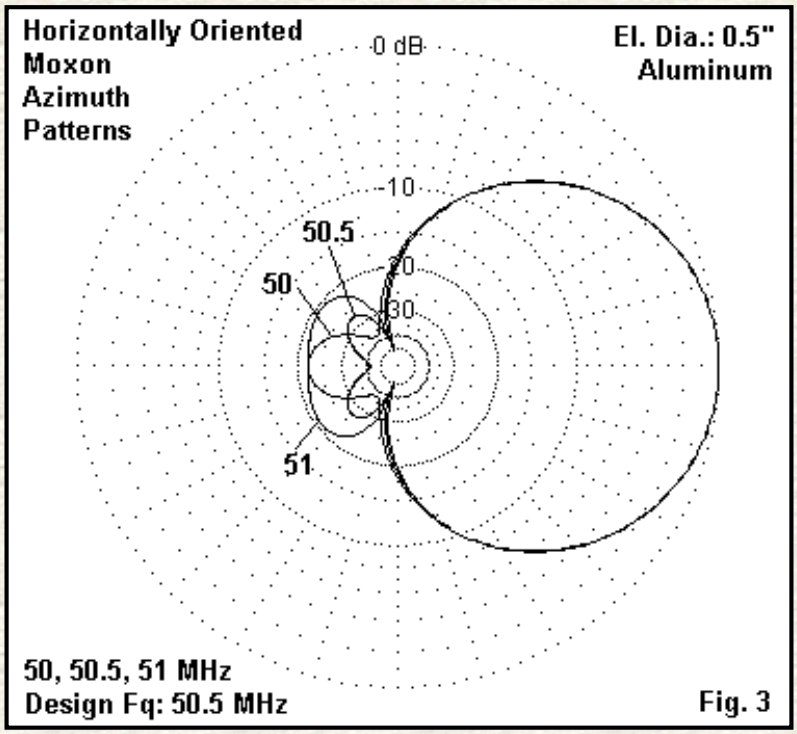


Fig. 3 overlays the design frequency and the passband edge azimuth patterns of the Moxon rectangle when oriented horizontally. As you can see from the patterns, taken for a version using a 0.5" diameter element set, as we move lower in frequency, the gain increases very slightly (too slightly to ever be measured in operation), and the rearward radiation begins to increase. Above the design frequency, the gain decreases by an equally slight amount, and, again, the rearward radiation pattern shows growth.

The performance of the antenna is virtually unchanged at the design frequency for any tubing size. However, the band-edge performance does change (in this case, using a 1-MHz passband). The fatter the tubing, the slower the rate of forward gain change. More significantly, the fatter the tubing, the slower the growth of rearward radiation lobes both above and below the design frequency. However, those changes are not so great as to override considerations such as the most convenient tubing size for constructing a Moxon rectangle.

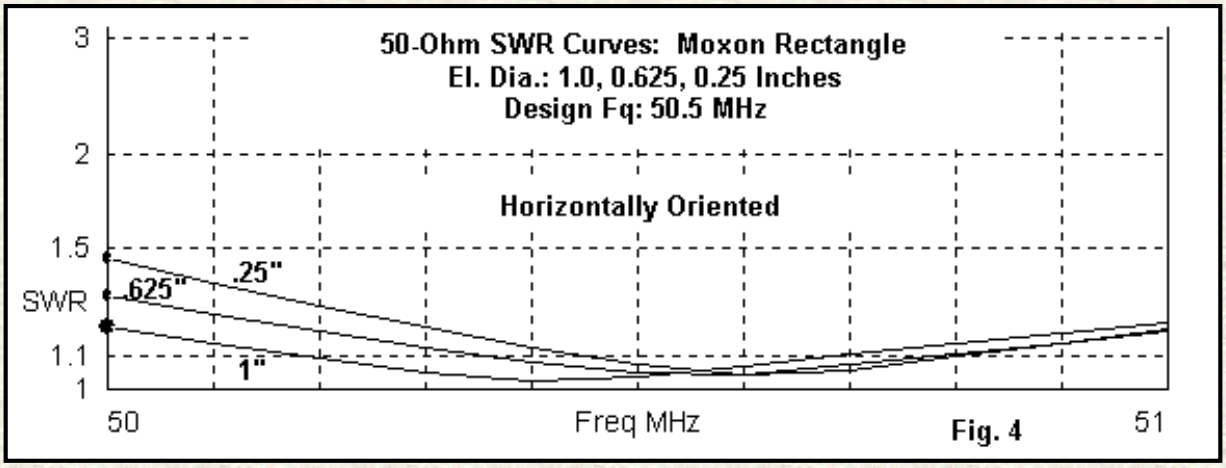

Fig. 4

Tubing size also makes a difference in the 50-Ohm SWR for the final antenna, as measured at the antenna terminals, as shown in **Fig. 4**. For a 1-MHz passband, almost any size tubing will do, and the SWR at the shack end of the coax is likely to be too low to get a definite frequency for the lowest value.

A Vertical Moxon Rectangle for 53.0 MHz.

The design principles do not change at all when we flip the Moxon rectangle for upper 6-meter service. However, the dimensions will change, since we are now using a design frequency of 53.0 MHz in order to cover the 52-54-MHz range. The following table provides dimensions, again in inches and again using **Fig. 2** as a reference.

. . . . . .

Dimensions for a 53.0-MHz Moxon Rectangle

El. Dia.	A	B	C	D	E
1.0	79.64	9.86	4.41	15.46	29.73
0.875	79.71	9.99	4.29	15.45	29.73
0.75	79.79	10.14	4.16	15.44	29.73
0.625	79.88	10.31	4.00	15.42	29.73
0.5	79.99	10.50	3.82	15.40	29.72
0.375	80.13	10.75	3.60	15.37	29.72
0.25	80.31	11.07	3.31	15.33	29.71

. . . . . .

The last decimal place in column E, the overall front-to-back dimension, may be a digit or two off the sum of B, C, and D due to rounding of the individual values. However, I doubt that any builder will be constructing the elements to a hundredth of an inch tolerances. In fact, in the construction section, we shall be slightly altering the dimensions to take account of the fact that we shall bend the tubing at the corners.

Once more, let's place a 0.5" diameter version of the antenna at a height of 25' above ground. At the design frequency, we shall obtain a 50-Ohm feedpoint impedance accompanied by a front-to-back ratio well above 30 dB. (Vertical orientation affects the front-to-back ratio less than horizontal orientation for an antenna within about 2 wavelengths of ground.) However, unlike the horizontal version of the array, the peak gain is only about 7.6 dBi. Let's see why.

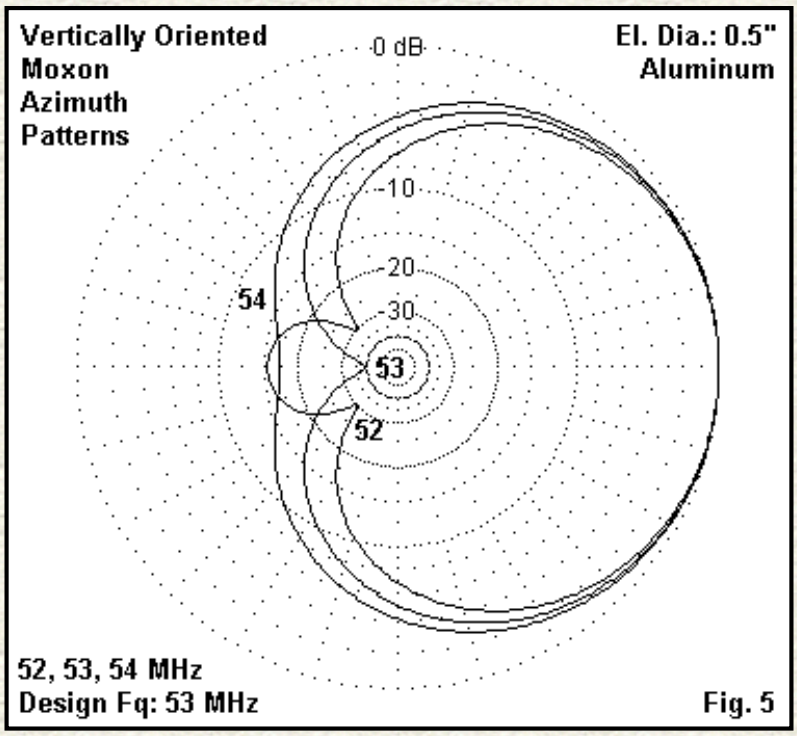

Fig. 5 overlays the azimuth patterns of the antenna at the design frequency and at 52 and 54 MHz. In all cases, we see a very wide beamwidth, over 142 degrees between -3-dB points. That increased beamwidth--about twice the value for the horizontal version--spreads the radiated power over a much wider area and thus reduces the peak gain. This is inherent in any parasitic array with all of the elements in a single plane. Nevertheless, both the horizontal and the vertical versions of the array have almost 4 dB gain over their counterpart dipoles at the same height.

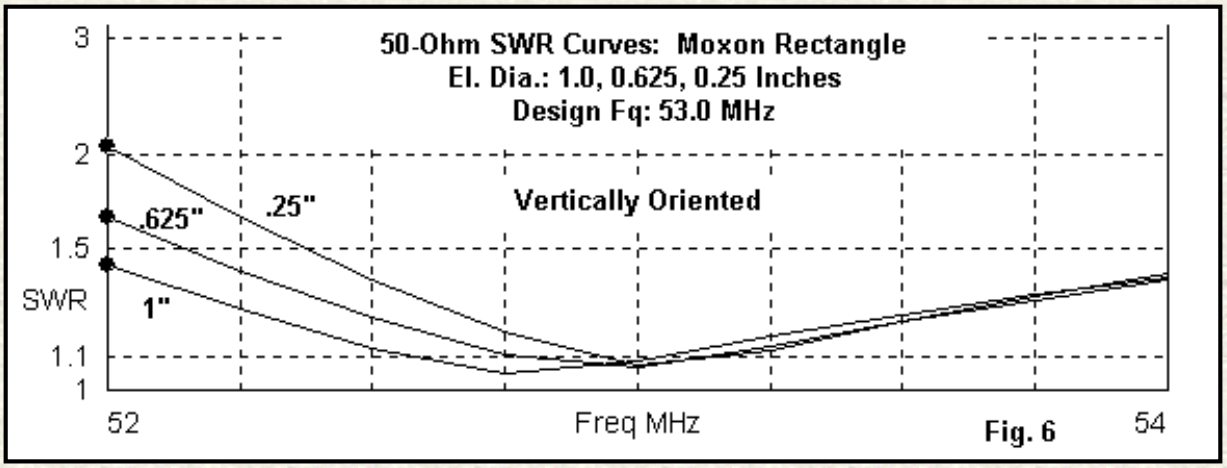
As the patterns show, the increased bandwidth that we require of a vertical Moxon increases the rearward radiation at the band edges. Once more, the fatter the elements, the less growth to the rearward radiation for any change in frequency relative to the design frequency.



In **Fig. 6**, we have the 50-Ohm SWR curves for the array at selected element diameters. The SWR increases more rapidly below the design frequency than above it. The antenna feedpoint impedance for the thinnest tubing actually is above 2:1, although at the shack end of the coax, where we usually measure SWR, it may seem lower than that value. Hence, one might well think in terms of at least an intermediate tubing size for the vertical Moxon.

The SWR climbs more slowly above the design frequency, suggesting that we might choose a lower design frequency and extend the coverage from 51 to 54 MHz. This tactic is possible, but at a cost. The forward gain and the front-to-back ratio degrade continuously as we move above the design frequency. Hence, with a design frequency of, say, 52 MHz, the array

performance would not be very good at 54 MHz.

Building a Moxon Rectangle for 6 Meters

There is an unfortunate tendency among newer antenna builders to see a design they like and then to grab almost any materials close at hand and slap together a version that almost works. Many a good antenna design has gotten a bad name in some regions because builders did not exercise the same care in construction as the original builder. To obtain performance that agrees with the design notes above, acquire the right materials and then build the antenna with all the care possible.

A good tubing size for a 6-meter Moxon--whether horizontal or vertical--is 0.5". This size is useful, since we can use #8 or #10 hardware for fastenings. Of course, the hardware will all be stainless steel, both for rust prevention and to avoid bi-metallic contact problems.

For a 6-meter Moxon rectangle, we shall need 4 6' lengths of 1/2" diameter tubing. This size tubing can be shipped from suppliers like Texas Towers by UPS. (Yes, we shall a some scrap left over for use as garden stakes.) Use 6061-T6 or 6063-T832. Hardware depot tubing has an unknown vintage, so good quality antenna tubing is highly desirable. Do not use aluminum electrical conduit or copper tubing. The conduit is too heavy, and so is the copper in any form rigid enough not to gradually fold over on its own accord.

We shall also require a short (under 6") length of 3/8" aluminum tubing and a similar length of 3/8" diameter fiberglass or similar rod. We shall be constructing the elements in halves, so we need to join and align them. The short length of 3/8" aluminum tubing will join the two halves of the reflector, making them electrically one. The fiberglass or equivalent rod will align the driver halves, but allow a gap for connecting the feedline. Finally, we shall require some 3/8" outer-diameter fairly rigid tubing, something light but straight. These tubes will fit inside the ends of the driver and reflector tails to hold the spacing constant under all conditions.

For hardware, we shall require some #8 nuts and bolts, along with some locking washers. We can use sheet metal screws to fasten the tail junction tubes in place. However, all hardware must be stainless steel, including the washers. Since some of this falls outside what home warehouse hardware bins contain, consider locating a hardware supplier or use an on-line ordering source like McMasters-Carr. From such sources, you can also obtain a small sheet of 1/4" thick UV-protected polycarbonate (trade-name Lexan) to use as boom-to-element plates. Polycarbonate cuts nicely with woodworking saws and drills cleanly with standard bits.

The needs for a single Moxon rectangle are small, so you may wish to combine orders with others interested in the antenna in order to make up the minimum order requirements for a given supplier. Since we have vowed to be careful, we need not rush to get parts, but can go slowly and get everything we need.

For a boom, you can use either metal or Schedule 40 PVC (if the PVC in your area is adequately UV protected--this varies around the U.S.). In the southeastern US, white PVC gives me about 10 years of service before becoming brittle.

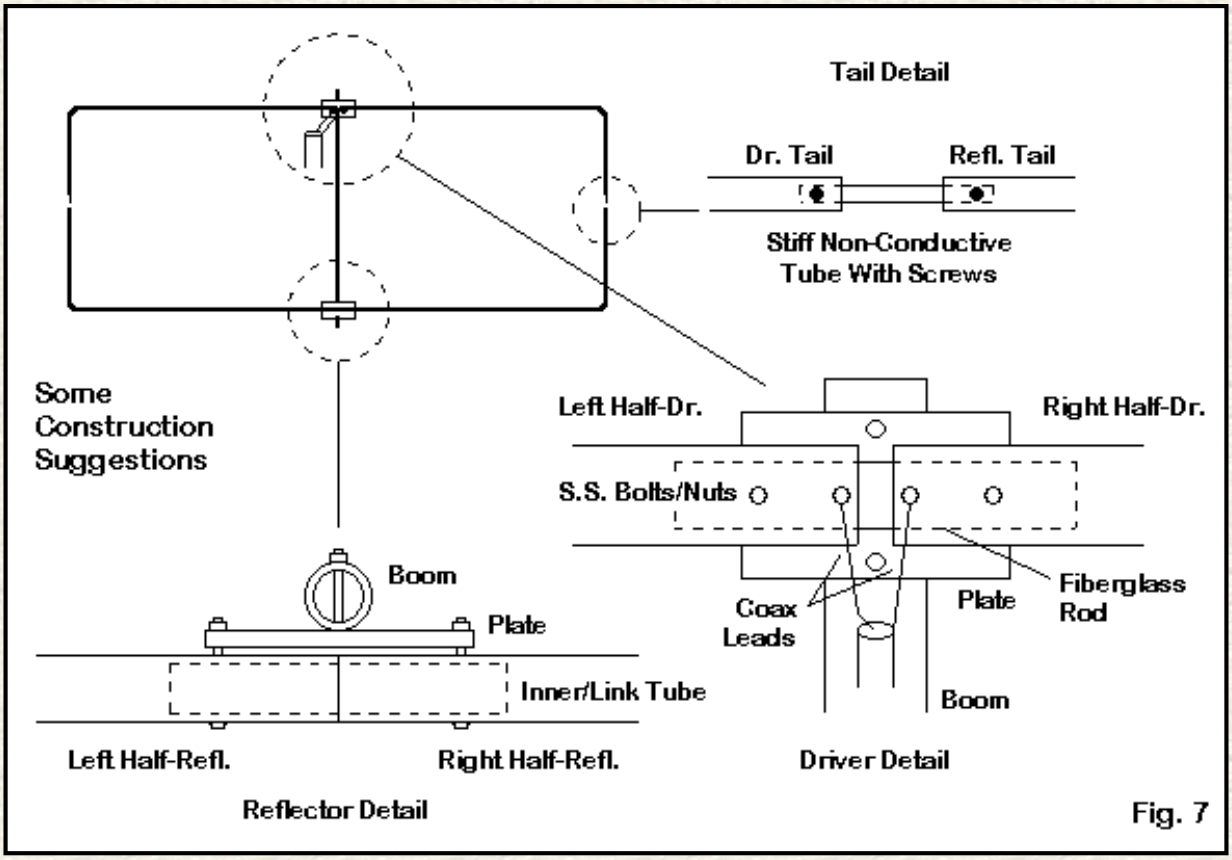


Fig. 7 shows some of the suggested construction methods that I use. you may have better ones, in which case, use them. There are 4 keys areas of construction concern.

1. *The reflector junction*: A 3/8" section of tubing a little longer than the boom-to-element plate joins the two halves. If we use polycarbonate plates about 4" long and 3" wide, we have plenty of room for the elements and the nuts/bolts for boom fastening. A 1" nominal PVC pipe is actually about an inch and a quarter in diameter and is very rigid for a boom that is less than 3' long. For the plate-to-boom bolts, #10 hardware is very secure, using only 2 bolts per plate. However, use a compression lock washer against the plate or obtain self-locking nuts (with a nylon insert).

Since a #10 bolt requires a larger hole, you may wish to fasten the elements to the plate with #8 hardware, again with compression lock washers against the plate. (Toothed lockwashers may gradually loosen by gouging the polycarbonate.) For all drilling of the boom and the elements, make up a jig from scrap wood to pin the material in place while you drill. If you can gain access to a drill press--even a small device designed to hold an electric hand drill--by all means use it. Align all holes before drilling instead of widening holes later to bring parts into alignment.

2. *The driver gap*: By using a 3/8" fiberglass rod to align the driver halves, we can fasten the driver and the rod to the plate using #8 hardware. Note that there are two sets of hardware at the driver: an outer set to pins the element to the plate and an inner set to which we shall connect the feedline. If you prefer, you can set the connection hardware at right angles to the element-to-plate hardware to keep the coax more in line with the boom.

The sketch shows direct connections between the element and the coax, with no connector. I have found that from 6 meters on upward, connectors and their associated leads contribute reactance to the feedpoint impedance. A direct connection and a short length of coax taped to the boom for strain relief simplifies feedpoint construction. Once everything is complete, seal the connections, especially since solder terminals may not be available in stainless steel. Plasti-Dip or similar materials provide a weather-secure coating.

A note on the gap: The gap at the feedpoint is part of the overall element length (or dimension A), NOT an addition to it. Whether you start with a 1/4" gap or a much wider one, let the driver side-to-side dimension remain constant. In effect, the coax leads make up the seemingly missing tubing. The driver gap is not critical from 1/4" to over 3/4", but closer is always

better in this type of antenna.

3. *The tail separation*: Because we must keep the tail ends at a specified distance and aligned, we need a short piece of non-conductive tubing to lock their relative positions. Almost anything will do here, if it is 3/8" in outside diameter and relatively rigid. We shall need only about 4-4.5 inches exposed, so even flexible nylon tubing will work, although rigid plumbing CPVC is superior. You may use sheet metal screws to fasten the tube inside the tail pieces--after careful measurement, of course.

4. *The element bends*: Bending aluminum tubing requires care to prevent crimping that will eventually result in a metal crack and break. The radius of the corner bends will depend on the tubing size used. A plumber's tubing bender is applicable only up to about 1/4" diameter tubing. Larger tubing requires larger bend radii, and that means a home-made jig.

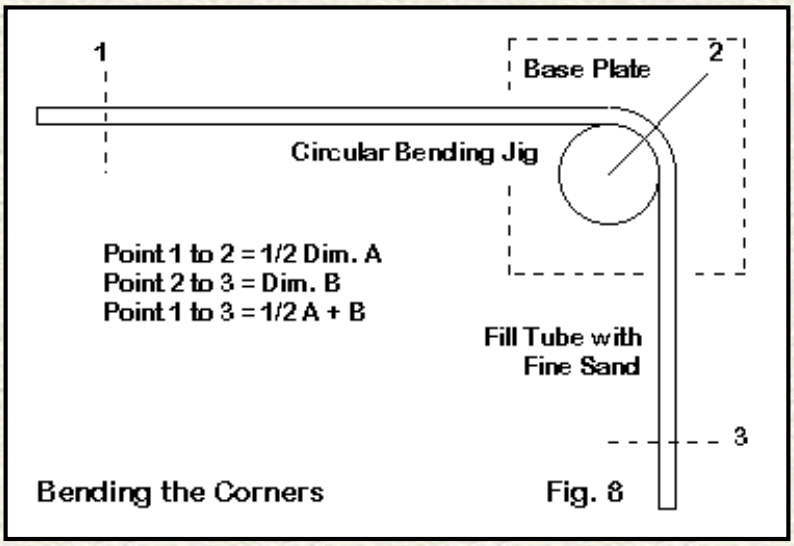

Fig. 8 shows a simple jig: a circle mounted on a base plate. The circle can be cut from plywood or be a pulley wheel. For larger radius bends, I have used such materials as a worn-out power mower wheel.

Mark a point on the 6' length of tubing that marks the center of the bent corner and leaves excess on both the tail and the parallel sections. Try to keep this mark at the center of the bend. As well, mark the tubing to indicate the parallel length (1/2 of dimension A) and the tail (B or D, as applicable). Fill the tube with the finest sand available and tape the end shut. If you prefer, warm the tube until it can just barely be handled with gloves. Pin one end of the tube (a nail in the base board will do) and slowly bend the tubing. The fatter the tubing, the more important it is to bend a few degrees and pause. Continue the bend until it is at least a 90-degree bend. A little more will not hurt, since a slight unbending of the tube does no harm.

Bend the tubing before you drill any mounting holes to make sure that all such holes are at right angles to the mounting plates. In fact, let's delay any drilling and do some work on the floor.

From the dimensions that apply to your tubing size, draw out the Moxon on the floor (or on paper taped to the floor). Be sure to mark the center or boom line as well as the points where the tails end. Next, lay the untrimmed bent pieces on the drawing. Because the corners are "clipped" by the bending, the pieces will just exceed the lines on the floor.

NOTE: For the adjustment of positions, be sure that the gap is constant and does not change!

With a constant gap distance as specified for the tubing size and measured against the marks made on the tubing, adjust the tube position to equalize the amount by which the tubes fall outside the original lines. At the same time, align the tubes. Now trim the tubes. Remember to trim a bit (1/8" or so per tube) off the driver to leave a gap for the coax connection. Smooth all cuts. Aluminum oxide sandpaper is best so that you do not leave residues of other metals on the aluminum. Clean the outer and inner edges of the tubes, since you will be inserting rods or tubes inside the main elements.

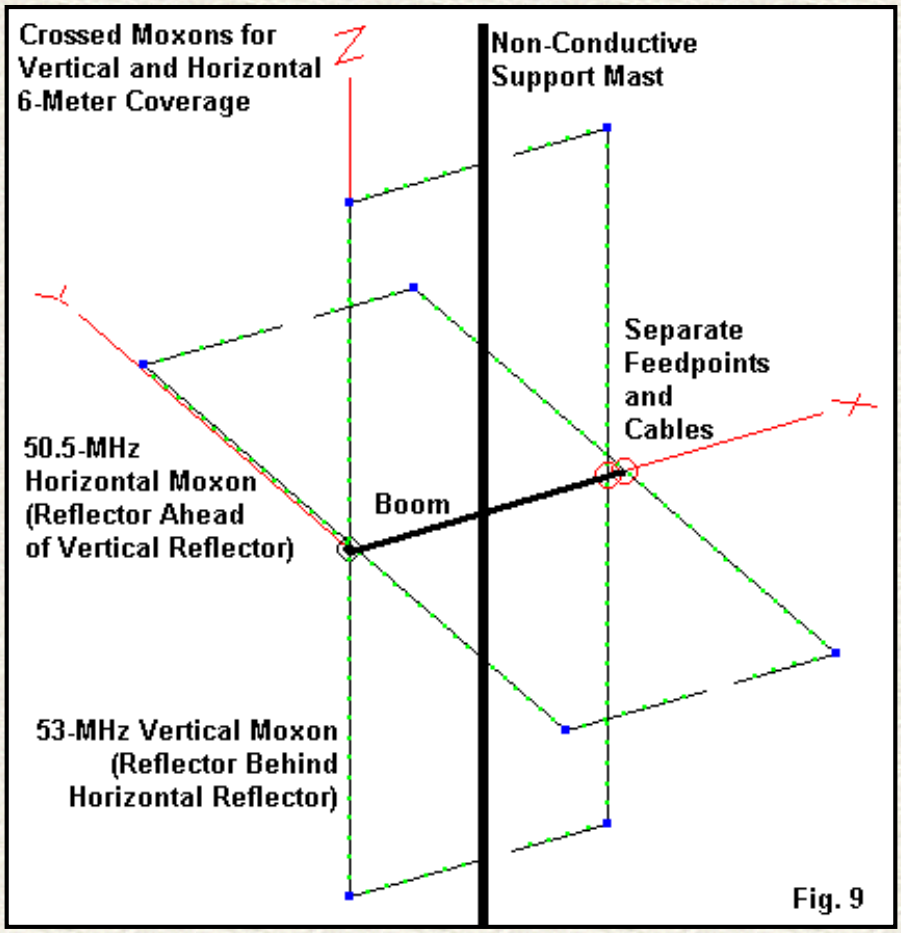
Now return to the assembly process and complete the Moxon rectangle. If you have used sufficient care, it should be right

on target on the first try. However, you can always trim a bit more from the reflector and driver tubes at their centers--and a little expansion that leaves a little inner reflector tube showing and widens the driver gap a small amount should do not harm.

I assume that you have a boom-to-mast plate and stainless steel U-bolt hardware. As well, I assume that the coax from the feedpoint has a connector and a double-female in-line connector. If those assumptions are correct, you are ready to put the Moxon rectangle into service.

Crossed Moxons

Suppose that you have both SSB and FM operations on 6 meters and that you decide that the Moxon has characteristics that are suitable for each job. Then you may wish to think about **Fig. 9**.



The outline sketches crossed Moxon rectangles. Since the low-end horizontal version is a bit larger than the vertical high-end version, let's place the horizontal reflector slightly ahead of the vertical reflector. Actually, it will make no difference if the two reflector join at the center. However, we shall need physically separate feedpoints--and separate feedlines as well. However, the assembly will fit on a single boom.

Crossing Moxons and operating them separately makes no difference at all to the performance of either one.

One precaution applies to either a single vertical Moxon or to crossed Moxons: we shall need a non-conductive boom if we attach the mast at the center of the boom. (6-meter arrays are heavy enough where I do not recommend extending the boom rearward for attachment to a mast without a further extension and counterweight.) Schedule 40 PVC has two sizes that nest reasonably well for stiffening the material for mast use: 1" inside 1-1/4" nominal (closer to 1.25" and 1.5" actual outside diameters). You will need about 3.5' to go from the boom to the edge of the vertical Moxon and perhaps another 2' above any metal structure (like a tower), plus a few more feet to reach a rotator. (An old TV rotator is more than sufficient to handle even the crossed Moxons). However, do not use more PVC mast than you need to do the job.

A Wire Moxon for 6 Meters?

As a final note, we should address the question of making a wire Moxon. A #12 or #14 copper wire Moxon is feasible for the horizontal version only. However, the thin wire will narrow the passband severely. If you operate within a very narrow spread of frequencies at the low end of the band, then you may consult one of the design aids and set up a wire version. It will perform well--as well a the tube version. As well, it may be easier to make sharp corners and trim to length.

However, a wire version of the vertical Moxon is likely to prove unsatisfactory for repeater hopping. It will work well for monitoring a single repeater--or a couple that are within a half-MHz of each other (allowing for the frequency split). However, for general coverage of the FM region of 6 meters, a version with fatter elements is strongly advised.

We can illustrate the opportunities and the limitatons of a wire Moxon for 6 meters with a simple example. Let's design a wire Moxon for horizontal use around the design frequency of 50.5 MHz. The dimensions will be as follows:

Dimensions for a 50.5-MHz Moxon Rectangle

El. Dia.	A	B	C	D	E
AWG #14 (0.0641")	84.86	12.53	2.61	15.95	31.09
0.25	84.31	11.65	3.44	16.08	31.18

I left the figures of the quarter-inch version for comparison. As shown in **Fig. 10**, the wire Moxon has a steeper gain curve and a sharper front-to-back curve than the tube version of the same antenna. However, for local and net operations, these figures may be very adequate.

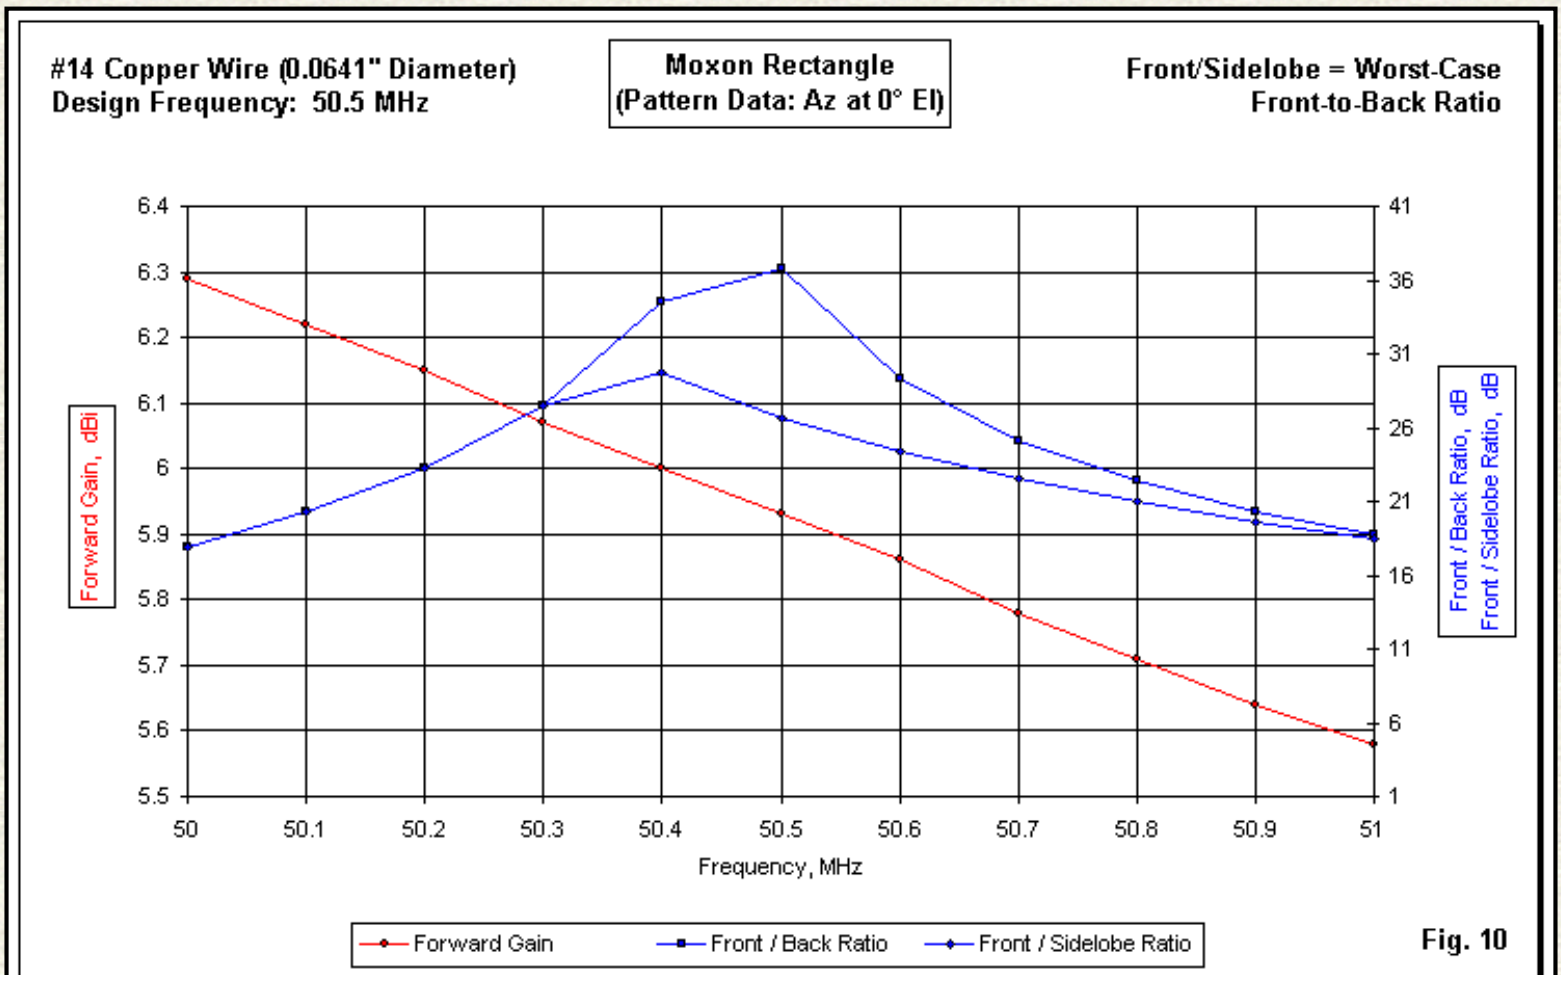


Fig. 10

Fig. 10

The SWR curve, while steepr than the ones for the tube versions of the antenna, guarantees coverage of the first MHz of the band. See **Fig. 11**. You may note in the two graphs that the front-to-back ratio peaks just below the design frequency, as does the 50-Ohm SWR curve.

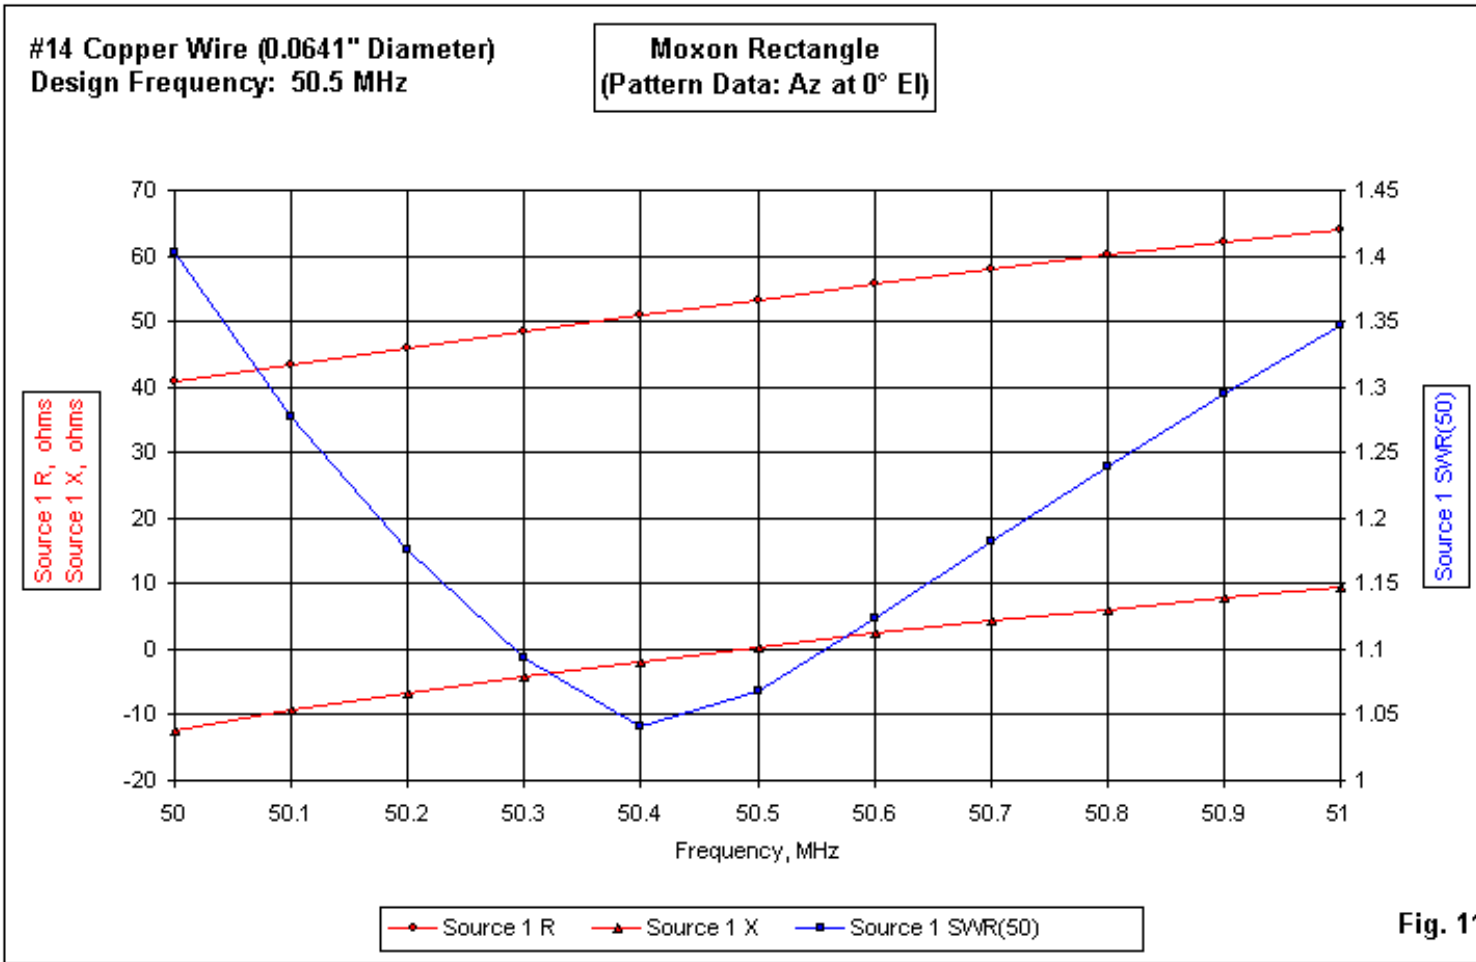

Fig. 11

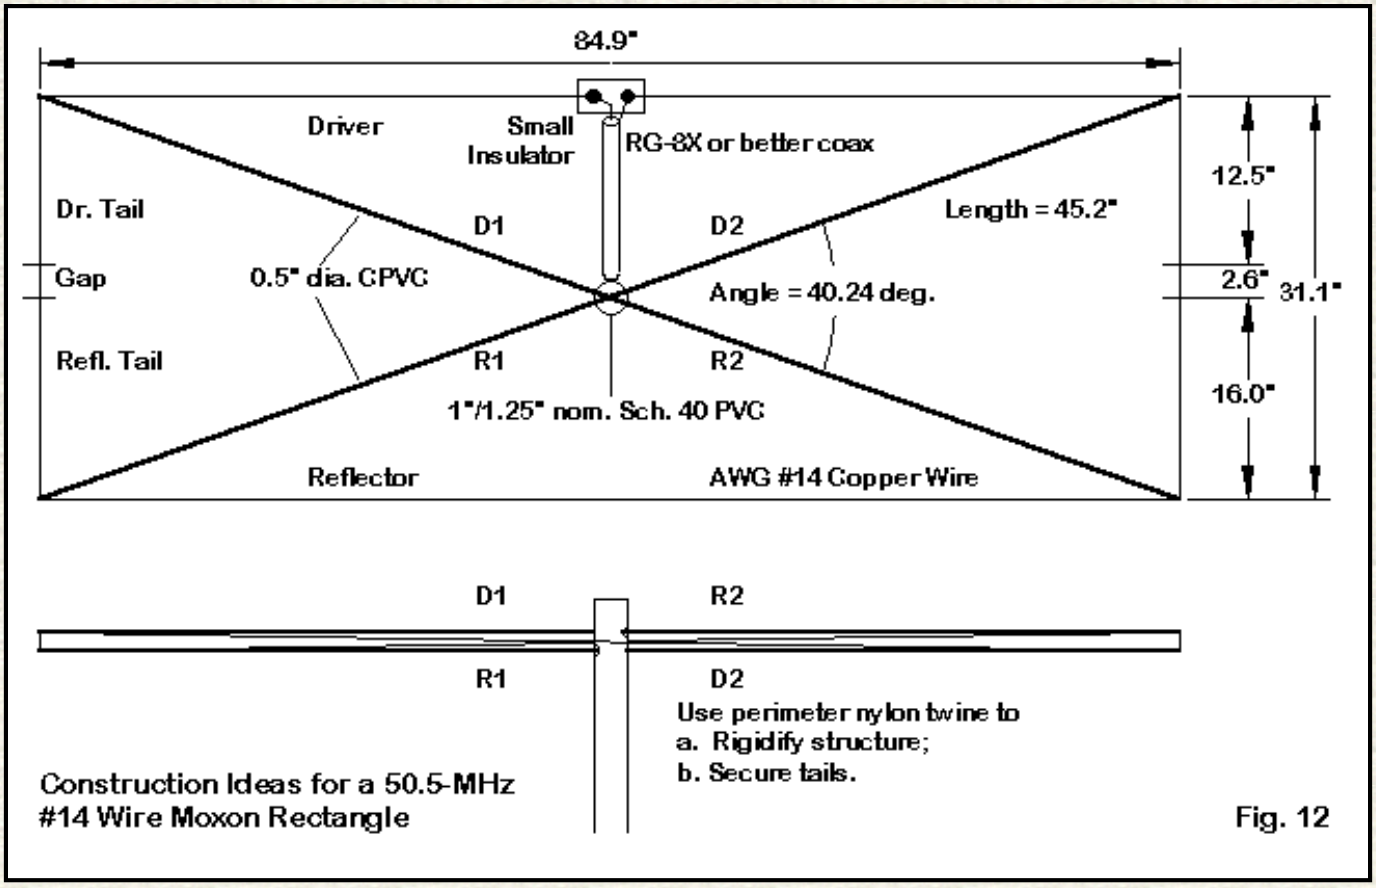
You can make the frame from 1/2" or 3/4" CPVC. By passing the frame through carefully aligned holes in a central Schedule 40 PVC mast, you can cement the structure together. Each cross arm will need to be just over 7.5' long (3.75' each side of the mast). As well, you will have to plan your angles for the holes carefully to get the correct shape between corners. However, if you are only a little off, you can stress the arms with Nylon line (1/8" to 3/16") to perfect the shape of the ultimate support structure. If you adjust the holes in the mast, then add through bolts to finalize the positions of the support arms. The details of a suggested construction for the frame, line, and wires appears in **Fig. 12**.



Even if you you get the angles between supports correct, you may still run a length of nylon or similar line from the corners along the line of the tails. Then, tape the tails to this line, and the ends (raw cut and not looped) will stay in alignment and maintain their spacing. (I tend to prefer to use a full perimeter line to pre-stress the frame so that it maintains its shape under all conditions.) The resulting wire Moxon very likely will be considerably cheaper then any of the tube versions, since we can make it from PVC and household wire, along with a little hardware at the feedpoint.

Whether the Moxon is the right antenna--and which version is the one to build--depends on your own analysis of operating needs. Do not build one unless it will do the job that you need. But if you do build one, build it carefully, and it will work correctly without further field adjustment.

A Six element antenna for the 50 MHz Amateur Radio Band / Version 4

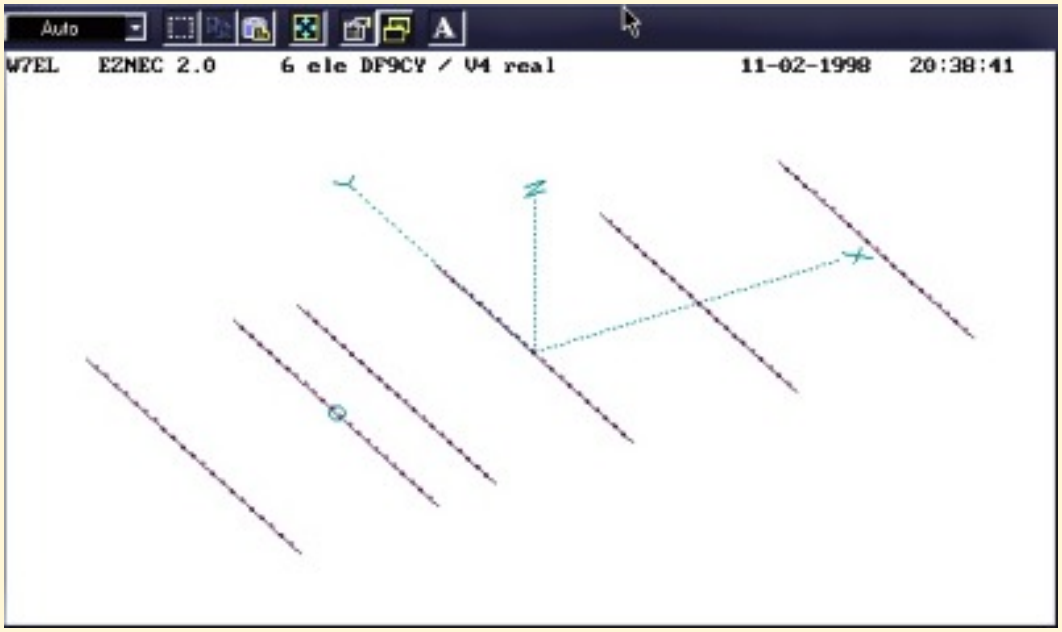
© Christoph Petermann DF9CY 1998

Last Update: 31 May 2001

A better view of the 6 element

I have mounted the 6 Element antenna about 2 meters above my 3 element antenna for 28 MHz. (The 28 MHz antenna is a well performing "EZNEC redesigned" CB radio antenna)

This plot shows the antenna "as seen" by the computer.



Here is a short description of my new SIX element antenna.
Design Frequency: 50.150 MHz

- **Usable Bandwidth: 500 kHz**
- **Return loss: better than 10 dB within 500 KHz with 22 dB @50.150 MHz.**
- **Gain: > 11.2 dBi**
- **Front/Back ratio: > 12 dB**
- **Vertical sidelobe suppression: > 12 dB**
- **Horizontal sidelobe suppression: > 19 dB**

Version List

- **Version 1:** Only a simulation version.
- **Version 2:** Has been published here. Version 2 has slightly changed element lengths and positions over Version 1. Gain has been reduced to 11.3 dBi, but it has an even better bandwidth performance. The first antenna of this type (Version 2) has been built by **Hellmuth, DF7VX.** It seems to work reasonably well. The design goal's resonance frequency has been hit exactly. Hellmuth is using this antenna since the 1998 Es season and worked a good number of DX stations with it. I have built a 2nd antenna and tried out a number of different feeds with it. This included folded 200 Ohms dipoles and Gamma matches.
- **Version 3:** This version was published here in July 1998. It has been built several times in England and America with good success.
- **Version 4:** The previous version suffered from having the resonance frequency a little low. I made some minor changes. This antenna is ready in operation here now and I am delighted with its performance in 12m above ground. It has a clean pattern with a good front/back ratio. SWR is excellent and broadband at least over the DX portion of the 6m band. It outperforms well the 4

element I have described here also.

- **N7BW Realisation**Here is a version built by John N7BW. The **6-ELEMENT** and the **FEED-POINT**, at the driven element with an open dipole. (Images)

ELEMENT #	POSITION	center-to-end element length	Diameter
	Meters	*Meters*	*Millimeters*
Reflector	0	1.450	12
Dipole	1.114	1.385	12 folded dipole
1 st Director	1.585	1.328	12
2 nd Director	2.657	1.328	12
3 rd Director	3.942	1.327	12
4 th Director	5.327	1.320	12

Driven Element

- I strongly recommend building a folded dipole. I did have VERY poor experiences with Gamma Matches in the past. They are for low impedance antennas only and they provide the necessary transformation. So they are narrow banded and if you have not the high quality material at your hand, you will sacrificy some of your gain you have made the antenna for.
- A folded dipole needs a balun: take a good cable like RG400 teflon for it. The velocity factor of this cable type is 0.82; a length of 2.45m will do the job. It is expensive, but you want the DX, don't you?
- If you do not want to build a folded dipole, make an open dipole mounted insulated from the boom. A 1:1 RG400 transformer is built within 10 minutes and -voila- you have your antenna going.
- I designed the antenna for 50 Ohm (i.e. 200 Ohms if you have a folded dipole).
- TIP: Buy the complete folded dipole from **KONNI Antennen in Esselbach**

Elements

The diameter of the elements is 12 mm AND NOTHING ELSE. The antenna will not work, if you take something else. (J'espère, que c'est O.K., Jaques ?) The elements are mounted insulated above the boom. I have about 4 mm space from the boom to the elements. I use industrial spacers mounted with a 4 mm metal (!) screw centric to the 20*20mm boom. The deviation from an element being really isolated is minimal. Indeed I bought the whole element at **KONNI Antennen**. Buy reflector elements only and cut them to the given length.

BOOM

This antenna is calculated for a 20*20mm of 2 mm strength boom which I made from material from a metal shop and some scrap from Tonna 2m Yagis ...
I replaced the support boom you see on the image by a longer one. This gives more strength. In February

1999 the antenna survived a monstrous wind storm with gales up to 165 km/h.

Interactions
If you put this antenna on top (or below) your existing antennas: be aware that you reduce the antennas' performances. Keep this antenna at least 3.0 m away from ANY shortwave antenna and about 1.5m from other VHF antennas.

Stacking
If you are intended to stack 2 antennas, space them minimum of 1/2 wavelength. At half wavelength, the existing vertical sidelobes wil DISAPPEAR with a gain around +2.1 dB. Stacking the antennas at 1 wavelength increases stacking gain to about 2.7 dB and sidelobes go up. I would like to space 2 antennas at 1/2 wavelength, but the space on the tower is limited.

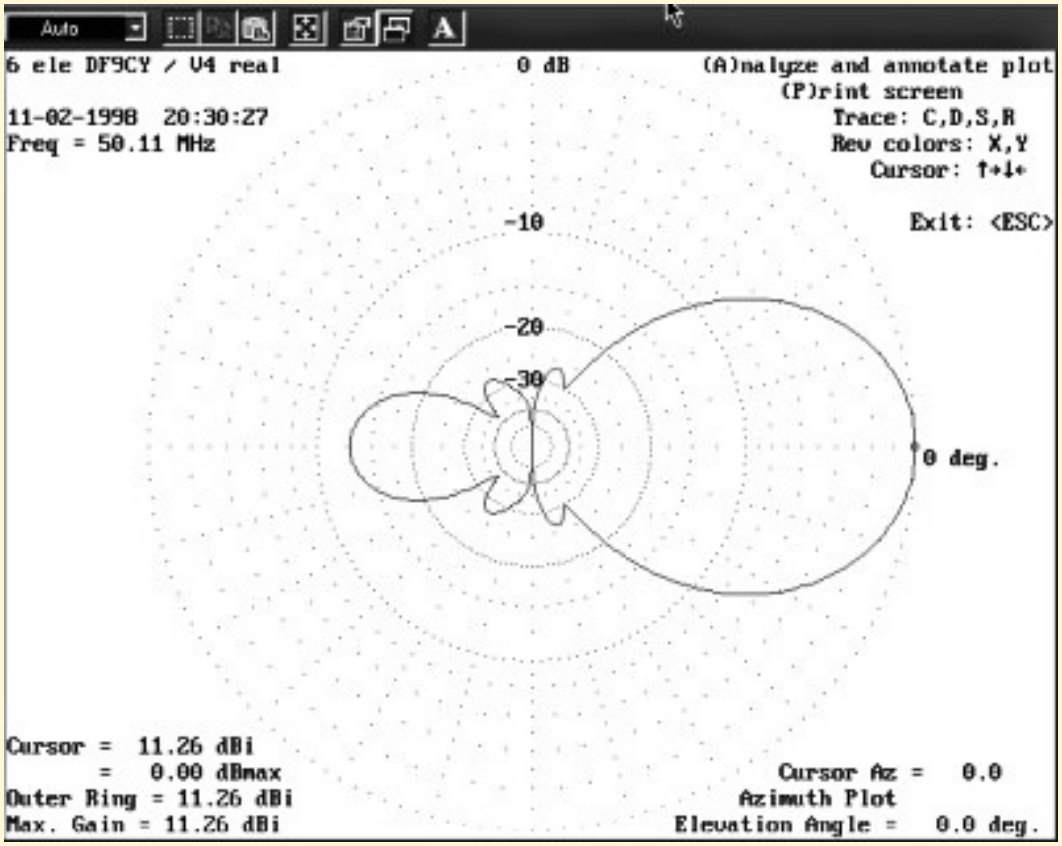
Performance
I have been reported and I can confirm myself: That antenna works. I see a clear pattern with the antenna up at 12m. There is almost no sidelobe and the F/B ratio is good. The SWR is also as expected.
It clearly outperforms the 4 element I did have up here through 1998. It is not more than 2.5 dB (or half a S-unit), but having more energy at the horizon gives you an extra advantage. The OZ7IGY beacon at 200 km line of sight is up about 2 S-units now (I am wondering myself ...) and the other beacon OZ6UHF at 300 km is also better now.
After a few months I can say, the antenna does a very good job. Tropo signals are often audiable over distances of more than 400 km.

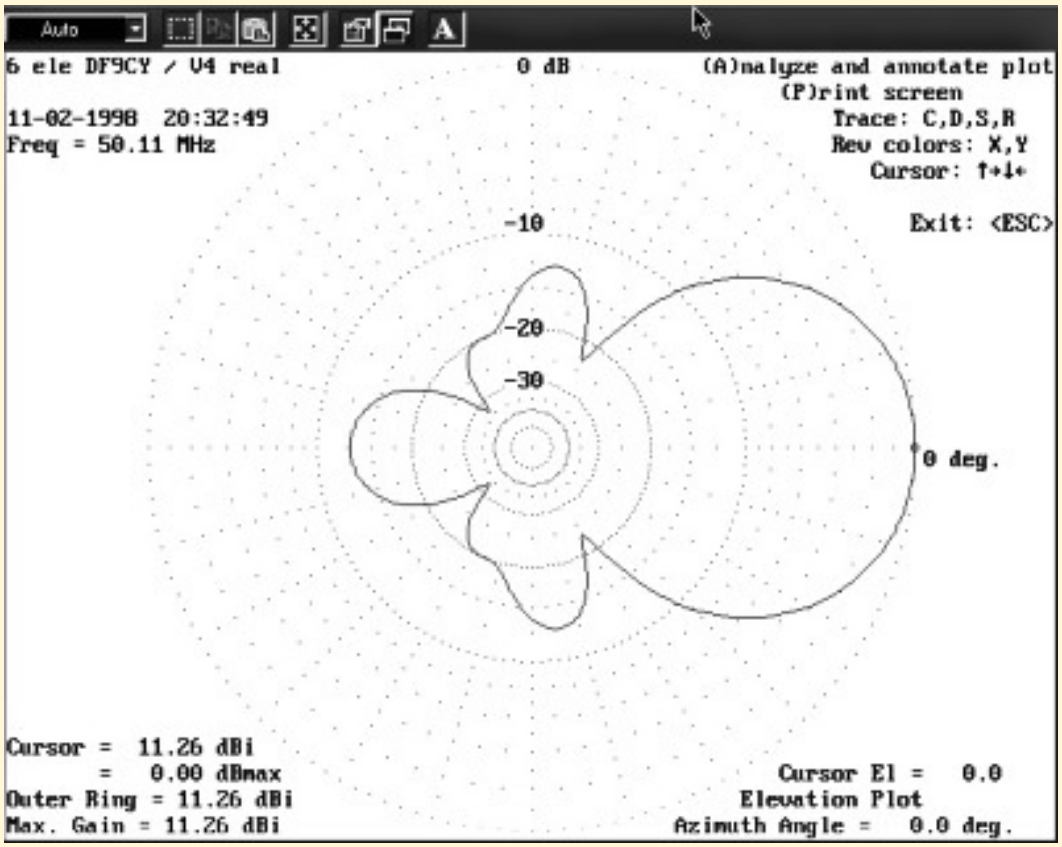
After 2-1/2 years ... (May 2001)
I am still very pleased with the performance of the antenna. It withstood all brute gale winds here in my "seaside-resort". But 30 black birds (ravens) destroyed the antenna completely already twice. Now I have an 8 mm aluminium tube in the centre of on element strengthening against the weight of these birds. DX performance is better than everything I had before. I like the clean pattern. Certainly the front/back ratio of 12 .. 15 dB could be better, but you can have this by giving up the clean pattern and some gain. I know of about at least 12 hams having built this antenna and so far all are quite pleased with it. I would like to have a stacked version of two at a spacing of 4m, but my antenna tower is somewhat weak for that. My feedline is a 22m run of AirCell cable. I get a strong enhancement in noise when I turn the antenna across the galactic centre in summer. I had a low noise GaAs-Fet amp at the antenna for a while, but this was not necessary; so it is down again. In October 2000 I moved the antenna from 10.5m to 13m above ground level. The patterns became even cleaner and I succeeded in nice F2 QSOs to Far-East and the U.S.. The nicest thing however is to work the DX with a flawlessly well-performing homemade antenna.

EZNEC
I provide you with the EZNEC simulation. So download the EZNEC-FILE: **50-6cy4r.zip**

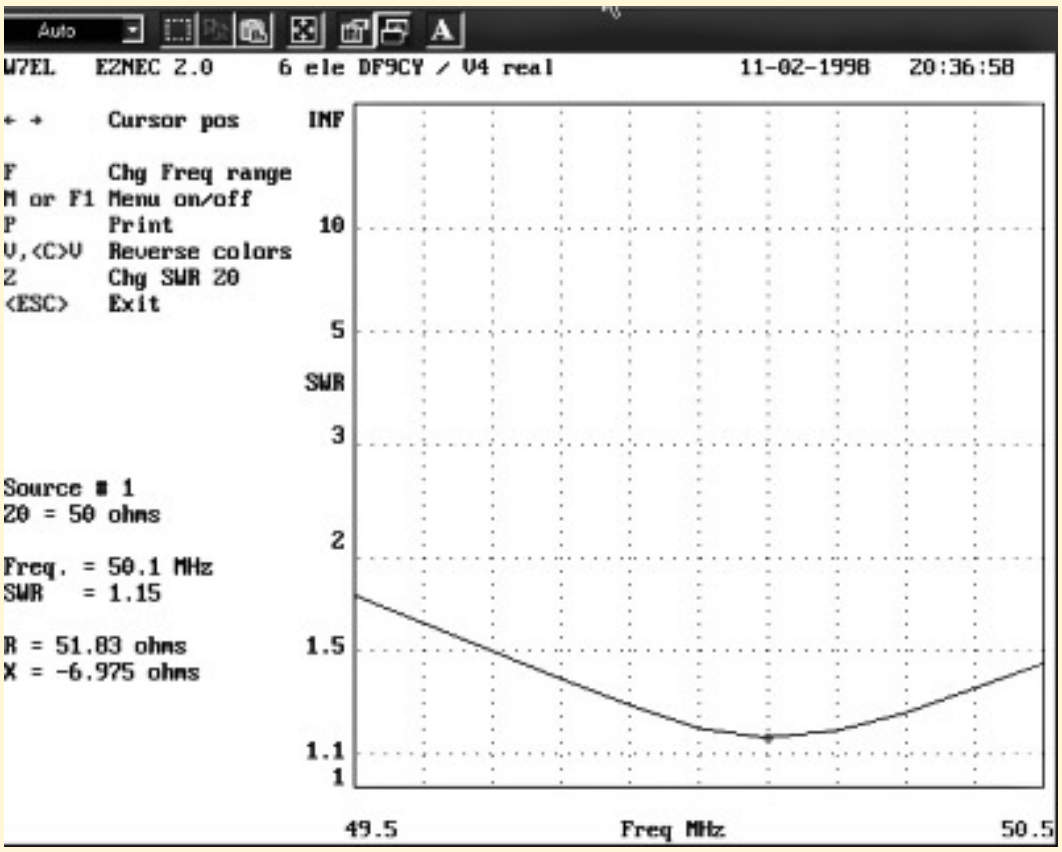
DIAGRAMS AND SIMULATIONS

Below are the diagrams for the azimuth plane (upper) and the elevation plane (lower). Sidelobes are barely visible in the azimuth plane and well 12 dB below maximum gain in the elevation plane. These are the free space simulations.

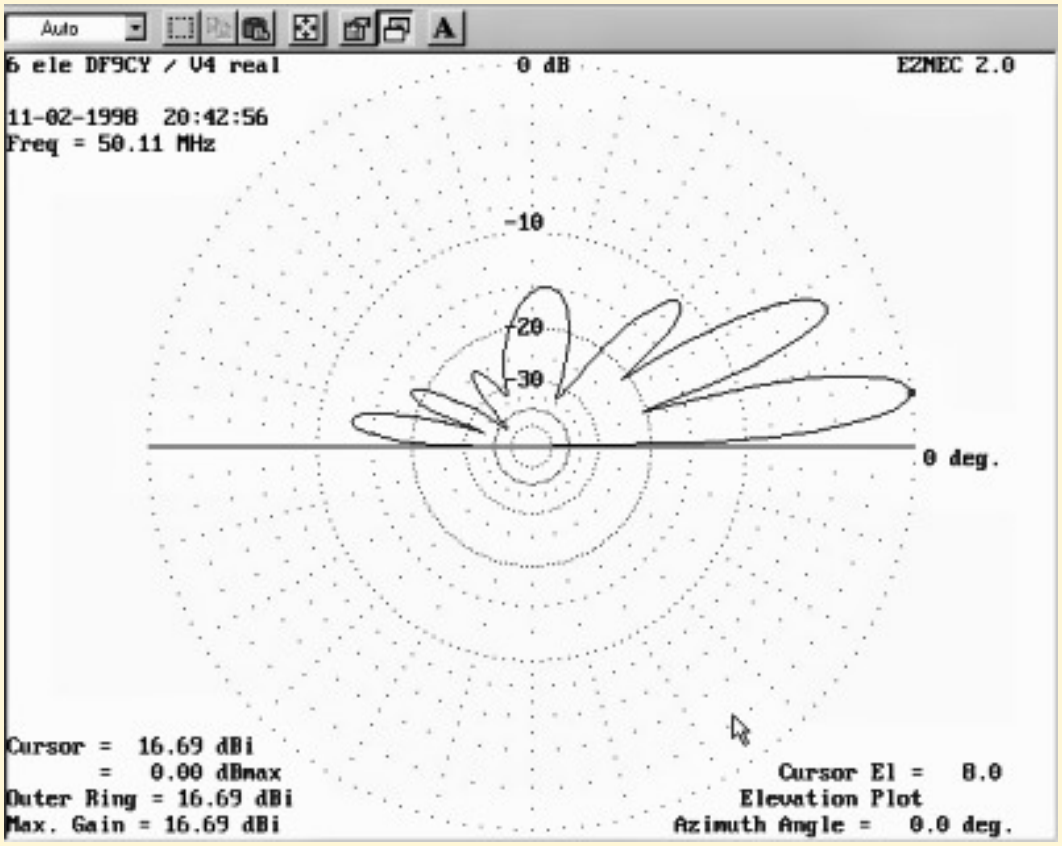




The SWR plot shows the optimum SWR at 50.110 MHz



This simulation shows the elevation pattern over real ground with the antenna mounted at 10 meters above ground.



My special thanks go to Roy Lewallen W7EL for programming this fantastic *EZNEC 2.0*

Antennas: (updated Feb 25, 2002)

8 element, 41 foot boom, mounted at 87 feet. 14.0 dBi gain, homebrew design (pictured on homepage) used for F2 & multi-hop Es: 1.75" diameter boom,center section has .125 wall, all others .062 wall..250" dia elements thru the boom insulated, add 8.7% boom diameter to element length for this boom. Tee match, 1.150" spacing, .250" diameter bars, length = 11.5 inches each side, fed with half wave length coaxial cable balun from UT250 with shorted and grounded quarter wave length stubs each side of Tee match. The grounded quarter wavelength stubs did absolutely nothing for suppressing rain static nor summer time "dry air static" common to this area. Will leave them out next time. Driven element dimensions may be too short as I forgot to re-measure it after final adjustments were made....will do that next time down.So far this cycle this antenna has performed extremely well on the F2 and TEP paths. Its clean pattern has paid off on suppressing noise and local QRM while looking for DX.

Element	reflector	driven ele.	dir #1	dir #2	dir #3	dir #4	dir #5	dir #6

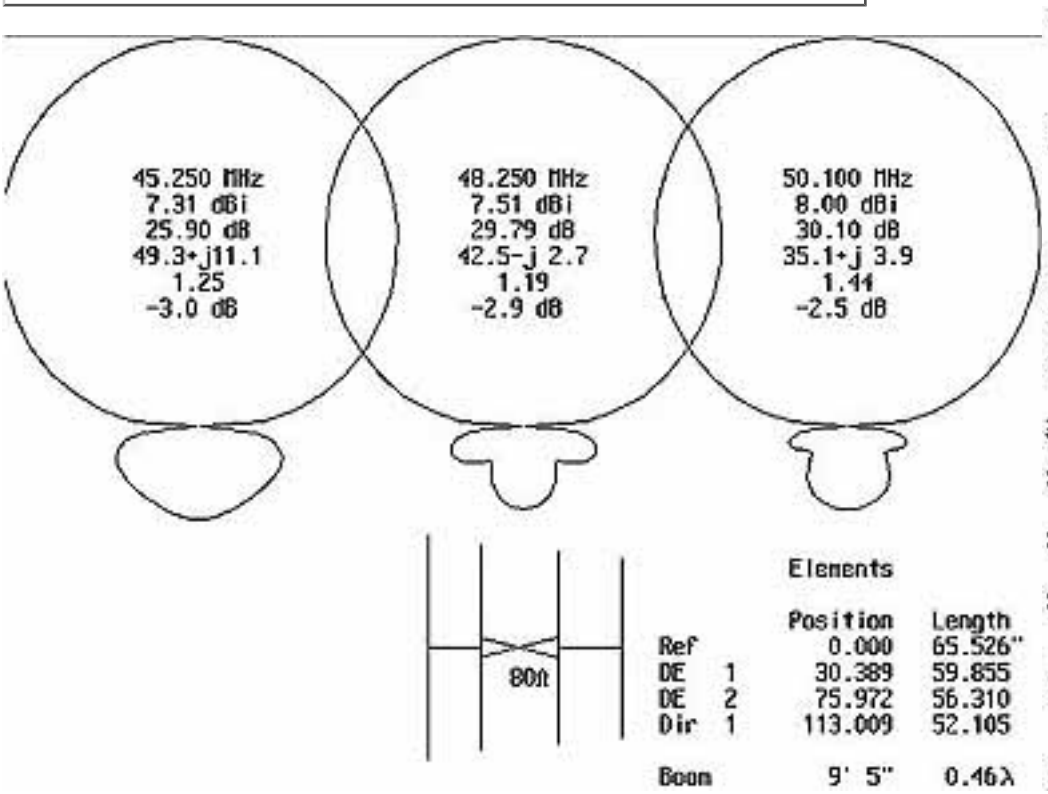
4 element broad band yagi

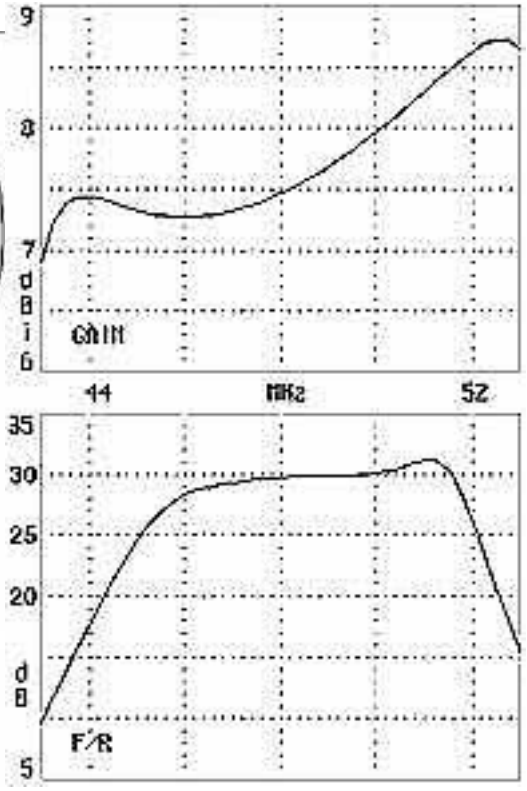
This antenna was the final choice for the all purpose noise cancelling/MUF antenna. It has a super clean pattern yet and enough gain to be useful. Too much gain would make it harder to use in noise cancelling applications. It is designed for many uses: 1) noise souce antenna for the noise cancelling receiver. 2) a 43 to 51 MHz antenna for observing MUF as the band opens up. 3) as a secondary wider beam width six meter antenna. All of the aforementioned points require an antenna design with a good pattern, resonable gain and good impedance.

Compare the gain-bandwidth of this antenna to the rather narrow gain-bandwidth of the 8 element yagi above. Many MUF indicators are between 40 and 50 MHz. Mounting tests will be be performed first to assure there will be adequate isolation between the 8 element yagi and this one. I do not want any deterioration of the 8 element yagi's performance. They will be 3/4 wavelength apart (15 feet). There should be around 20 db isolation between the two antennas (17 db measured...yuk!). I'm still amazed at the computer performance of this antenna considering the bandwidth....

The boom is 9 foot 7 inch, long 1 inch OD 0.065 wall. Elements are .250 inch diameter alu tubing as usual and are thru the boom and insulated. The driven elements are split in the middle and mounted on Delrin blocks. The phasing/matching lines made from UT141 semirigid coax (only outer conductor used). Impedance of the open wire line isn't that critical and can run anywhere from 70 to 100 Ohms without much effect. Add 5.1% of the boom diameter for thru the boom insulated compensation to the element lengths for this boom. Results of testing will be posted when I get them. Antenna seems to perform as expected. Better signal to noise ratio that big yagi at lower freqs and of course great directivity. Impedance is as computer predicted at <2:1 due to higher impedance openwire feeder to eliminate water accumulating between the conductors. The output of this antenna is split or switched to drive the filter/preamplifier/R8500 and the noise cancelling receiver. It's a great ant with multiple uses for us one tower guys. A separate low power T-R relay is used to isolate the output of this antenna when transmitting on the 8 element yagi.

Element	reflector	driven ele, #1	driven ele. #2	dir #1
Length	131.05	119.7	112.6	104.2
Spacing	0	30.39	75.97	113.0





Open wire feeder made from UT141 semidrigid coax, only the outer conductor is used, spaced .150 inches. This is greater impedance than the 80 Ohms so it won't collect water between the conductors. It is important to maintain the air dielectric. Delrin spacers are used throughout. Balun is ferrite beads on outside of coax held in place with shrink tubing.

---

6 element , 24 foot boom, 12.1 dBi design used for Es: Units=inches, .250" dia elements thru the boom insulated, 1.0" diameter with.125 wall center section and all others .062 wall. Add 5.1% boom diameter to element length.Tee match, 1.150" spacing, .250" diameter bars, length = 14 inches each side, fed with half wave length coaxial cable balun, RG142.

Element	reflector	driven ele.	dir #1	dir #2	dir #3	dir #4
Length	116.227	113.50	109.720	107.170	105.708	103.436
Spacing	0	40.5	80	142	216	287

4 element , 15 foot boom, 10.8 dbi gain, designed for light weight portable antenna. Clean pattern: all lobes >-21 db. Usually run on 21 foot mast. Boom = 1.0 inch diameter with .062 wall. .250 diameter elements with .049 wall. Thru the boom insulated elements in table above already have add 5.1% diameter of boom (.050 inches) added to element lengths.Tee match: .250 diameter rods, 1.0 inch spacing, 12.75 inch length on each side from boom center with 1.625 inches protruding beyond shorts. Shorts are made from 1/4 x 1/2 inch copper bar. RG142 half wave length coaxial balun. Antenna picks up 1 db gain over the shorter boom 12 footer. This one built with splice at the driven element for easy assembly while portable.

Element	reflector	driven ele.	dir#1	dir#2
Length	115.4	112.55	107.6	106.2
Spacing	0	47.7	108.5	177.7

3 element, 5.2 foot boom, designed for super clean pattern (side lobes> -29 dBc) and low gain! Antenna used for 50 MHz noise cancelling receiver. Half wavelength coaxial balun, RG -142. Units=inches, .250" dia elements thru the boom insulated, 1.0" diameter boom, add 5.1% boom diameter to element length. Tee match 1.0"spacing, .250" diameter bars, length = 11 inches each side, fed with half wave length coaxial cable balun.

Element	reflector	driven ele.	dir #1
Length	118..0	114.2	106.5
Spacing	0	24	62

All antennas were designed with YO, Yagi Optimizer.

Radio:

Homebrew hi level transverter, Rx filtered for 50 to 51 MHz pass band, -45 dBc at 54 MHz, noise cancelling input, adjustable phase & gain. 22 dB conversion gain, 2.5 dB noise figure. Terminating low pass filters on Tx.

Incorporating a FT1000D modified for use as the primary 50 MHz IF radio. TS930 had more than 60 thousand hours of six meter operation on it. (tired). First IF filters need to be added to FT1000D.and similar to 930 transverter mods need to be incorporated but I am finally using it. Going to add a new 8 pole first IF filter, PIN atten and hi level bipolar first IF amplifier replacing the original dual gate mosfet aa 73 MHz.

Icom R8500 receiver used for band segment scanning and third receive frequency. Adding a 43 to 51 MHz "MUF" antenna (above) to drive a 5 pole band pass filter and hi level preamplifier and splitter which will become the "extra" input for several uses in near future. Design will appear under application notes.

3CX800 amplifier, homebrew, 1200 Watts (+60.8 dbm +/- 0.02 db) output at 1 dB output compression point (CW mode). Modifying a TL922A amplifier for "instant on" six meter amplifier.

90 feet of 7/8 inch hardline & 85 feet of 0.5 inch hardline to antenna feed point

Optimised Six-Metre Yagi

by Brian Beezley, K6STI, ***Issue 39, October 1993***

Here's a design for a 5-element beam on a 23-foot boom with an unusual combination of performance characteristics. This Yagi comes within 0.2dB of the maximum gain possible on the boom length while keeping all back lobes 20dB down. This performance combination is very rare. The trick was to optimise the design over a narrow frequency range, 50.000 to 50.250MHz. Many 6-meter beams, both homebrew and commercial, are designed to work to 51 or even 52MHz. These designs invariably sacrifice forward gain and pattern quality for wide SWR bandwidth. When optimising a design over a narrow bandwidth, fewer elements are needed. As long as you have a certain minimum number, Yagi forward gain is determined by boom length, not element count. Elements added to the interior of this design won't increase its gain. (They may increase the bandwidth over which the pattern and SWR remain good, but this design adequately covers the low end of 6 meters.)

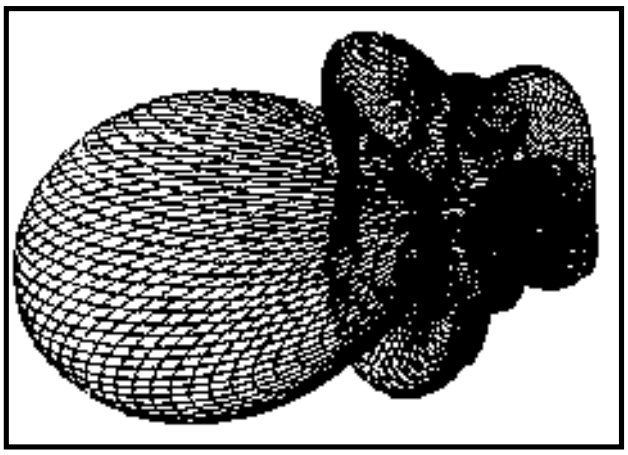

Figure 1 - 3D plot - Peak 10.26 dBd @ 50.110MHz

The free-space forward gain of this Yagi varies from 10.2 to 10.4dBd over 50.000 to 50.250MHz. These figures include conductivity losses of 0.08dB for 6061-T6 aluminium elements. When matched at 50.135MHz, SWR is less than 1.4 across the frequency range. The worst-case back lobe is 20dB down at 50.000, 21dB at 50.100, and rises to 16 dB at 50.250MHz. This design was simultaneously optimised for maximum forward gain, minimum worst case back lobes, and adequate and impedance. Conventional F/B was not optimised. This parameter takes the rear pattern into account at a single point.

The tuning of Yagi elements depends not only on their length but also on diameter, diameter tapering, and mounting method. These factors affect element self-impedance and thus alter antenna response. Thinner elements, tapered elements, conductive mounting brackets, and through-the-boom mounting shorten effective element length. Design dimensions are given for insulated, untapered, 0.375" diameter elements, for insulated, untapered, 0.5" diameter elements, and for elements with Cushcraft A50-6S tapering and mounting. If you use different elements or mounting methods, you'll need to adjust element lengths for optimum performance.

This design has a special property which makes it easy to adjust element tuning experimentally. The azimuth pattern has three back lobes which are equal in amplitude

only at 50.100 MHz. Since rear-lobe amplitude changes rapidly with frequency, you can easily verify that your antenna is correctly tuned. If the rear lobe is larger than the other two back lobes, the effective length of your elements is too long. If smaller, your elements are too short. You can use this simple test to obtain correct electrical behaviour for any physical element mounted by any method. When adjusting parasitic-element lengths, make equal changes to all parasitics. The input impedance of this design is about 12.5 Ohms. You can use any matching method as long as you observe the fundamental rule of Yagi matching: Never alter parasitic-element lengths or spacings of an optimized design to get a good match. Driven-element length has virtually no effect on gain or pattern, so you're free to adjust this dimension when matching. Don't after element spacing. Change parasitic-element lengths only to move the equal-back lobe frequency to 50.100 MHz.

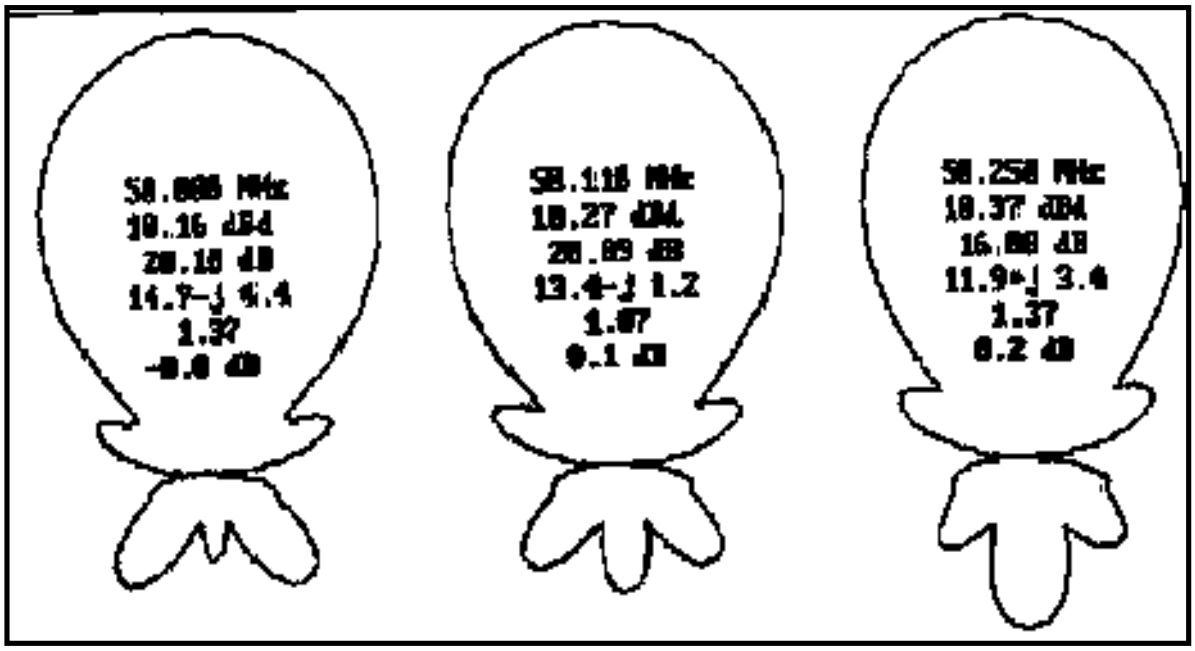

Figure 2 - Polar Plots @ 50.088, 50.110, and 50.250MHz

When I built this antenna in 1989, I gamma-matched it. However, I wouldn't do this with the knowledge I have today. A gamma match can induce current on the shield of a coaxial feed line. It can also induce current in the boom unless the driven element is insulated. These stray currents can reduce forward gain and degrade the pattern. You may be lucky as I was and get away with gamma matching, but why take a chance? Use a hairpin, T-match, or folded dipole and a good balun. The 12.5 Ohm input impedance transforms to a feed impedance of 50 Ohms for an equal diameter folded dipole. You can feed the folded dipole directly with 50 Ohm coax if you use a current type balun. You can make one by slipping ferrite beads over the coax or you can simply coil the coax into a few turns near the feed point. This design was developed in 1989 but was not published for some time. A carefully constructed, untapered, insulated-element version of this design came out 220KHz low. (I had to DF cordless phones below the 6-meter band to find the equal-back lobe spot!) I thought that perhaps some obscure environmental factor was responsible for the discrepancy (like the conductivity or dielectric constant of my composition roof). In typical ham fashion, I simply cut a quarter inch off each element tip and used the beam

successfully. But the 220-KHz anomaly continued to bother me. It wasn't until I began to use the sophisticated Numerical Electromagnetics Code (NEC) that I finally understood what was going on. NEC predicted that the antenna would perform as originally measured. The MININEC-calibrated algorithm I used to optimise this design had a built-in frequency offset! I immediately recalibrated all of my antenna-design programs to NEC. I subsequently found references to the MININEC frequency offset in the professional literature. If you optimise this Yagi for maximum forward gain without regard to pattern, impedance, bandwidth, construction tolerances, or reason, you can squeeze 0.2dB more out of the design. However, the back lobe degrades to just 11dB down and input impedance nose-dives below 5 Ohms. You say that you can match anything? That you never leave 50.110? That you don't experience rear-signal QRM on 6 meters, and that you want all the gain you can possibly get? What about those damn power leaks that always seem to start up from every direction whenever the band opens? What about the 3CO DXpedition which shows up on 50.300 and gets chased off the island before you're done retweaking your match up on the tower? If you're greedy about Yagi forward gain, you'll live to regret it.

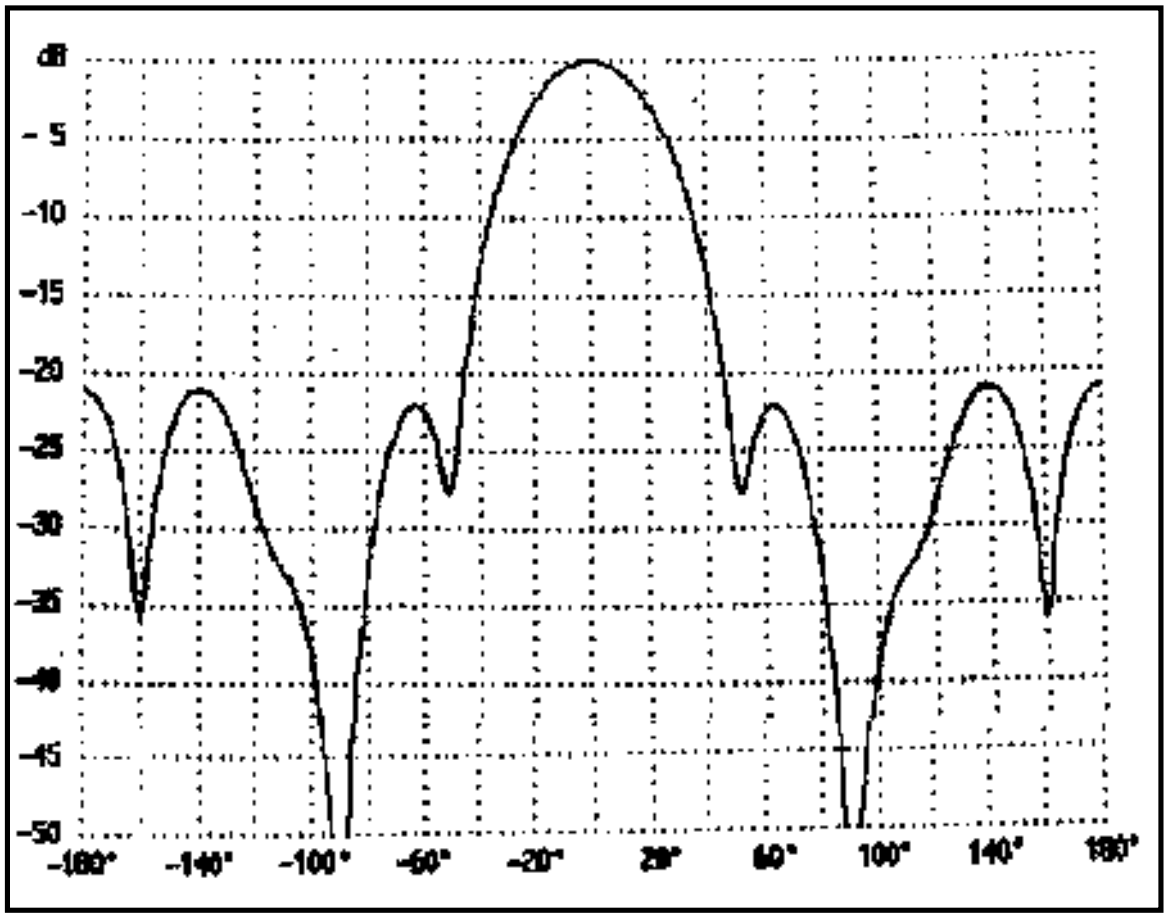

Figure 3 - Polar Plot - 50.110. 0dB = 10.26dBd

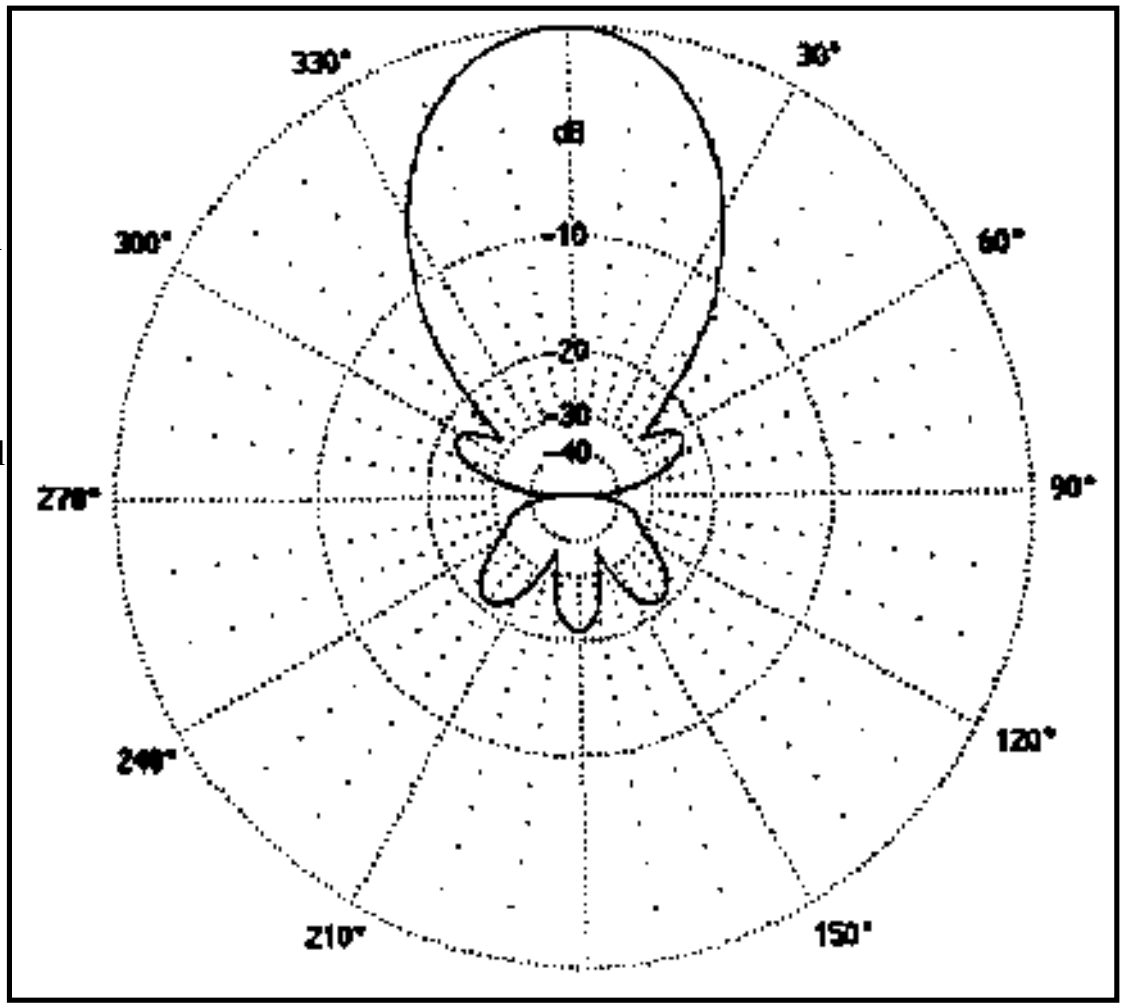
You can stack two of these Yagis for more gain. An H-plane stacking distance of 27 feet provides 3.1dB additional gain in free space. (Other stacking distances shift the equal-back lobe frequency away from 50.100MHz and require element readjustments However, unless the array is very high, you won't come close to free-space stacking gain in practice. The elevation patterns of Yagis at different heights don't combine favourably. For example, adding a second Yagi 27 feet below one at 50 feet improves gain less than 1.2 dB at elevation angles below 5 degrees. E-plane stacking is an attractive alternative. If

you space the booms 29 feet horizontally, you'll get 3.0dB gain over a single Yagi regardless of height. The 3-dB beam width will be 9 degrees, with deep nulls at 20 degrees and side lobes 9.4 dB down at 31 degrees. Before you go to the trouble of E-plane stacking, think carefully about the operational inconvenience of such a narrow main lobe. The cross boom must be non-conducting near the Yagis. If you'll settle for an improvement of 2.6dB, the 8-element Yagi listed below is much more manageable than a side-by-side pair of 5-element designs. To give you idea of how this Yagi compares with other designs, tables 1 and 2 show some NEC results at 50.110 MHz:

Figure 4 - Polar Plot - 50.110MHz



A50-5S, A50-6S, and 617-6B are wide-band Cushcraft designs. 6M2WL and 6M2.5WL are M2 Enterprises designs. NBS-5 and NBS-6 are National Bureau of Standards designs empirically optimised for maximum forward gain. Five is the subject of this article, while Four, Six, Seven, and Eight are other computer optimised, narrow-band designs. Gain figure-of-merit is antenna gain minus maximum practical gain (maximum gain for the boom-length with reasonable input impedance and bandwidth, a definition which is vague but which can be evaluated mathematically as a function of boom length). As N6ND says, for a really good signal you need dBs in the air and dBs on the desk. This simple Yagi design will take care of airborne dBs. Desktop dBs are a matter between you, your licensing authority, and your spirit of adventure.

Element Postitions and half lengths for Optimised 5-element Yagi (inches)

Position	E1-#1	E1-#2	E1-#3
0.00	57.54	57.42	58.43
44.06	54.85	54.59	55.39
107.89	53.48	53.16	53.88
194.86	52.59	52.23	52.89
270.62	52.59	52.24	52.90

Element Positions and Half-Lengths For Optimized 5-Element Yagi

El #1: 0.375" diameter, non-conductive mounting bracket

EI #2: 0.5" diameter, non-conductive mounting bracket.

El #3: Cushcraft A50-6S element mount 24" half-length of 0.75" diam., 0.625" diam. tips, U-bolt mount

Half-lengths are lengths measured from the centre of the boom to the element tip.

SIX METERS

ARRL ANTENNA Vol 5 COMPENDIUM contains an article I wrote providing details about two portable 6 meters antennas I developed, a two-element quad and a three-element yagi with telescoping elements.

Both antennas were designed for easy construction and quick assembly and disassembly. The quad provides a measured gain of 4.2 dB over a dipole and the yagi 5.8 dB over a dipole. Details are given describing the methods used to measure the gain of both antennas.

Here is a photo of the 2 element quad taken when camping by the ocean. I am looking for new grids.

The following picture was taken on a beautiful summer evening while operating portable. The 6 meter portable yagi with collapable elements is clearly visible against the evening sky.

I have scanned a copy of the article "Two Portable 6-Meter Antennas" here Reprinted with the persmission of the ARRL. Copywrite ARRL. All rights reserved.

ARRL ANTENNA Vol 5 COMPENDIUM is still available (January 2003) from ARRL (208 pages. First edition, © 1996-99, The American Radio Relay League, Inc. (ISBN: 0-87259-562-5) #5625 -- $20.00 USD:

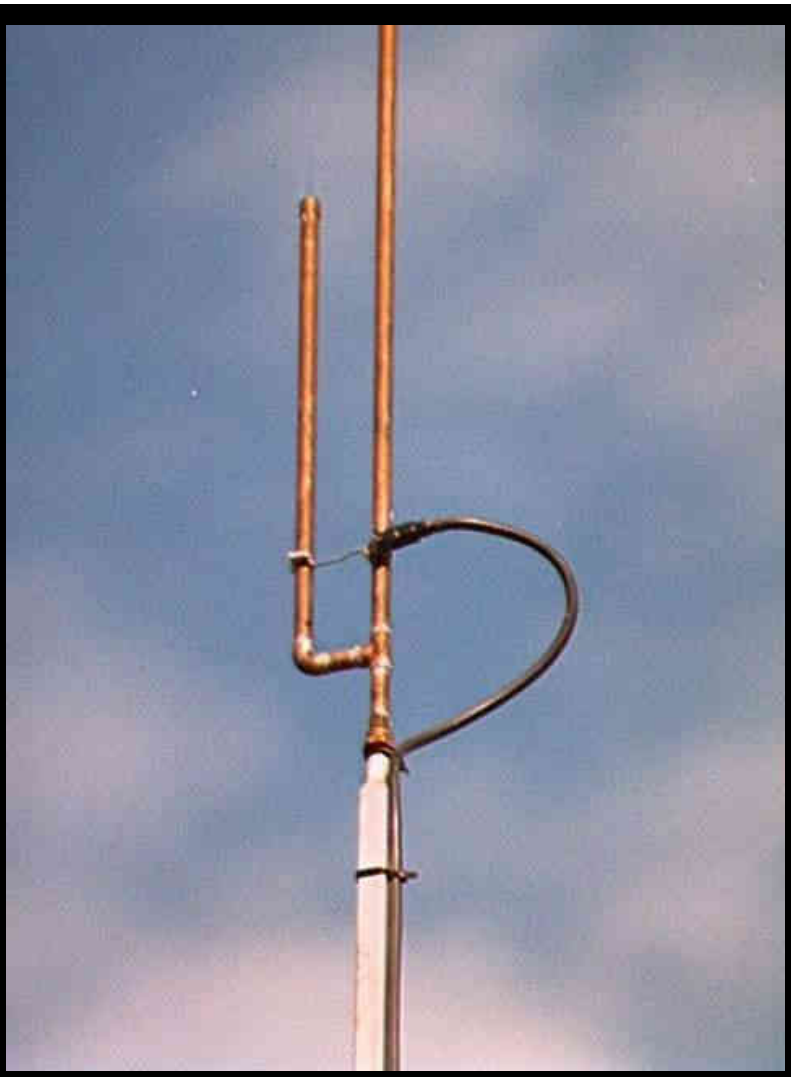
Copper Cactus Dual-Band Super J-Pole Antenna Project

Your going to like this super J-pole project, This home made j-pole is easy to build and sturdy, While looking for an jpole antenna project to build I remembered seeing a Marine antenna called the Super J-Pole in the 1988 ARRL Antenna Handbook, which claimed a 6 db gain over a quarter wave ground plane. I didn't have a machine shop at my disposal to fabricate the parts shown in the Marine antenna article so I set about redesigning the antenna using materials that were easy to find and work with. I have had very good results working with copper J-Poles, so I built my refined version of the classic J-Pole. I then added a short insulated section, the extra half wave of vertical length, and the needed half-wave matching stub.

Here is a schematic drawing of the home brew J-pole (Click Here) Word doc

Materials

Put the Heat to it



All the materials except the S0239 fitting can be found at any good hardware store, and the whole antenna can be made in less than an hour.

In my design I use 1/2" copper schedule M tubing and 1/4" soft copper tubing. I had experimented with using Teflon insulator, but have since changed my design to use a 9" length of hardwood dowel with three coats of lacquer as the insulator, for more strength.

Clean all the tubing, and then from the 1/2" tubing cut one piece each of the following lengths: 57-1/2"; 38"; 19"; 2", and a piece about 3" long for a stub to mount the antenna. In addition to the tubing, buy a 1/2" elbow, a 1/2" Tee, two 1/2" end caps a 1/2" threaded fitting, and a cast iron floor flange for mounting. Get a piece of 3/16" or 1/4" soft copper

Now fire up the torch and start the assembly process from the bottom. See Figure 1. Use flux on all joints, solder the 1/2" threaded fitting to the mounting stub, and solder the 1/2" Tee fitting. Then proceed with the 57-1/2" section, 2" cross piece, and 19" section. Pay close attention to getting the 19" piece parallel to the 57-1/2" piece. After these have cooled, drill through both the 57-1/2" section of the 1/2" tubing and the hardwood dowel about 1/4" from the top end of the 1/2" tubing, and the bottom of the 38" section of the tubing. (See Photo A.) Then insert the 1/4" tubing to the 1/2" tubing and sweat solder the end caps. After these have cooled, clean the entire antenna, bend the half wave matching section to a half circle of about 4" radius around the antenna to help the balance and match.

tubing 42" long. Find the center of the 1/4" tubing and bend it around a 1"-to-1-1/4" diameter water pipe or dowel.

Simplify the Feed Point of the J-pole

The feed point also needed to be made simpler, so I elongated one of the mounting holes of a panel mount SO-239 fitting and inserted a stainless steel adjustable band clamp. This goes on the 57 1/2" long section of 1/2" tubing. A short 2-3/4" length of # 14 copper stranded wire is soldered to the center terminal to go over to the 19" section. I used another stainless clamp to attach this. (See Photo B.) While experimenting to find the proper feed point, I found that the distance above the crossbar should be about 3".

Part's List

- 1 10-foot section of schedule M 1/2" copper tubing
- 1 1/2" copper elbow
- 1/2" copper Tee fitting
- 2 1/2" copper end caps
- 1/2" copper threaded fitting (for mounting)

Building Suggestions

1. You may use a Fiberglas rod as an insulator, but you will have to be very careful with the torch or you may weaken or burn the rod, or make it brittle.

2. When cutting the 1/2" copper tubing, cut the 57-1/2" piece from one end of the 10" length, and the 38" piece from the other end. By doing this you will have factory-cut edges for inserting the 1/2" dowel.

3. Be sure to keep the flame of the torch away from the insulator to avoid burning it.

4. Use paste flux on all joints when fitting the pieces together. Use enough flux, since you will be cleaning the entire antenna with solvent after assembly.

5. Use a weight to hold the 19", 57-1/2", and 2" pieces, and the Tee and the elbow, flat when they are sweat soldered together.

6. Use a ruler or caliper to check the spacing between the 19" and 57-1/2" pieces, to keep them parallel to each other.

7. When drilling the SO-239 fitting, use the drill press. Be careful not to drill into the threads of the fitting. After the holes are drilled, file the opening flat for a better band

- 1 1/2" cast floor flange (for mounting)
- 1 Piece of 3/16" or 1/4" soft copper tubing 42" long
- 1 Piece of 1/2" hardwood dowel of Fiberglas rod
- 1 SO-239 panel mount coaxial fitting
- 1 Piece of # 14 stranded copper wire
- 2 3/8" by 7/8" stainless band clamps

Tools needed:

- Tape measure
- Tubing cutter
- Propane torch
- Solder and flux
- Electrical tape
- Caulking compound
- Screwdriver
- A weight to keep parts aligned while soldering
- Steel wool or a Scotch Brite pad (for cleaning all copper)
- Spray can of clear exterior lacquer (to finish-coat completedantenna)

clamp fit.

8. After the best match has been found, you may want to solder the SO-239 and the stranded wire end to the 1/2" tubing.

9. When the antenna has been cleaned and matched, spray the entire antenna with a coat or two of clear lacquer to keep it looking nice.

10. After everything else has been done, apply silicon or a butyl rubber compound to the insulating section, then cover the joint with electrician's tape for a weather tight seal.

11. A 1/2" pipe coupling and a length of pipe may be used in place of floor flange for mounting in a roof tripod.

Suggestion by KB9TIO

An Improved(?) feed arrangement is to use copper couplings, same size as the tubing. Split the coupling lengthwise, bend out @ 1/4" and notch for the so-239 inner ring. attach with sheet metal screws an/or solder so-239 to coupling. repeat with 2nd coupling and solder other end of #14 wire to flat on coupling. this provides a strong joint and very easy tuning by sliding the couplings up or down the tubing as needed. this tip was given to me by Tom-KB9OZZ

Thanks, Matt KB9TIO

Suggestion by **KD7GQC**

I have also seen variations on the J Pole which omit the insulator section. In the first, the center conductor is soldered directly to the driver element, and the entire antenna is thus at DC ground. The second variation is also an all-copper design, but you capacitively couple the RF to the element, by wrapping several turns of insulated wire from the center conductor around the driver section of the J pole. I can't vouch for the second approach, but the first seems to work great, for installations where a DC "short to earth" is not a problem. It seems to me that eliminating the insulator section makes for a simpler, and potentially stronger, design. Kudos on a great antenna! 73s, Brian KD7GQC

One last suggestion: put a piece of steel about 1/2 or 3/8 of about a foot and a half up the center of it (from the base) this will strength the bottom portion of the pole.. put a small curve in it so it touches the inner wall of the pipe.. my parents use this j-pole and live in a windy area.. and this fixed that problem.

In order for these instructions to work great.. Please send me feedback on if you had problems and what can be done to help the next ham.. I don't get much feedback on the copper cactus J-pole, Guess that's good in a way, but would love to either way **Praise or Suggestions** about this project.

Recommend This J-Pole to a Friend

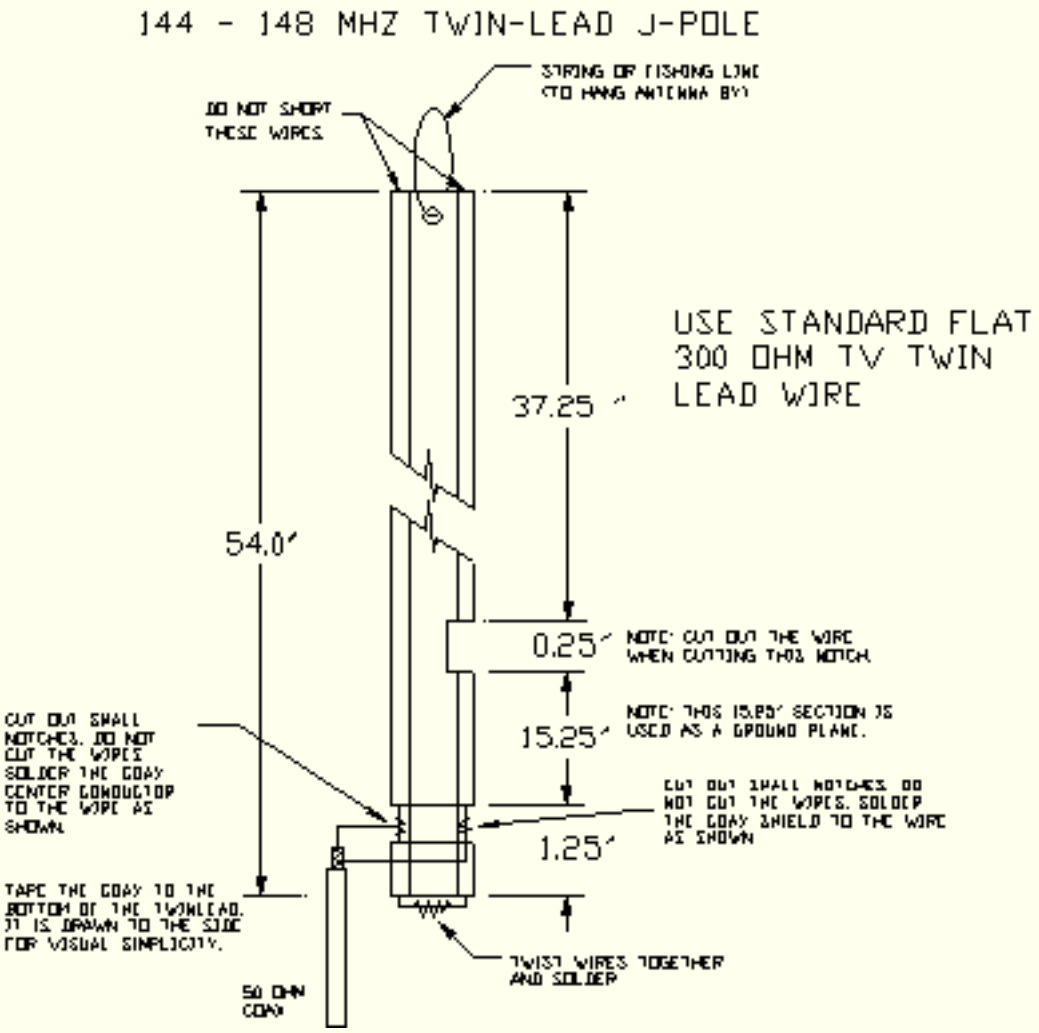
Emergency Antennas

- ***300 TV Twin-lead J-Pole Antenna (Approximately 3 dB Gain)***

  This is an easy antenna to make from existing or inexpensive materials. It rolls up for easy storage and can be deployed in seconds; just hang from the nearest ceiling or attach to the end of a fiberglass fishing pole or PVC pipe. Better than a rubber duck (what isn't?).



- ***¼ wave Mag Mount as a Portable Antenna***

If you need to operate portable and only have a mag mount antenna available, try placing any large piece of metal underneath it. This might be a refrigerator, stationary car, or a metal rain gutter. You might also try making your own portable ground plane by placing some aluminum foil over a large piece of cardboard (2 feet x 2 feet minimum).

- ***American Legion J-Pole***

  If you are able to operate fixed portable, try the "American Legion J-Pole". Attach it to the top of a 10 foot section of PVC pipe and mount this to a camera tripod. Attach weights to the legs for stability. This makes a very nice fixed station antenna.

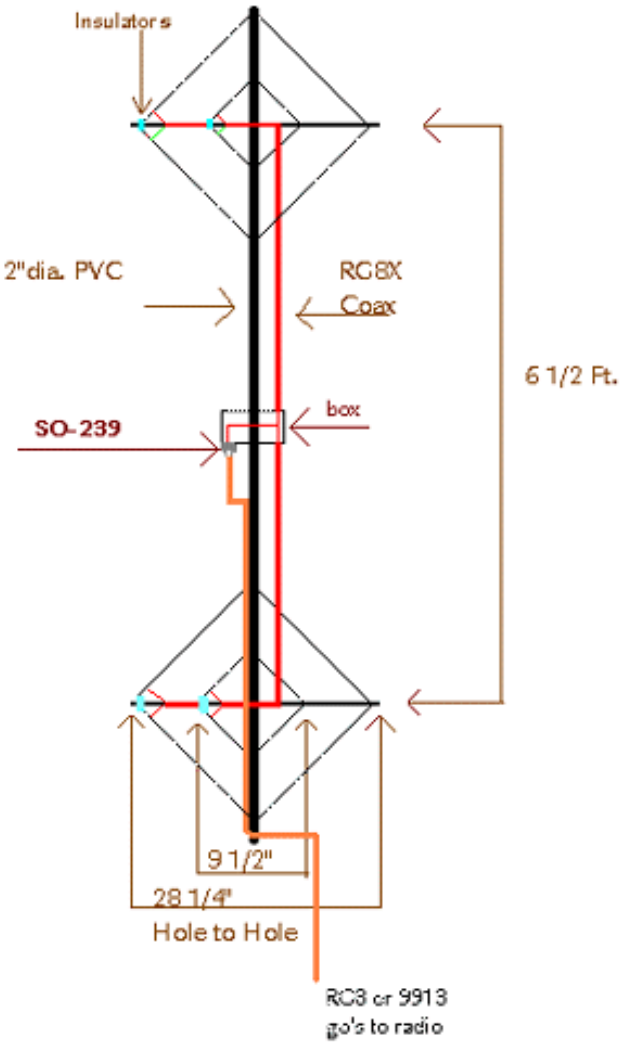
Specifications for antenna at bottom of diagram



KE4UYP's Biquad

144/440 MHZ

Specifications

This is a vertically polarized Broadside and Collinear Array each Loop is a vertically polarized Broadside Array both the right and the left side of the Loop is a bent 1/2 wave dipole working 180 degrees out of phase with the other one and that gives you 4.15dbi of gain The two Loops are Stacked one above the other this makes a Collinear Array at one wavelength at 2m that gives you 5.15dbi of gain so the Total gain of the Antenna is 9.15dbi all this from four pieces of wire and some PVC pipe.

One of the easiest construction techniques for building this antenna is to use 3/8" fiberglass rods for the horizontal spreaders that pass straight through the two inch PVC pipe you can hold them in place with two nylon tie wraps one on each side of the two inch PVC pipe pulled tight around the

fiberglass rod.

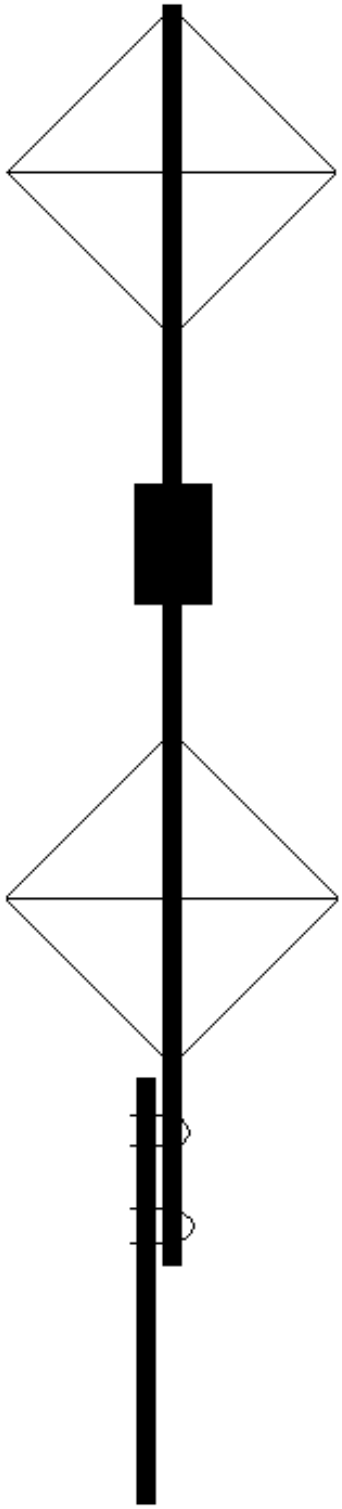
You can make insulators from half-inch diameter PVC pipe 3 inches long. Drill a 3/8" hole 11/2" from one end of the pipe all the way through both sides of the pipe, then drill two 1/8" holes near the ends of the PVC pipe for the antenna element wire to go through. Then you can slide this pipe on to the fiberglass rod.

If you solder the coax connections then seal it with epoxy tape it will be 100 percent reliable and weather proof, also make sure you extended the two inch pipe twelve inches past one of the loops you can U bolt that part of the pipe to your mast, of course this would be for FM operation. See attached drawling.

This is a inherently broadbanded antenna so fine-tuning the elements is not necessary the reason why these elements are shorter than a standard element is because when you connect two driven elements in parallel with each other this creates and an excessive amount of inductive reactance and the easiest way to remove this is to simply make each element shorter normally these elements would be three inches longer on 2 meters.

The impedance of one loop is 100 ohms so when you put the two loops in parallel you get 50 ohms this makes a perfect match for coax cable. If you are using this for 2 meter SSB then of course you need horizontal polarity and the loops would be side-by-side this puts the feed points at the bottom corners of each loop. the antenna would then be mounted on the mast from the center.

The formula for calculating the overall loop lengths is 11665.4 divided by xxx.xx Mhz's the answer will be in inches.



Back to home page

The Simple Collinear

Wherever there is a need for a vertically polarized omni-directional antenna with gain, a collinear is used. The vertically polarized collinear takes the form of two or more half waves in-line and in-phase, resulting in an omni-directional pattern with maximum radiation near the horizon. The techniques used to ensure that the half waves are in phase are:

1. Interspersing the in-phase half waves with quarter wave stubs. This is the method described in the ARRL Antenna Book.
2. Making the antenna out of half wavelengths of coax with the outside of the coax used as the radiating elements and the inside of the coax used as the phasing elements.
3. Interspersing the half waves with resonators to provide the necessary phase reversal.

Each of these techniques is designed to reduce or prevent radiation from the out-of-phase components of the antenna. The Simple Collinear uses a different technique.

The Simple Collinear makes use of the fact that large diameter elements within an antenna can radiate more readily than small diameter elements. Therefore if the large diameter elements are in phase and the small diameter elements are in phase but out of phase with the large diameter elements, radiation from the large diameter elements dominate.

Shown above is a schematic of a 5 element collinear—3 large diameter elements and two small diameter elements. Each element is about ½ wavelength long, and since the phase switches every half wavelength, the 3 large diameter elements are in phase and the 2 small diameter elements are in the opposite phase. The result is an antenna with about 2 dB less gain than if all the elements are in phase. Simulations show that this can be applied to very large arrays. A 45 element array (23 large diameter and 22 small diameter elements) is simulated to have 14.38 dBi gain.

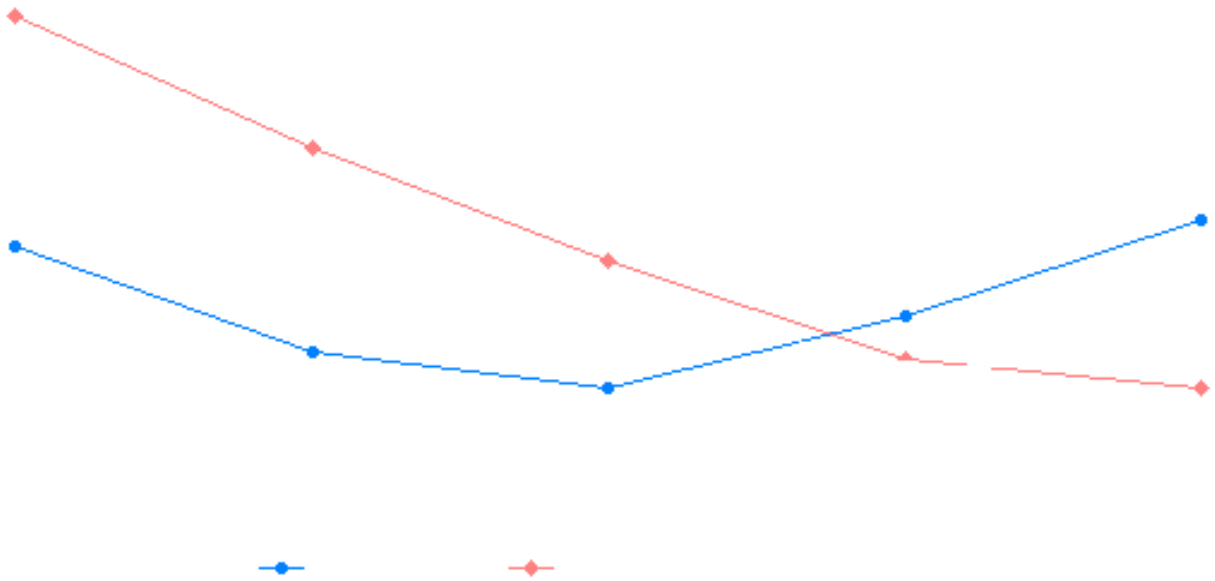
Performance vs Number of Elements			
# of Elements	Gain (dBi)	Z (ohms)	Ideal Gain
1	2.06	79 + j14	2.06
3	3.76	103 + j7	5.41
5	5.17	117 + j1	7.32
11	8.09	144 - j14	10.49
23	11.33	176 - j42	13.6
45	14.38	207 - j90	16.48

Large diameter elements = 1 inch.
Length of large diameter elements = 38.15 inches.
Small diameter elements = 0.040 inch.
Length of small diameter elements = 40.95 inches.

Ideal Gain assumes all elements have
1 inch diameter and are fed in the center.

The table above shows the gain and impedance of a 2 meter 45 element antenna, consisting of 23 elements, 1 inch diameter and 38.15 inches long and 22 elements 0.040 inch diameter and 40.95 inches long. The antenna has its feed point the center of the lowest element, although it could be fed at the center of any of the 45 elements. Also shown in is the performance of various versions of the same antenna, varying the number of elements between 1 and 45. Note that the gain increases by 3 dB for each doubling of the number of elements. I stopped the simulation at 45 elements because I can't imagine building an antenna larger than this—at least at this time. Also shown in this table is the simulated gain of an ideal antenna assuming all 45 elements have 1 inch diameters and are fed in phase with voltage sources. Note that gain is only about 2 dB higher than the simulated real antenna. This is because the in phase currents are distributed quite uniformly across the antenna, an effect achieved by adjusting the lengths of the elements slightly from half wavelength. The 0.040 diameter is a compromise between making the diameter small to reduce the radiation, but not so small that ohmic losses become important. The 45 element array is simulated to have only 0.1 dB loss due to ohmic loss in the 0.040 diameter copper elements. All these values were determined using K6STI's AO Antenna Optimizer MININEC program.

A 5 element test antenna was simulated and built. It was optimized for 5 elements and not created from a reduction of the 45 element array in the table; its gain was simulated to be 5.7 dBi and impedance about 100 ohms at 147 MHz. The small diameter elements were simulated to be 0.015 inch because for a small array, radiation from these elements is more of a factor and ohmic loss is less of a factor. All elements were 38 inches long. The 1 inch elements were made from aluminum, but any metal will have negligible loss—copper, aluminum, galvanized, or steel are all ok. The small diameter elements should be 0.010 to 0.020 inch in diameter (#30 to #24). There will be a slight reduction of gain if #24 wire is used. I used #26. Support of the antenna in the small diameter sections was provided by ¾ inch diameter schedule 40 PVC pipe. Guying was provided by 3/16 inch polyester cord. The antenna was fed through a quarter wave transformer made from RG59U. A few ferrite beads on the RG59U provide any needed current balun action. The antenna was installed on the roof in place of an old TV antenna. Simulated and measured SWR, with measurements taken at the end of the transformer, are shown.



This antenna has many attributes. It is easy to model. It is easy and inexpensive to build. A high gain version can be built in-situ, adding a couple of elements at a time, adding guying as elements are added. It is broadband. Even the 45 element version is simulated to have an SWR less than 1.7 across the 2 meter band (144-148 MHz). Current distributes well over the entire antenna making the aperture efficiency high.

Here are some possible applications.

1. Small versions like the 5 element antenna described can be roof mounted for repeater access.
2. Versions of this antenna should be good for applications in the field such as for contesting or DXpeditions, giving good gain and good height cheaply.
3. This antenna would make a good base station antenna for 2 meter and higher repeaters. Down tilt can be designed in if desired by slightly shortening the elements.
4. It should be a good antenna for communicating via Tropospheric propagation.
5. Several could be put together to make a phased array.
6. It could be used as a feed for a cylindrical parabolic antenna. Large cylindrical parabolic antennas should be easier to make than large paraboloid (parabola of revolution) antennas.

Keywords: The Simplest Collinear

Build a 2 Meter DDRR for Mobile

By W5GVE

This is a story of an antenna and its modification over time into "better" forms. Part of the improvement was by design, and part was just plain good luck. When you are working closely with an antenna, unless you keep very detailed records, it is difficult to discern which is which after the fact.

PURPOSE

The original objective was to build an antenna for 2 meters FM (146-148 MHz), vertically polarized, and omni-directional. The world is already full of such antennas; why something new? The truth is that I needed a short antenna that wouldn't scrape against the low-hanging trees of the desert where shade is precious, or against the 7 1/2 foot ceiling of the multi-story parking garages in the cities I occasionally visit.

Many years ago, I was intrigued by the DDRR antenna. It originally was a quarter wavelength radiator sprouting up from a ground plane, taking a sharp turn to the horizontal and coming around in a circle to almost meet itself where it sprouted. Sort of an open loop parallel to the ground with one end connected to the ground. This obviously horizontal antenna behaved in an outrageous fashion—***it radiated vertically!*** There's no free lunch however and, as originally described, it worked about half as well as a full-sized quarter wave vertical wire. But, if you could stand the tariff, it ***was*** low to the ground—$1/10^{th}$ as tall as the vertical.

I stood it as long as I could and finally built one for the Citizen's Band (27.5 MHz). This was years ago, and as I recall, the mobile CB-DDRR was three feet in diameter, six inches tall and looked like a pair of hula hoops. It was built of 1/2" aluminum cable-TV trunk cable held together at crucial points with automotive hose clamps. And, it worked! At least ***until my wife saw it,*** and said she could not be seen dead driving around town under it! So, DDRRing went dormant for a decade.

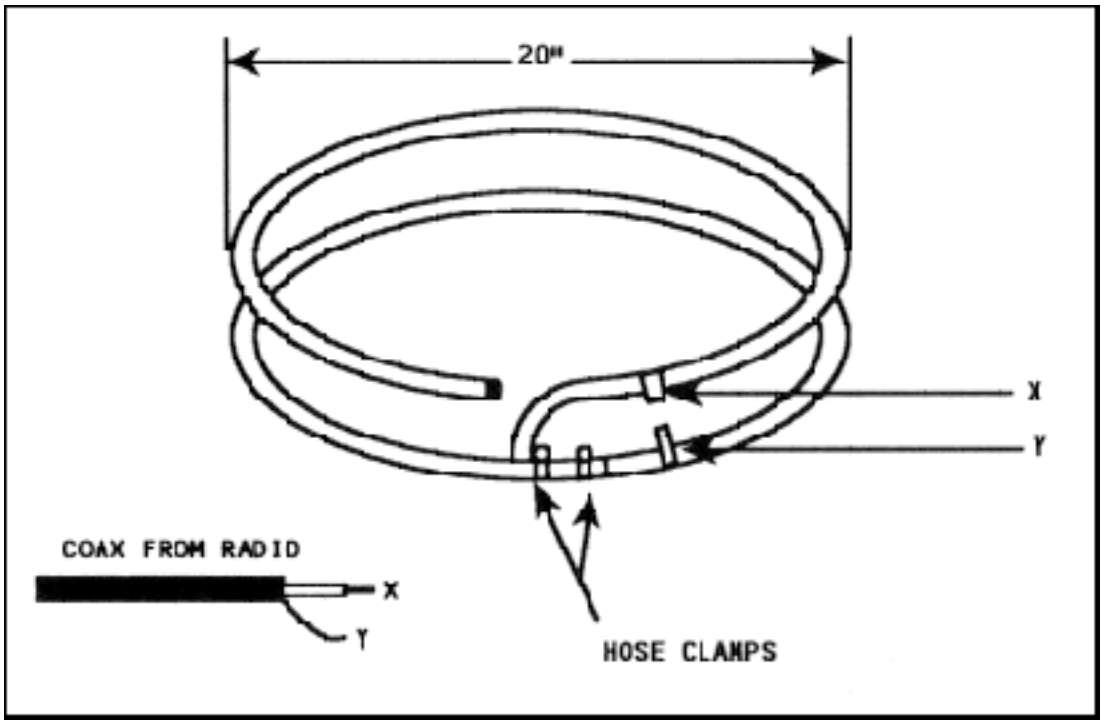
In subsequent years, more articles appeared on the DDRR in its quarter-wave version, and later, a half-wave model. I didn't try either and pretty well believed what I was reading. As the need for the 2M low profile antenna grew, my mind turned to the 1/4 wave DDRR, throught the 1/2 wave DDRR and ended on the great idea of maybe a 3/4 wave DDRR!

A 3/4 wave edition would not be any taller than a plain vanilla (1/4 wave) DDRR, and would have much greater capture area. It seemmed like the perfect solution. If it looks weird, so what? My wife has her

own car now. All systems were GO, so I began. Not having a whole lot of imagination, I began by resurrecting the concept of the CB-DDRR, 1/2" aluminum TV cable and all.

At 147 MHz, a wavelength is quite close to 80" and 3/4 wavelength is 60". The diameter of a 3/4 wavelength DDRR is 20". I arbitrarily decided that 3" in height (center to center) would probably be tall enough to help capture incoming wave fronts, and it ***did*** resemble the old CB version.

Figure 1



WORKED LIKE WOW!

For testing purposes, I taped it to the roof of my little Chevrolet station wagon. Wow, did it ever work! I compared it to the 5/8 wave vertical magnetic mount whip on the other end of the station wagon roof, and the 3/4 wave DDRR equaled or exceeded the commercial whip. One little problem. It had a great gain off one section of the antenna, average elsewhere, and a tiny area of a slight null. Further tests showed it had a substantial amount of horizontally polarized radiation in addition to the desired vertical radiation. What was going on? The Mark I version has problems!

DIRECTIVITY

I believe the 3/4 wave DDRR showed directional characteristics because its physical structure is about 1/4 wavelength in diameter. Current on exactly opposite points of the radiator's circumference are 3/8 wave (30") out of phase, electrically, but are 1/4 wave apart (20") physically. I did not have the means to work this out theoretically, but it seems reasonable that this physical configuration would simulate radiation patterns of discrete radiators phased and separated in this manner. I decided this was the kind of a problem that could not be overcome. It could be developed if, some day, I want to build a directional vertical low-height radiator. Maybe some day.

POLARIZATION

The method of feeding the antenna was the same as I used years ago on the CB-DDRR. Since the DDRR can be looked upon as a section of parallel conductor feedline, with one side joined to a ground plane, one end is effectively shorted and presumably at a very low impedance point, and the other end is at a very high impedance, it seemed reasonable that at some point near the low end there are a pair of points at 50 ohm—just right for direct coax feed. It worked on the CB-DDRR and I figured it would work on the 2M version too.

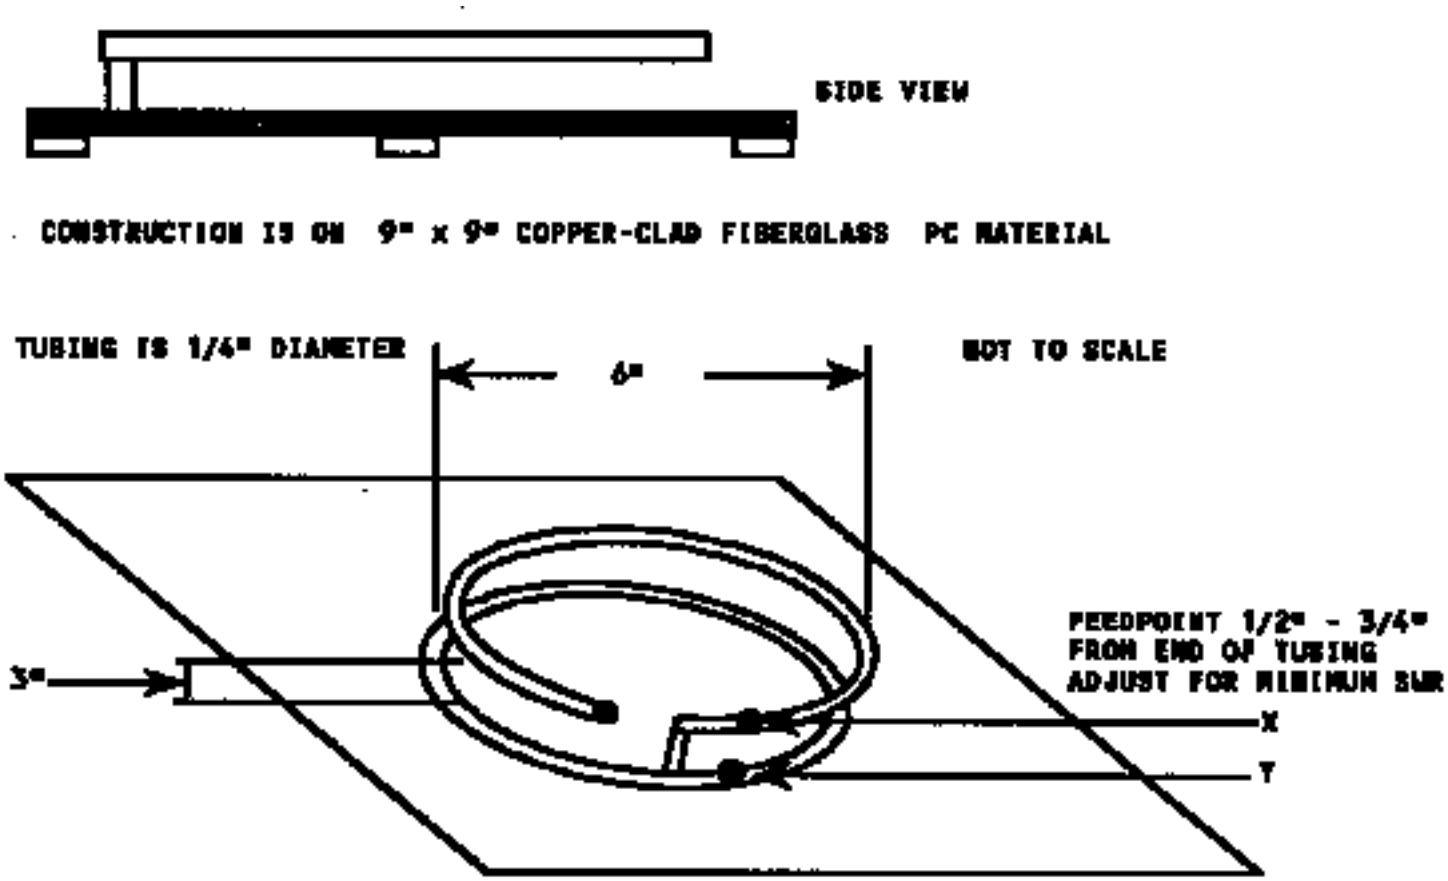
A straight transmission line antenna, laid out horizontally, would radiate horizontally polarized energy. But when the same antenna is curled up into a loop, about 1/2 wavelength in diameter, it radiates vertically polarized energy. In order to get a good match (50 ohms, with low reflected power) I had to skew the feed points slightly. That is, the center conductor of the coax was connected to the upper line at a point NOT directly over the point where the coax braid is connected.

TOO MUCH SKEW?

I believe the skewing of the feed points resulted in the mostly vertical, but partly horizontally polarized radiation. Again, this is an area for further eXperimentation, since I did not pursue it at this time. So much for the 3/4 wavelength DDRR.

Considering the phasing problem that gave me the unwanted directivity, I concluded that some of this could be expected with a 1/2 wavelength. So, I decided to do a plain old 1/4 wavelength DDRR, but by using some of the information about transmission line radiators I had picked up in the intervening years since the CB-DDRR, mainly the work of ***Ted Hart, W5QJR.*** The better the conductivity of the radiator, the better the antenna. That rules out aluminum tubing and hose clamps.

Figure 2



SOME SUCCESS

I decided to begin with a 1/4" diameter copper tubing, formed into two 6" diameter loops, separated 3". One loop is tack-soldered at 3" intervals to a 9" square of copper-clad fiberglass printed circuit board stock. The coax braid is soldered with no length to the circuit board. The center conductor is taken up 3" and soldered to the free loop about 2" from the shorted end. Matching is accomplished by three methods: adjustments of the tap on the free loop; trimming the free end of the loop (raising frequency of resonance); and bending the free end of the loop up or down (raising and lowering, respectively, the frequency of resonance). The results? Equal to the 5/8 mag-mounted vertical whip! The Mark II is a success. Now to improve on this!

THE NEXT VERSION

The Mark III version was also begun on a 9" square of circuit board material. It has great surface conductivity, is stiffer than solid sheet copper, can be soldered readily, and can be attached to a magnet for car-roof mounting. Instead of a double loop of 1/4" copper tubing, the Mark III uses a single 20" long loop of 5/8" copper tubing, a 5/8" copper "L", and a 2" piece of 5/8" tubing to space the loop over the ground plane. Matching is the same as the Mark II's, with the exception of soldering to the loop. I had to use a fancy homemade copper clamp-low resistance, moveable, and IT CAB be soldered!

Once the best tap point has been determined, drill a small hole at the point. Use a sheet metal screw and a copper tab to solder on the coax center connector. The adjustments for best match are limited to two: trimming the end of the loop with a tubing cutter and moving the feed tap. This is a high-Q device, and moving the feed tap has a very large influence on the resonant frequency, as well as feed point

impedance. Performance? Equals or exceeds the 5/8 wave vertical whip in all respects. Being fairly high Q, it has a useful bandwidth, a little narrower than the whip—about 2 1/2 MHz.

Figure 3

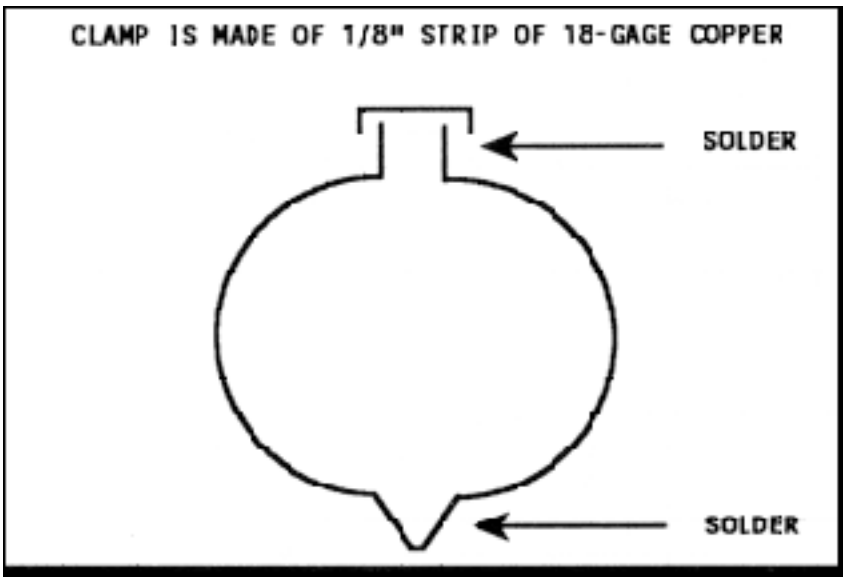


Figure 4

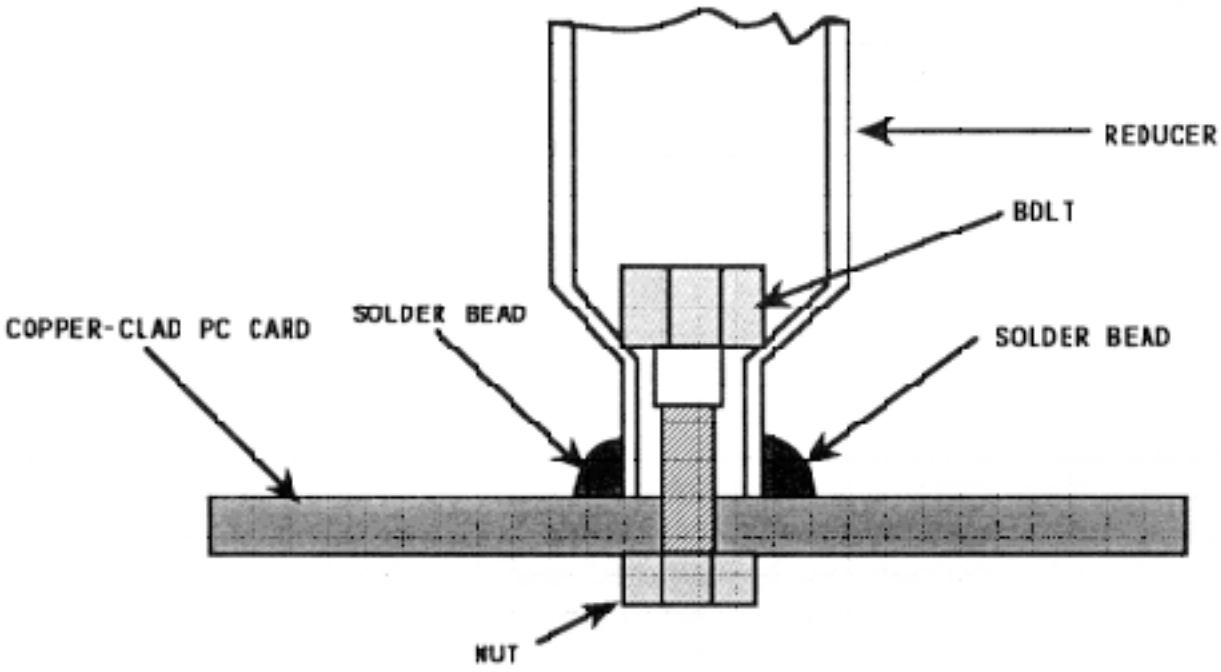

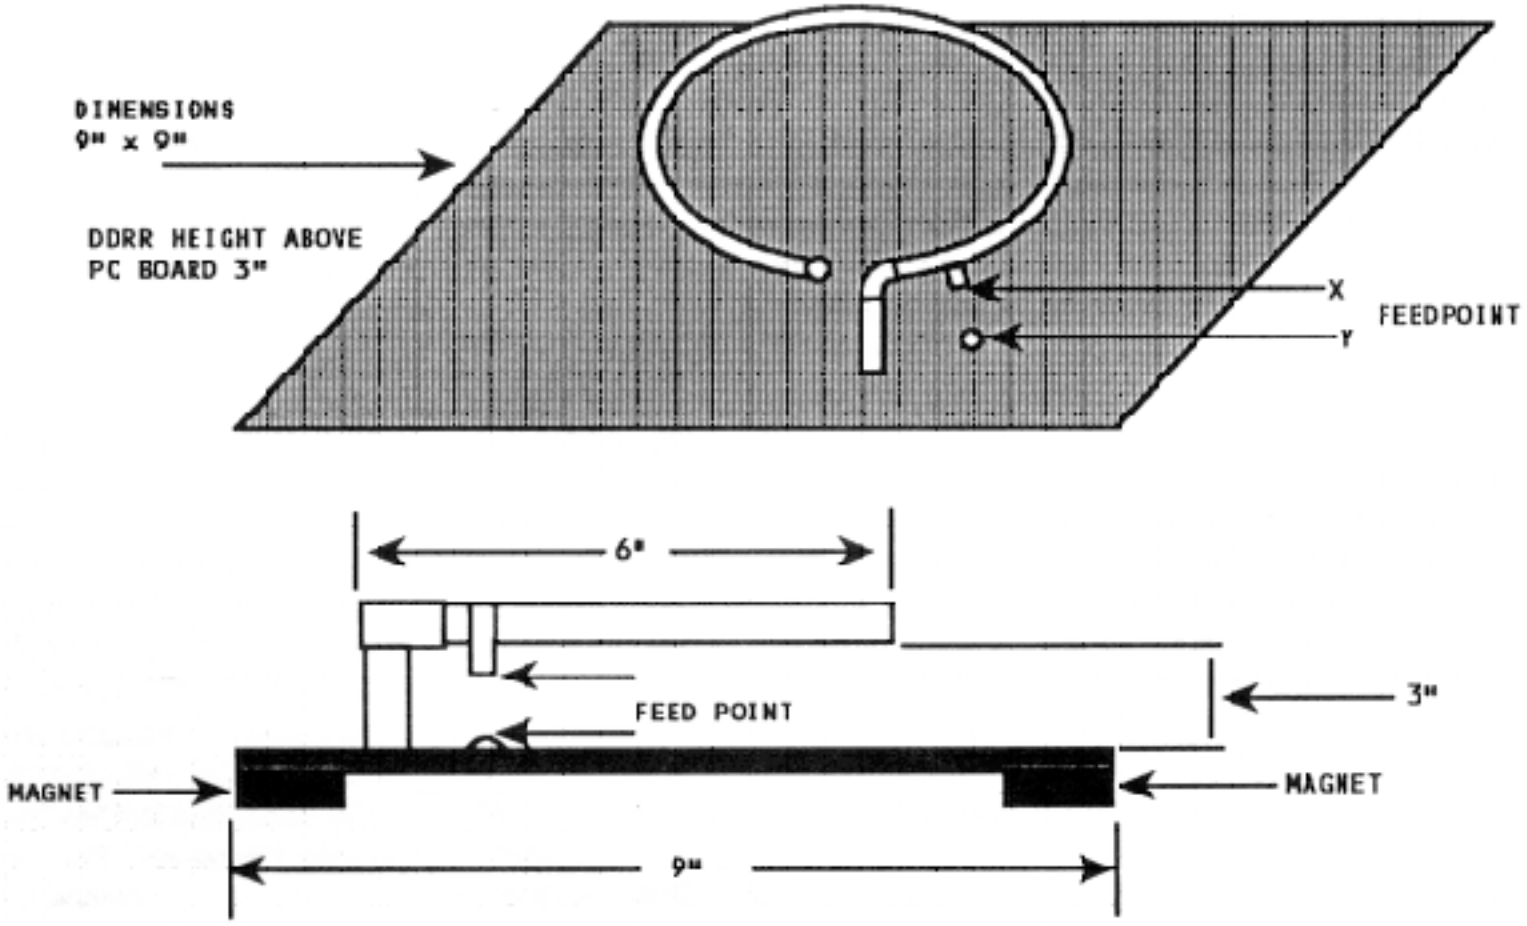

SPECIAL CONSTRUCTION DETAIL

Fixing the butt of the free loop of the Mark III to the ground plane took some real effort. I finally solved the physical problems by clamping a bolt inside the 2" vertical piece of 5/8" tubing in the jaws of a vise and clamping the tubing again below the bolt head to form a shoulder against which the bolt can be pulled tightly, securing the loop to the ground plane. Gently solder the butt to the circuit board, flaming the tubing and not the PC board. **-30-**

The Cycloid Collinear, a CP Omni

Figure 1

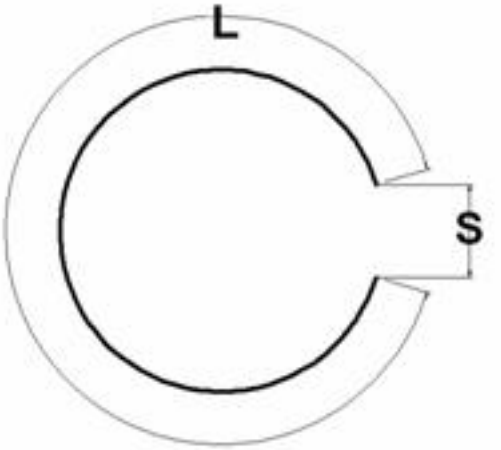
Despite the advantages of circular polarization, amateurs have made little use of it. One of the main reasons is the difficulty in making a good circularly polarized omni-directional antenna (cp omni). This paper describes a wide band, high gain, multi-element cp omni with a single 50 ohm feedpoint with instructions for building a 2½ element cycloid collinear for 2 meters.

There are no commercially available cp omnis for amateur use [1], although there are many available for the fm broadcast band [2,3]. A common design is the cycloid which consists of a horizontal loop approximately lamba/2 in circumference, with short vertical extensions at the loop ends [2,4]. The radiation from the horizontal loops is approximately omni-directional and approximately equal to the radiation from the vertical sections (and is 90 degrees out of phase), resulting in circular polarization. The impedance of this antenna is not 50 ohms and requires a matching section [4]. If more gain is desired, then two or more elements can be stacked collinearly, with each element fed separately [2].

A simpler way to combine elements is to extend the vertical sections of each element until they touch. However doing this increases the vertical radiation and the antenna becomes mostly vertically polarized. Simulations have shown that this makes a very good vertically polarized omni with a small amount of horizontal polarization. The vertical polarization radiation can be reduced by reducing the diameter of the vertical wires [5]. The antenna described here is just such an antenna.

A test antenna was modeled for 146 MHz consisting of three horizontal loops

made of 3/8 inch diameter soft copper tubing and two #18 (0.040 inch diameter) vertical wires. Mininec is required for the modeling because nec cannot simulate an antenna made of two wires of very different diameters [6,7]. The design goal was to design a right hand circularly polarized antenna with 50 ohms impedance at 146 MHz.



A loop drawing is shown in Figure 2. For the top and bottom loops, L = 33 9/16 and S = 1 ¾. For the center loop, L = 28 and S = 1 ½. Cut the copper tubing to the lengths shown and bend them to approximate a circle with a gap as shown. All dimensions are in inches.

Then support the elements in some way. I used a ten foot length of ¾ inch schedule 40 pvc pipe. The spacing between the elements (and the length of the vertical wires) should be 57 7/8 inches. Figure 3 shows how the vertical wires and the loops are connected together. This figure is drawn from the point of view slightly off axis from the top or bottom of the antenna. The polarization from an antenna assembled in this way is right hand circular polarization (rhcp). The antenna is fed in the center of the center loop through a balun.

Figure 1 shows the assembled antenna on the roof. No patterns were taken, but the good agreement between the simulated and measured SWR (Figure 4) gives confidence that the antenna is working properly.

The simulated gains at 146 MHz are:

Right hand circularly polarized gain = 4.54+/-0.59 dB.

Vertically polarized gain = 2.76+/-0.05 dB.

Horizontally polarized gain = 0.63+/-1.45dB.

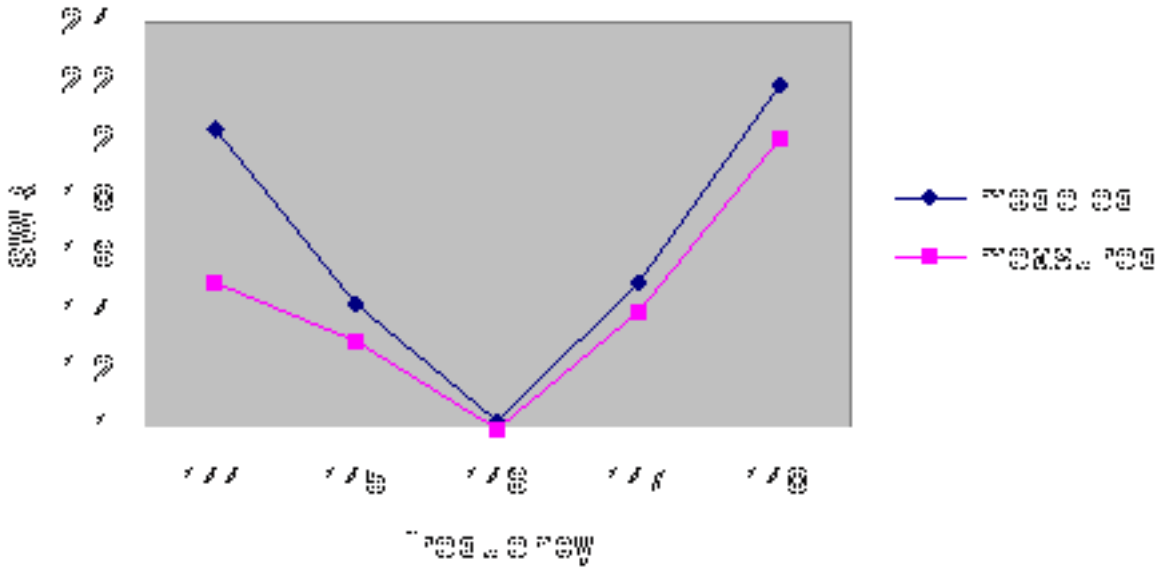


Figure 4

Adding more elements will improve the gain. If you decide to change the design goals using different diameters, more elements, or different frequency, you should resimulate using mininec. If you decide to make a mostly vertically polarized omni using the same diameter for the vertical and horizontal elements, then nec (which is more accurate than mininec) can be used.
I have not said anything about why you would want a cp omni. Please refer to the references for discussions on circular polarization.

keyword: omnidirectional

The HO Collinear, a Horizontal Omni

Figure 1

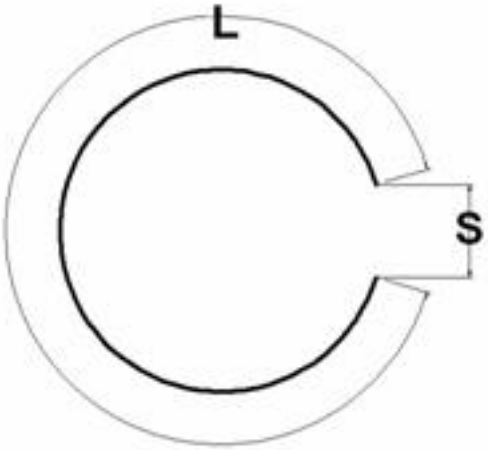
This paper describes a high gain, multi-element horizontal omni with a single 50 ohm feedpoint with instructions for building a 4 element array for 2 meters.

There are several ways to make a horizontal omni [1,2,3,4,5]. One popular type is the HO which is a half wave dipole folded into a square or a circle [6,7]. The impedance of this antenna is not 50 ohms and requires a matching section. If more gain is desired, then two or more elements can be stacked collinearly, with each element fed separately through power dividers.

A simpler way to combine elements is to connect the loops together by adding vertical extensions to the ends of each loop. The lengths of the loops and vertical wires are adjusted for maximum horizontal gain consistent with a 50 ohm feedpoint in the center of the bottom loop using an antenna modeling program. Since I decided to use 3/8 inch diameter soft copper tubing for the horizontal loops and # 18 wire for the vertical wires, I used mininec because nec cannot be used for antennas made of two wires of very different diameter [8,9]. It is possible to build this antenna with only one diameter wire, in which case nec can be used [10].

A test antenna was made for 144.5 MHz consisting of four horizontal loops made of 3/8 inch diameter soft copper tubing and two #18 (0.040 inch diameter)

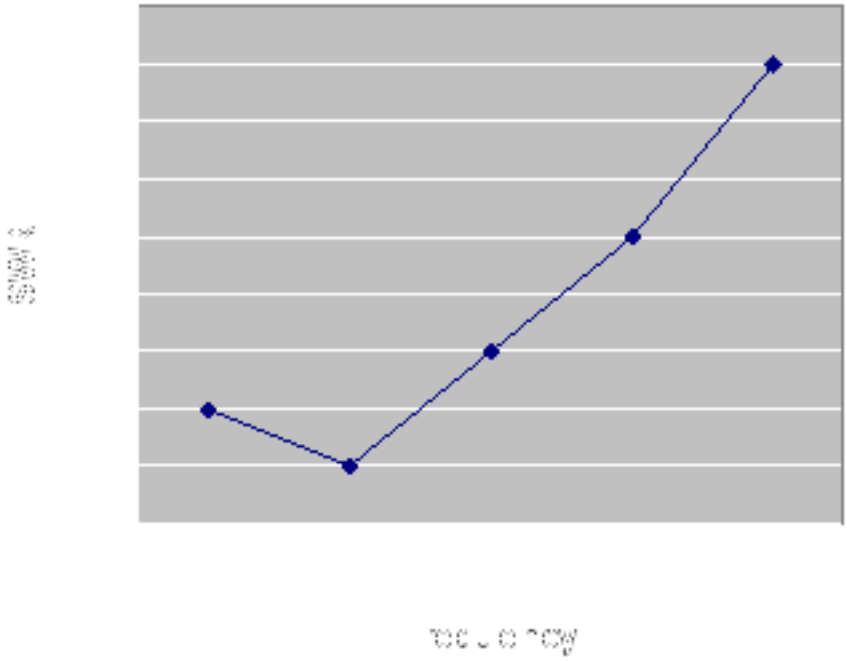
vertical wires. A loop drawing is shown in Figure 2. For the top and bottom loops, L = 31 7/16 and S = 1 5/8. For the middle loops, L = 28 5/16 and S = 1½. Cut the copper tubing to the lengths shown and bend them to approximate a circle with a gap as shown. All dimensions are in inches.



Then support the elements in some way. I used a piece of ¾ inch schedule 40 pvc pipe. The spacing between the elements (and the length of the vertical wires) should be 20 7/8 inches. Figure 3 shows how the vertical wires and the loops are connected together. This figure is drawn from the point of view off axis from the top of the antenna. The antenna is fed in the center of the bottom loop through a balun.

Figure 1 shows the assembled antenna on the roof. No patterns were taken, but the SWR (Figure 4) agreed with the simulated SWR (except for a 1% frequency offset error) which gives confidence that the antenna is working properly. The simulated gain is 3.27+/-1.22 dBi.

Figure 4



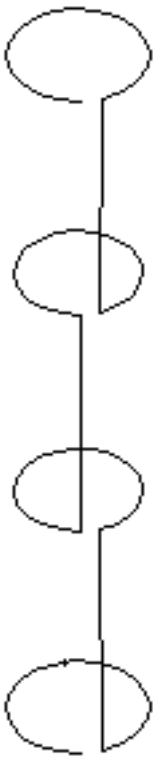


Figure 3

Adding more elements will improve the gain. If you decide to change the design using different diameters, more elements, or a different frequency, you should resimulate using mininec. Mininec

typically has frequency offset errors, so the final design may have to be tweaked a bit. I increased the vertical wire lengths from 20 to 20 7/8 inches from my original simulation (keeping the loop lengths the same). The frequency can also be adjusted by varying the gap at the end of the loops. Closing the gap lowers the resonant frequency (and also the impedance). Increasing the gap increases the gain variation (ie, makes it less omni). If you decide to use the same diameter for the vertical and horizontal elements, then nec can be used, but it may not be possible to get to 50 ohms.
One further comment. The spacing between the loops is smaller than is usually used in collinear arrays. This is because the electrical length between the centers of each loop is a half wavelength. The radiation from the loops is kept in phase by reversing the wire direction between adjacent loops (See Figure 3).

Fan-tenna... An antenna made from a fan?

Did you ever look at a broken household item and think 'I can't throw this out, there just must be some use for it in my ham shack'! That was the case when our fan gave up the ghost one summer. The more I looked at the metal cage of that fan, the more it started to look like the perfect radial system for some future two meter ground plane antenna.

Some quick figuring (234/Frequency [MHz]), showed that if the cage radius is anywhere near 19 inches, it would make a 'fan-tastic' ground plane. As it turned out, my cage had a smaller diameter, in fact it was only about 10 inches, but I went ahead with the project anyway.

In an effort to create an easy to build, not to mention cheap, antenna, I decided to raid the hall closet to confiscate an old wire hanger to use as the vertical portion of the ground plane. I cut the wire a bit long to leave plenty of room for adjusting to a 1 to 1 SWR. With the help Bob (N3LSS), and his 2 meter hand held, we cut and trimmed, and ended up with a textbook 19.25" vertical radiator and a perfect match.

Construction:

Construction is extremely simple. First you'll need a connector, to properly mate with the one on the end of your coax. I used an SO-239 connector from my junk box. Insert the connector through the center of one side of the fan cage. My fan cage conveniently separated into two halves and provided easy access for mounting the connector.

If the center section of your cage is plastic, be sure to attach a jumper from the connector to the metal portion of the cage.
Solder the coat hanger to the connector.
Lastly, attach your coax after routing it through the back side of the other cage half.

If you like to tweak and prune, start with a vertical length of about 21 inches. Cut off only 1/4 - 1/2 inch at a time! If you don't have access to an SWR bridge for the two meter band, just cut the whip to 19 1/4 inches and your match will be very close.
If outdoor use is anticipated, I'd suggest using an aluminum rod in place of the coat hanger in order to survive the winds.
Although a 19 inch radius cage is optimum, as this design shows, a cage diameter even half that size works so don't bother to try and modify its length at all.

Pretty 'fan-cy' huh?

Test out:

But does it work? We are fortunate to have access to a local repeater which has a unique feature. It provides a voice announcement of your signal strength into the repeater. A quick test with the new fan-tenna indoors, in front of a window, and on the ground floor, provided a better than expected 30 over signal.
Additional tests from the same location, using the hand held's existing whip, proved that the new ground plane was far superior and provided an amazing improvement in gain. Yes indeed, this antenna does work!

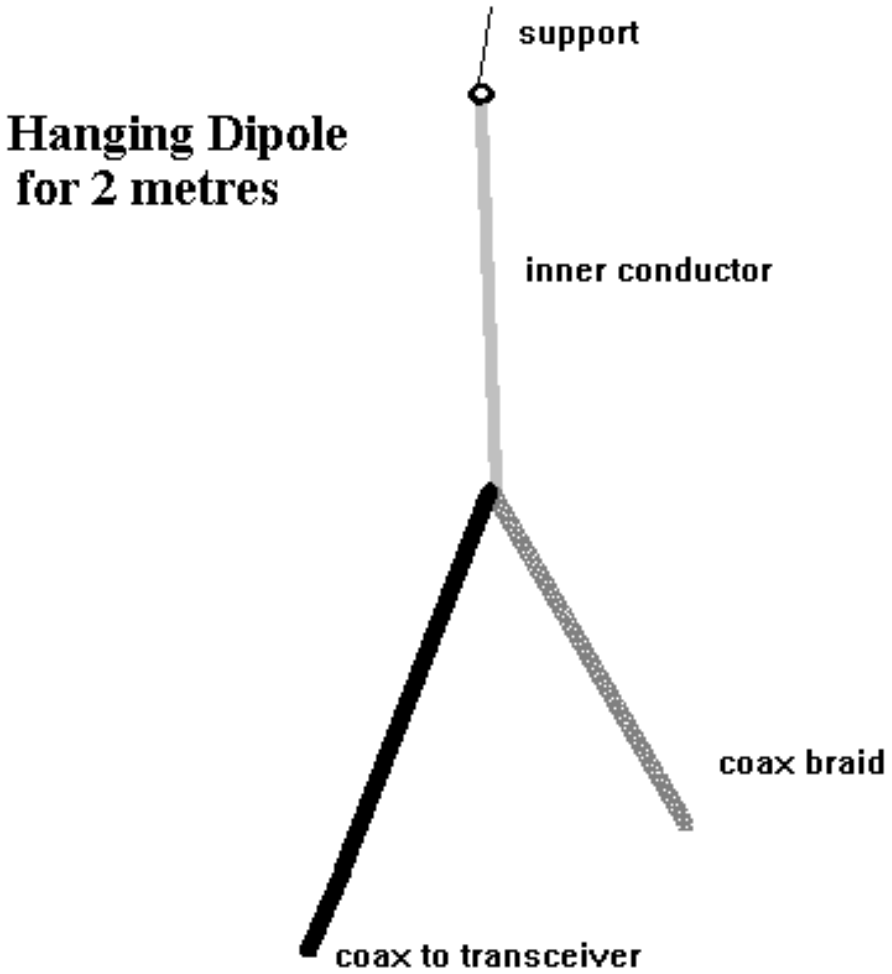
Build a hanging dipole for two metres

Described here is a simple omnidirectional, vertically-polarised dipole for two metres. Made from coaxial cable, it can be rolled up and stored in a small container. It may be used as is indoors, or waterproofed for use outside. No extravagant gain claims are made; this dipole has no more gain than any other. However, it should be significantly more effective than the antenna that came with your handheld. The cost of building the project is around five to ten dollars. Allow about 20 minutes to construct and erect the antenna.

A single length of 50 ohm coaxial cable forms both the antenna element and the feedline. The antenna is made by removing a quarter wavelength of outer jacket and bending the braid back along the cable towards the transceiver to form a vertical dipole. This means no metal work or wiring is required (apart from attaching the BNC or PL259 plug).

Download this image for a drawing of the completed antenna.



Parts required

The following is required to complete the project:-

- 3-4m RG58 coaxial cable (not critical - use longer length if height is needed or the operating position is distant from the antenna)
- PL259 or BNC plug (to suit transceiver)
- small metal lug, washer or nut
- tape measure, scissors, small screwdriver, long-nosed pliers, multimeter, fishing line, soldering iron

Construction

- Solder the PL259 or BNC plug to one end of the RG58 cable.
- From the other end of the cable remove 48 cm of the black plastic outer covering to expose the braid.
- With a small screwdriver (Phillips head is best) gently part the braid to make a small hole near where it ceases to be covered by the plastic jacket. Aim to make it about 5mm in diameter.
- Use either pliers or a screwdriver to pull the inner conductor out from inside the braid through the hole in the braid (Fig 2c).
- Fold the braid back along the cable towards the plug. Solder the end of the braid to prevent fraying.
- Remove about 5mm insulation from the inner conductor.
- Solder the end of the inner conductor to a small metal lug or nut.
- Thread fishing line through the lug or nut and hang the antenna in its desired position.

The antenna is now operational. You may wish to check the SWR and make it longer or shorter if the SWR is above about 1.5:1 at 147 MHz.

Erection and use

The antenna should be hung vertically for best performance. Keep it away from metal objects and have it as high as possible. Where signals are weak, hang the antenna near a window facing the repeater. If you intend to use the antenna outside, apply sealing compound to stop moisture entering the cable. Not doing this will mean poorer performance over time as cable losses increase.

The Grid Yagi

Figure 1

The Grid Yagi (or Grid Quad) is a high performance yagi antenna that can be built with readily obtainable inexpensive materials. Described here is a 6 element 2 meter version with a boom length of about 1 wavelength, shown in Figure 1.

The boom is made of 1½ inch pvc pipe, although any suitable material can be used, such as steel, aluminum, fiberglass, or wood. The elements are cut from 2 inch by 4 inch galvanized welded wire fencing, with a wire diameter of 0.078 inch, which is what #14 steel wire becomes when it is galvanized, and are shown in Figure 2. This fencing material and pvc pipe are available in any hardware store. The driven element and the four directors are all 24 inches by 24 inches. The reflector is 32 inches by 24 inches. The driven element has an 18 inch slot in it and is fed at the bottom of the slot. At the other end of the slot is a shorting wire.

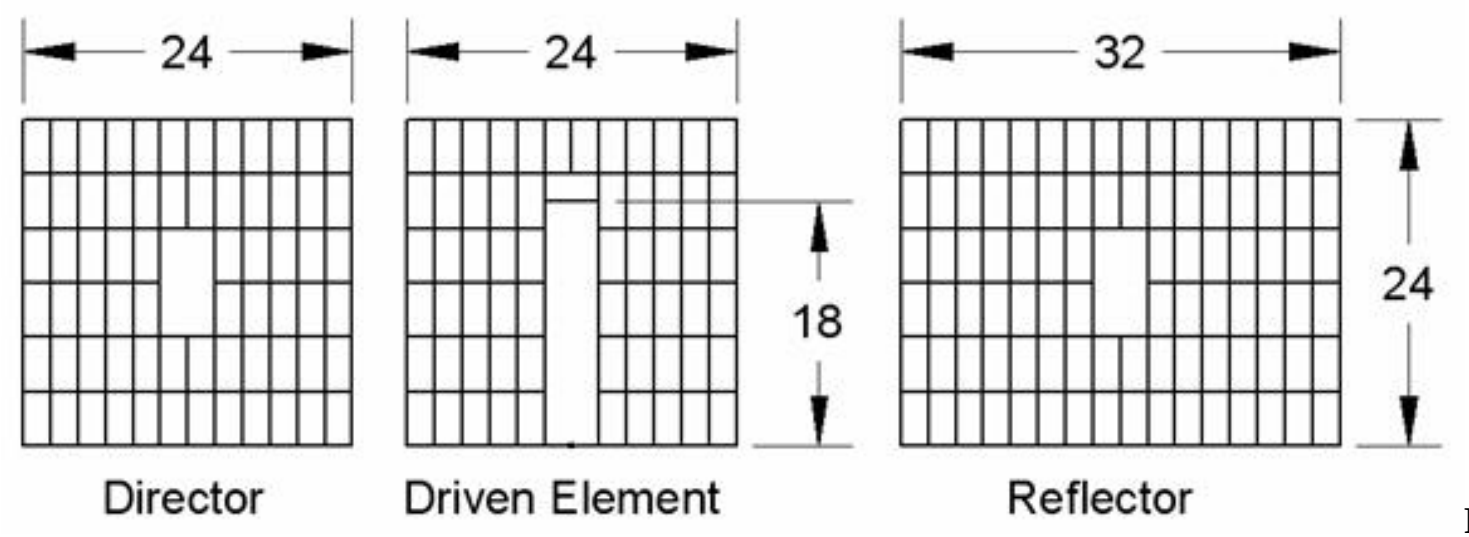

Figure 2

I attached the elements to the boom using 1/8 inch diameter fiberglass rods. Holes were drilled in the boom, and the rods passed through the holes and around the wires of the elements, two rods per element. Figure 3 shows the two fiberglass rods passing through the boom and around the wires of director D4. Rods were also used to stiffen the driven element where the feed slot was cut (not shown). The fiberglass rods were obtained locally at Tap Plastics [1]. It should be possible to use other stiff materials such as shish-kabob skewers. The element positions are shown in the Table. The elements can be glued in place or left unglued for easy disassembly.

Figure 3

Elements	Position
REF	0

DE	12 inches
D1	24
D2	38
D3	63
D4	86

Simulations were done using 4nec2, Arie's version of nec2, available free at Ray Anderson's Unofficial NEC Archives [2].

The antenna was fed with approximately 50 feet of RG-8 type coax with a measured loss of 1.3 dB through a W2DU type balun [3] with three Amidon beads, type FB-43-1020 [4]. Figure 4 shows the simulated and measured SWR. The SWR measurement was done using a MFJ-259B SWR Analyzer. I could have adjusted the length of the slot to move the SWR minimum to another place in the band if I desired.

The simulated gain is 11.9 dBi at 144 MHz, 12.1 dBi at 146 MHz and 12.3 dBi at 148 MHz.

VHF ANTENNA Projects and Ideas:

2 METER ANTENNA DESIGN GALLERY

The KB1DIG & KB1GTR Ham Page

The J-pole is one of the most popular home-brew antenna designs for vertical 2-meter Amateur Radio. Another interesting home-brew project idea is the Halo design horizontal antenna. I did some experimenting with a few variations of these type of antennas and came up with the designs posted on this page. The main reason I considered building my own antennas was to gain a greater understanding of RF technologies and to save some money in the process. Each antenna has a unique use and are actually fun to build. Most of the parts can be found at your local hardware store. If you try one of these please drop me a line to let me know how it turned out.

Send E-mail to: buck0@comcast.net Good luck building! 73's Steve KB1DIG

Personal note: 11/21/01

Please understand that the intent of this new section is not to sound off or show off. This is the first addition I've made to this page in quite some time. I was worried about changing something because it has become so popular. Links to this antenna page have been turning up all over the Web. That's great! I've enjoyed answering all the e-mail. A lot of things have happened in the last few months that have inspired me to continue this new project. My wife, Kim, now has her Ham ticket! Her Call is KB1GTR and I'm very proud of her. We both had the opportunity to help with the NYC/WTC Relief Effort through the Salvation Army Team Emergency Response Network, or SATERN. We were working with Logistics Communications from Oct. 7th through Oct. 18th. Looking back on our experiences, we determined the need to expend our capability for emergencies on a daily basis. Aside from already being involved with local 2-Meters as Net Control Operators, we recently joined the New Hampshire ARES/ RACES.

Thanks for all of your support! 73's Steve KB1DIG

we remember...the day the world changed

EMERGENCY EQUIPMENT IDEAS

GO KIT: DAILY EMERGENCY COMMUNICATIONS GEAR IDEAS

Nov. 21st, 2001, By Steve KB1DIG & Kim KB1GTR

How do we get all this HT equipment out of the drawer and into our hands when we need it? With a little research, we came up with the ideas and links posted in this section. Our favorite *quote* comes from C. Edward Harris, KE4SKY, VA RACES State Training Officer: *"It is better to have the bare essentials always handy than to leave a bulky pack someplace where you can't get to it."* This has been our inspiration for this project. As always, we are open to your suggestions and comments.

THE BOX: PORTABLE EMERGENCY COMMUNICATIONS STATION IDEAS

Jan. 9th, 2002, By Steve KB1DIG & Kim KB1GTR

Time for Plan B! This is a spin-off of the Go Kit project. Intended for portable long-term usage and also good for Field Day Events. Something requiring a little more power output than the HTs. A diamond in the rough. This "Box" is going to be under constant refinements this year with your suggestions and comments.

Anderson Powerpole Ideas: Get Everyone Connected!

Nov. 6th, 2003, By Steve KB1DIG & Kim KB1GTR

Anderson Power Products and Powerpole® connectors. We have been doing research on this product and here are some of our findings. This overview may be familiar. Most of this information was found from different sources on the Internet and several Web links are listed on this page. We hope this will offer some new insight into how to go about integrating this Anderson Powerpole product into everyone's emergency power equipment needs. Our suggested attempts at leveling the playing field.. Also, keeping costs reasonable for the high-tech low budget practical minded Amateur in all of us. We are not experts and have no affiliation with the manufacturers or sales vendors mentioned. If you have something to contribute to this page and topic please send us your ideas and comments.

The following are some good emergency antenna projects to consider building. There are several reasons to consider building your own antennas for emergency work which include:

1. They are not expensive so if you loose them, or they get destroyed during the event you're not out big bucks!
2. You will gain a greater understanding of RF technologies especially antenna design.
3. You will learn how to improvise!
4. Last but not least, its fun!

Each antenna has a unique use. Please consider experimenting and playing! Share your success on the weekly nets as well!

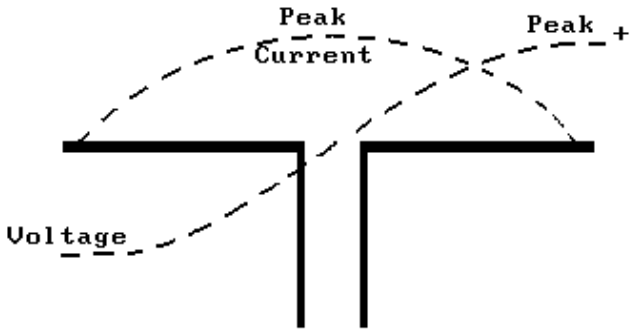
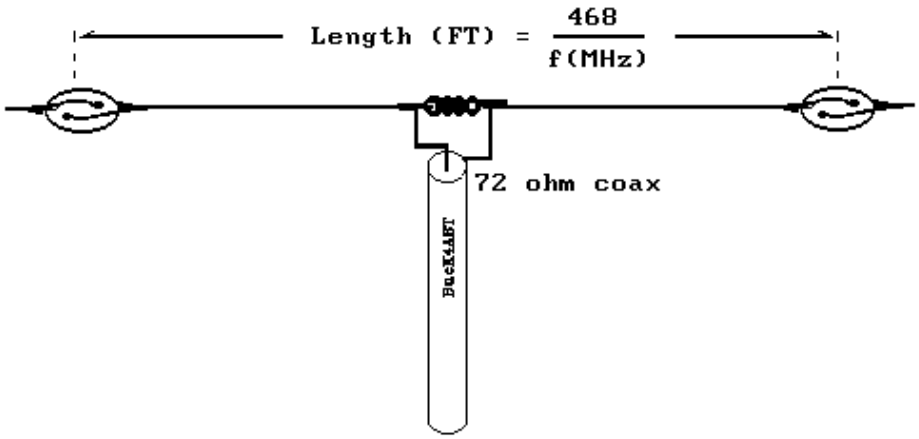
- **Design your own QUAD antenna.**
- **A 4 element, six meter QUAD design using *Design-A-Quad*.**
- **Antennas and Antenna RF Meters**

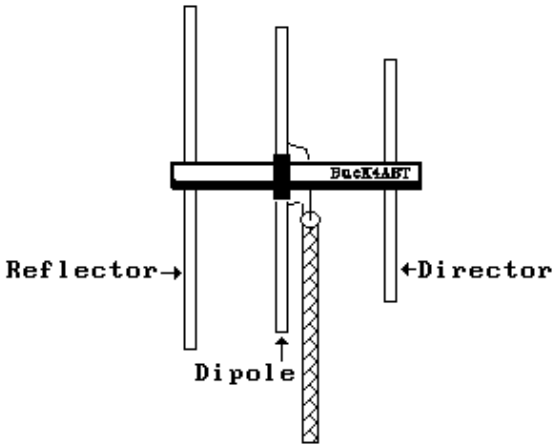
BUT FIRST.... let's review some antenna "basics" in pictorial form.



The basic dipole consists of two charges or elements which receive signals of opposite polarity.

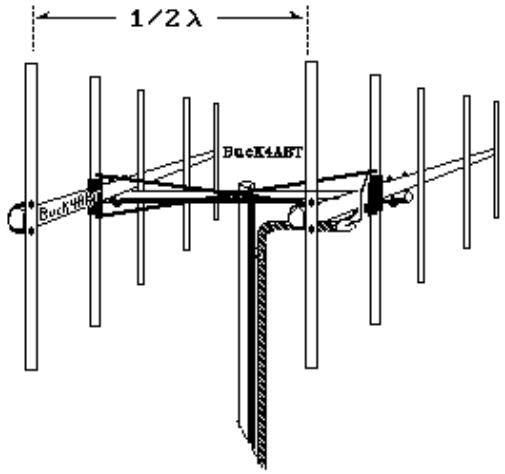


A dipole is a half-wave antenna fed at the center. The impedance at the center is near 72 ohms.

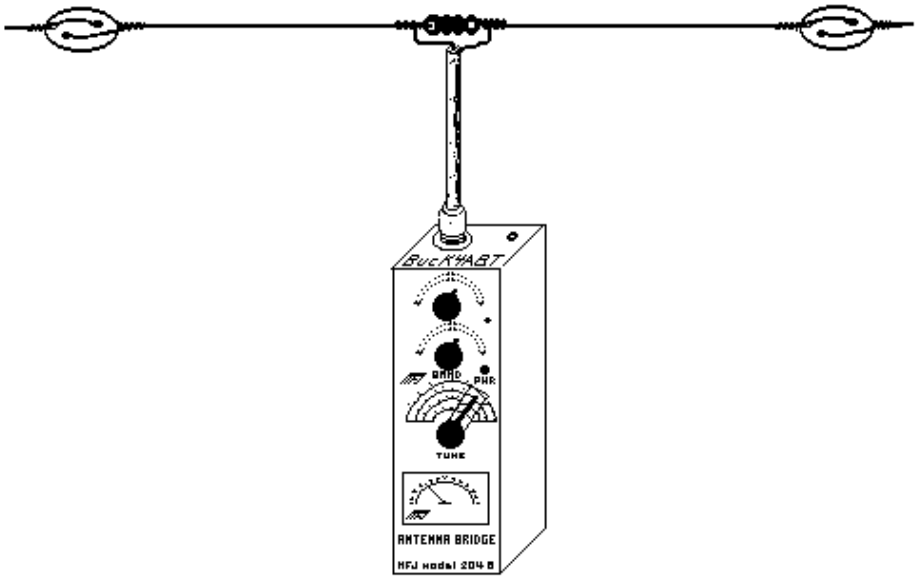


Adding a reflector and a parasitic element (director) to the dipole greatly improves its gain and directivity. Thus, the dipole becomes a "YAGI" antenna.

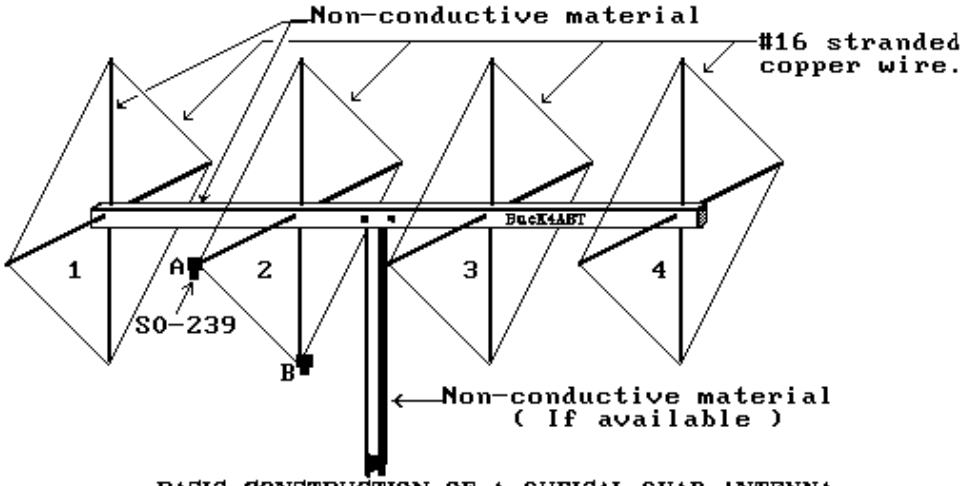
Good photos of VHF & UHF YAGI



Two yagis, stacked 1/2 wavelength apart will render another 3 dB of gain.

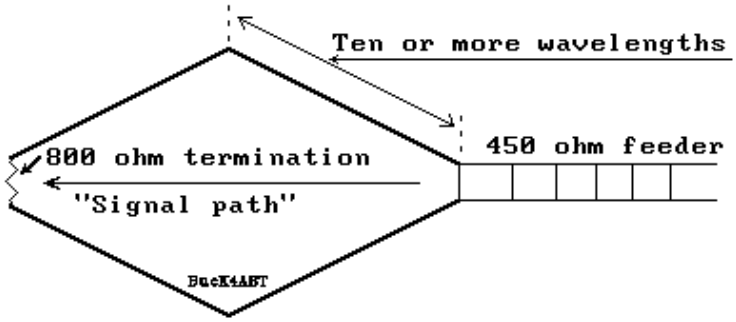


By using the "ANTENNA BRIDGE" the guess-work is removed and the correct cable length and impedance is sooner realized.

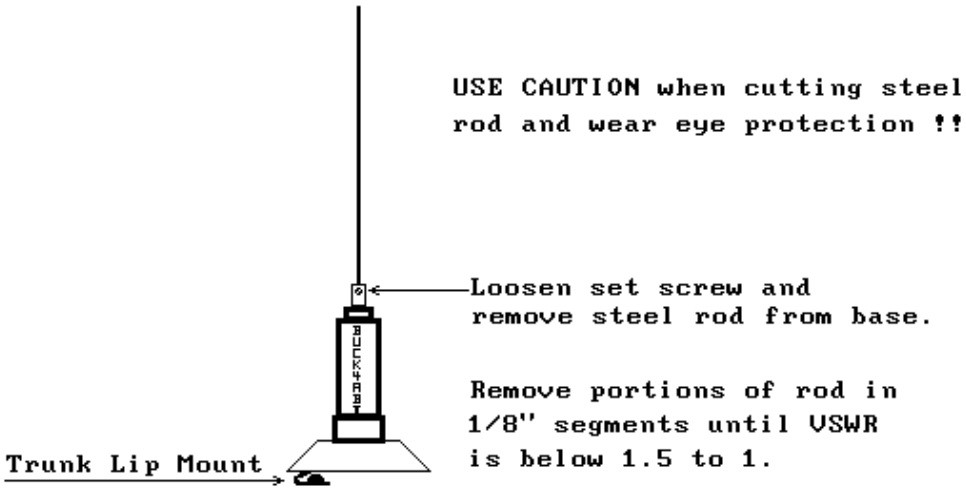


BASIC CONSTRUCTION OF A QUBICAL QUAD ANTENNA

The "QUAD", feed point "A" for vertical polarization. Feed point "B" for horizontal polarization. Element (1) is reflector, (2) is driven element, 3 & 4 are directors.



The "ROMBIC" is a highly directional and very high gain antenna. It also requires a large parcel of real-estate.



Method used to modify some CB antenna for ten meter use. NOTE: DO NOT over-tighten set screw.

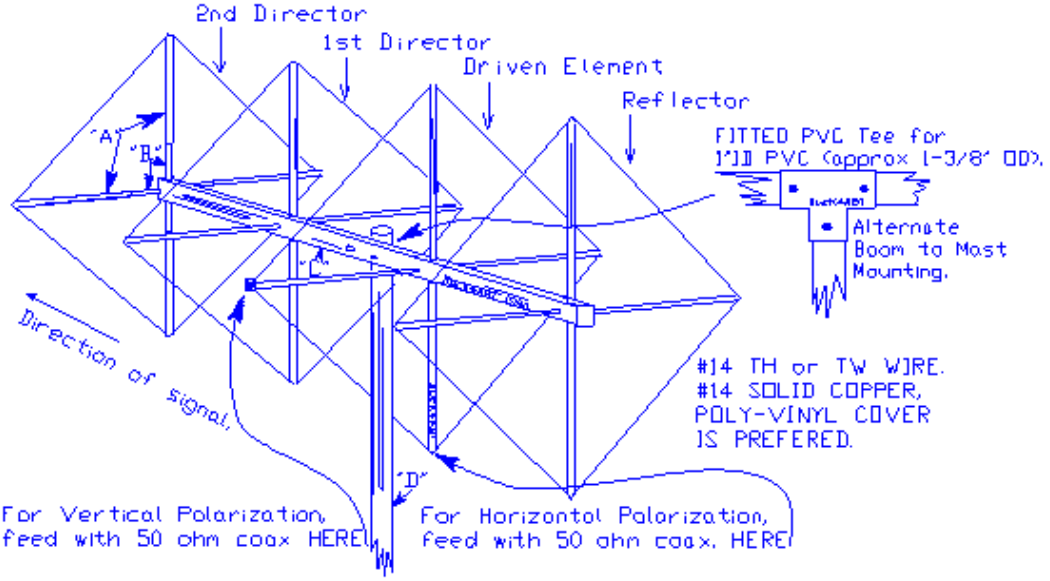
CLICK HERE AND DESIGN YOUR OWN "J" Pole

Design-A-Quad Antenna



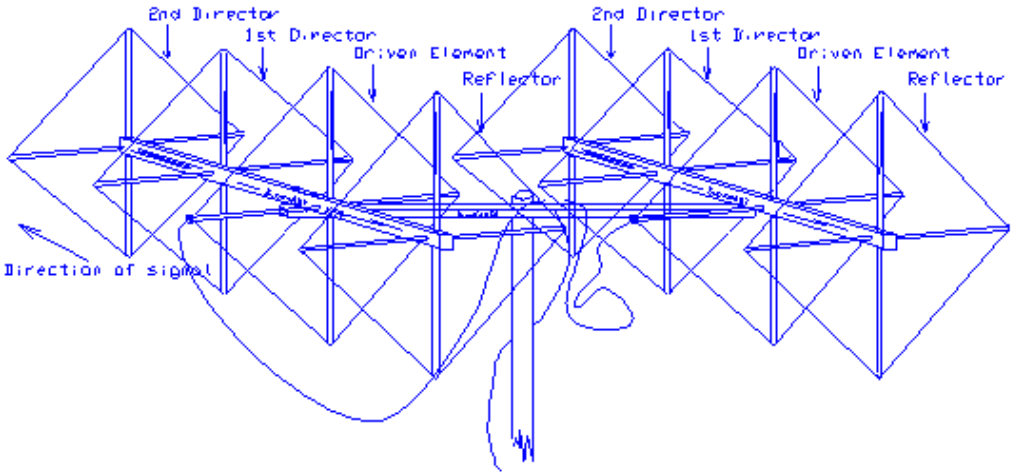
"A" = 1/2" ID hot/cold PVC. PVC should fit securely over 1/2" OD wooden dowel "B."

"B" = 1/2" OD wooden dowel 2 ft long through 1" ID boom. Dowel should extend approximately 9-1/2" out from each side of 1" ID boom. Fit 1/2" PVC ("A") over dowel. Make sure spreader is long enough to support each wire element length as determined by the calculations below. Once PVC is in place over the wooden dowels, drill with small bit and use short wire or picture hanger nail to secure on the dowel. Hot glue may be used as an additional keeper over the wire or nail head.

"C" = Boom may be made from square fiberglass or from round PVC 1" ID. Boom is drilled with 1/2" bit at points where wooden dowels are to be inserted.

NOTE: Make sure the vertical and horizontal dowel holes are drilled offset so the dowels will by-pass each other inside the boom. Drill dowels with 1/16" (or smaller) bit each side of boom and secure with small nail or wire to hold (centered) in place. BOOM is thick wall "Sked 40" 1" ID PVC.

"D" = 1" ID (sked 40/Thick wall) PVC 48" long. Use "fitted" wooden dowel inside to make it more rigid and provide "body" to area where "U" bolts may be attached (rotor head and to boom). See alternate boom mounting.



Horizontal "stacking" of quads will improve the signal strength by at least 3 DB. The QUAD's inherent immunity to terrestrial noise, makes it the ideal antenna (beam) for Packet Radio use.

Measurements and dimensions for the QUAD antenna are found using the QUAD design calculator below.

Calculate the total wire length for each element of a quad antenna.

REFLECTOR = 1030 / F (MHz)

DRIVEN = 1005 / F (MHz)

DIRECTOR 1 = 975 / F (MHz)

DIRECTOR 2 = 960 / F (MHz)

ELEMENT SPACING ***between:***

1) Reflector & Driven Element = 730 / F (MHz)
2) Driven Element & 1st Director= 600 / F (MHz)
3) 1st Director & 2nd Director = 600 / F (MHz)

Enter the formula for the antenna calculation

Divided by Freq MHz

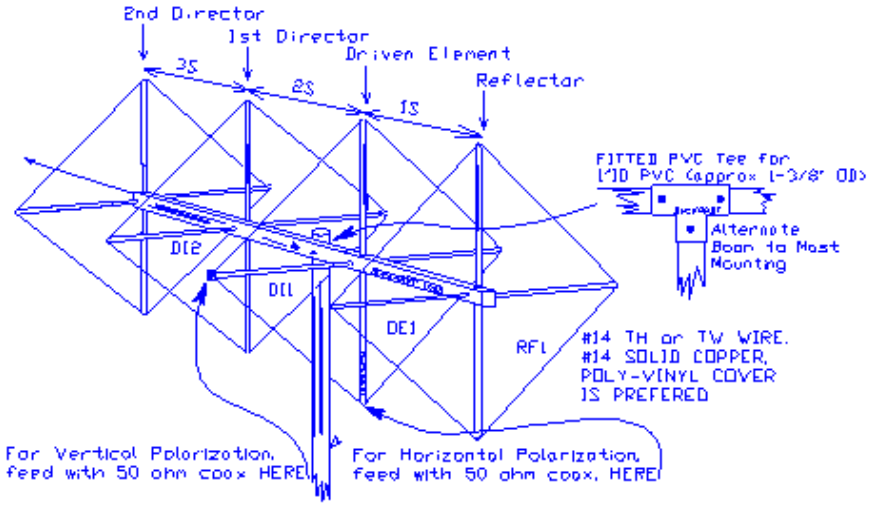
Total wire-length in feet is ***FEET.***

Total wire-length in inches is ***INCHES.***

One of four sides in FEET = **<- Use ONLY this number for "element spacing" when entering the *element spacing* numbers (constants; 730 or 600) above!**

Total all spacing measurements (in inches) then add 2 inches for each end.

THE QUAD SHOWN BELOW IS AN EXAMPLE OF A QUAD DESIGN USING *DESIGN-A-QUAD* ABOVE



AN EXAMPLE OF A 4 ELEMENT, SIX METER QUAD

TOTAL ELEMENT WIRE LENGTHS	LENGTH OF ONE SIDE
RF1 = 241-3/4 INCHES	60-1/2 INCHES
DE1 = 236-0"	59-.0"
DI1 = 229-.0"	57-1/4"
DI2 = 225-.0"	56-1/4"

ELEMENT SPACING
1S RF1 to DE1 = 43 INCHES
2S DE1 to DI1 = 34 INCHES
3S DI1 to DI2 = 34 INCHES
ADD 2 INCHES AT EACH END
TOTAL BOOM LENGTH = 115 INCHES

When stacking two of these quads, use 44 inch lengths of 75 OHM cable from Coax "TEE" connector to each Quad. Coax from transmitter to "Tee" is 50 ohm coax. As viewed above, for vertical polarization, feed both quads as shown (left side). For Horizontal polarization, feed both quads at bottom of the driven element (as indicated).

ANTENNA INSULATORS

Weatherproof, (TENYTE) insulators. Perfect for your DIPOLE or Windom antenna.

For the apartment dweller, you can now hang the 20 meter doublet in the attic. I've QSO'd with stations all over the world with the 33 ft dipole in the attic of my garage. One insulator at the center, and one at each end.

It's great for other HF WINDOM, single, and multi-band dipole antennas. Dielectric strength is superior to the old ceramic insulators, without susceptibility to cracking or breakage under impact or extreme temperature changes.

For those who want lightning protection, here is one of many, lightning protection device.

A Secondary Lightning Protector

Remember the axiom; ***"An ounce of prevention is worth a pound of cure."*** This lightning protector contains a modified spark gap that provides that ounce of prevention. We offer this device as a *secondary* radio protector. Remember, there is no substitute for a good earth ground, AC line surge, and spike protection.

Keep all ground leads as short as possible. Where lightning is involved, we make no warranties.

At BUX COMM, *We don't cut corners!

The components used in the manufacture of our BALUNs are from top quality components, beginning with the Silver Plate SO239 connectors. The center insulator is teflon™(E.I Dupont). The wire we use to wind the ferrite donut is heavy-duty, silver flashed wire, with teflon™ insulation that will handle RF voltages above 5000 volts, and temperatures above 2000 degrees. The binding posts are heavy-duty, tempered brass, with end holes and side-thru holes to accommodate either type loop-thru connection. A double-shoulder brass capture nut is used to add a secure bite and improve antenna wire electrical connections.

BUX MOBALUN

When you hear those strong HF mobile signals, here's one reason they stand out from the rest.

By installing the BUX MoBalun near the input to your antenna, you deliver more RF energy to the antenna. At the same time, the BUX MoBalun prevents RF from traveling back along the shield (high SWR) of your coax. High power rating, Low-permeability toroid, with Internal composition fiber-glass to prevent vibration during mobile operation. For input and output connectors, we use only the best Silver plated, Teflon insulated, SO239 connectors. 500 watts PEP. ***This MoBALUN is also ideal for marine antenna installations.***

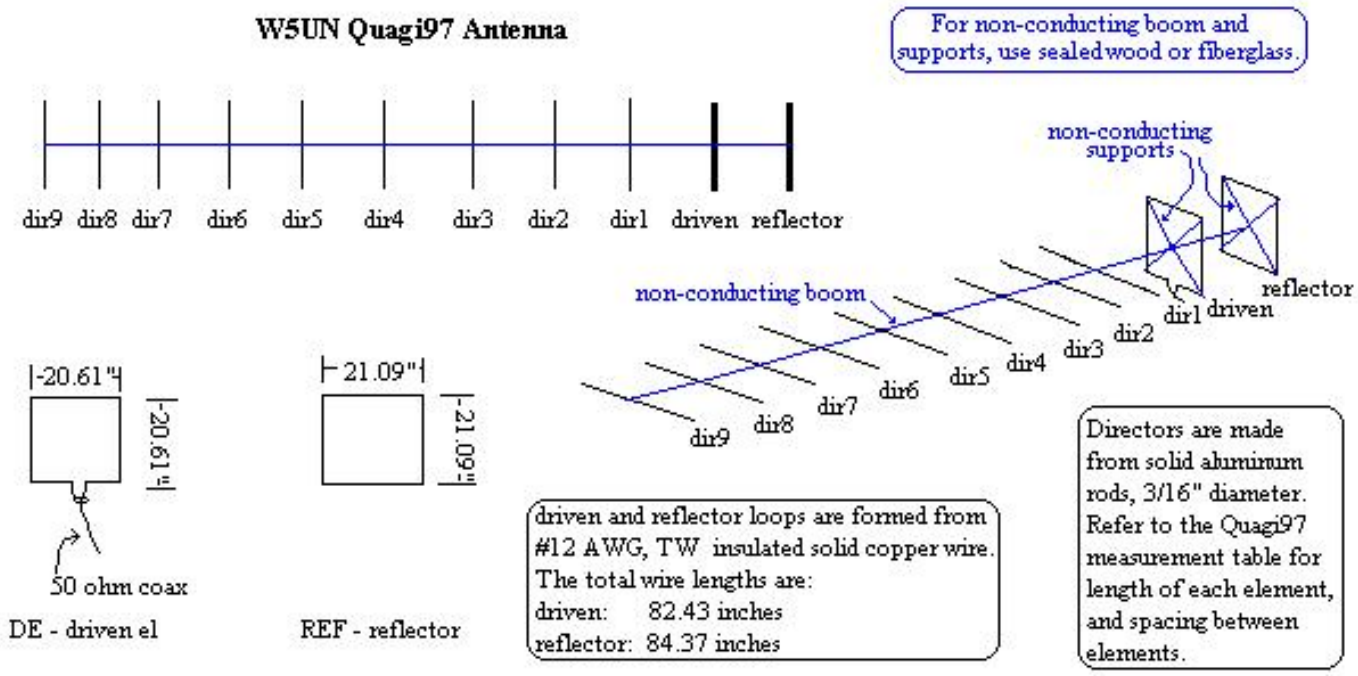
THE W5UN 2 METER QUAGI 97
Issue 2, July 17, 1997

The W5UN Quagi 97 is a computer optimized quagi derived from the original W5UN Quagi of the early 1980s. The length of the 1997 model has been deliberately shortened to allow it fit on a 24 foot boom. Performance is substantially higher than that of the original antenna. It now compares favorably with yagis of the same length. The two programs used to optimize the updated antenna were AO6 and NEC 2.

This antenna has not been verified by actual construction. Gain and front to back will be as stated below. The only component of the antenna that needs verification is the 50 ohm match. *Who would like to be the FIRST to build the actual prototype model??* Full consultation will be available to the prototype builder during construction. Contact w5un@wt.net if you wish to be the first!



Antenna Characteristics:
23' 9"
11 Element Gain: 13.56 dBd at 144.100 Mhz
F/B : 23 dB Stacking: Optimum: E Plane: 13.73'
Optimum: H Plane: 12.86'
Stacking can be reduced up to 90 percent of optimum and still achieve acceptable stacking gain. Optimum stacking is recommended, however. W5UN QUAGI 97 Dimensions in FREE SPACE:

Element	Boom Pos.	El. Length	Material
Reflector	0.0000"	84.37" loop.	#12 solid INSULATED copper wire *
Driven	16.2500"	82.43" loop.	#12 solid INSULATED copper wire *
Dir 1	37.1875"	36.168"	3/16" aluminum rod
Dir 2	70.1875"	36.052"	3/16" aluminum rod
Dir 3	102.5000"	35.817"	3/16" aluminum rod
Dir 4	135.8125"	35.475"	3/16" aluminum rod
Dir 5	169.0625"	35.179"	3/16" aluminum rod
Dir 6	202.8125"	35.090"	3/16" aluminum rod
Dir 7	234.2500"	35.324"	3/16" aluminum rod
Dir 8	264.8750"	35.617"	3/16" aluminum rod

```
Dir 9      285.0000"     35.108"       3/16" aluminum rod
```

* #12 TW insulated solid copper wire is common house wire, found at most hardware and building supply stores. Do not strip the insulation.

The above dimensions may be used for non metallic booms like wood or fiberglass.

If you wish to use a metal boom with through the boom insulated elements, please apply the following correction to the directors only. The reflector and driven quad elements must remain insulated from the boom.

Boom Diameter	Correction	Add
0.750" or 19.050MM	10.56%	.0792" or 2.02MM
0.875" or 22.225MM	12.14%	.1062" or 2.70MM
1.000" or 25.400MM	13.66%	.1366" or 3.47MM
1.125 or 28.575MM	15.13%	.1702" or 4.32MM
1.250" or 31.750MM	16.54%	.2068" or 5.25MM
1.375" or 34.925MM	17.90%	.2462" or 6.25MM
1.500" or 38.100MM	19.21%	.2882" or 7.32MM
1.750" or 44.450MM	21.67%	.3792" or 9.63MM
2.000" or 50.800MM	23.91%	.4783" or 12.15MM

(End of Table)

Further information concerning use of metallic booms with insulated 'thru-the boom' mounted elements follows:

PROVEN ACCURATE FOR BOOM DIAMETERS SMALLER THAN .055 WAVELENGTHS.

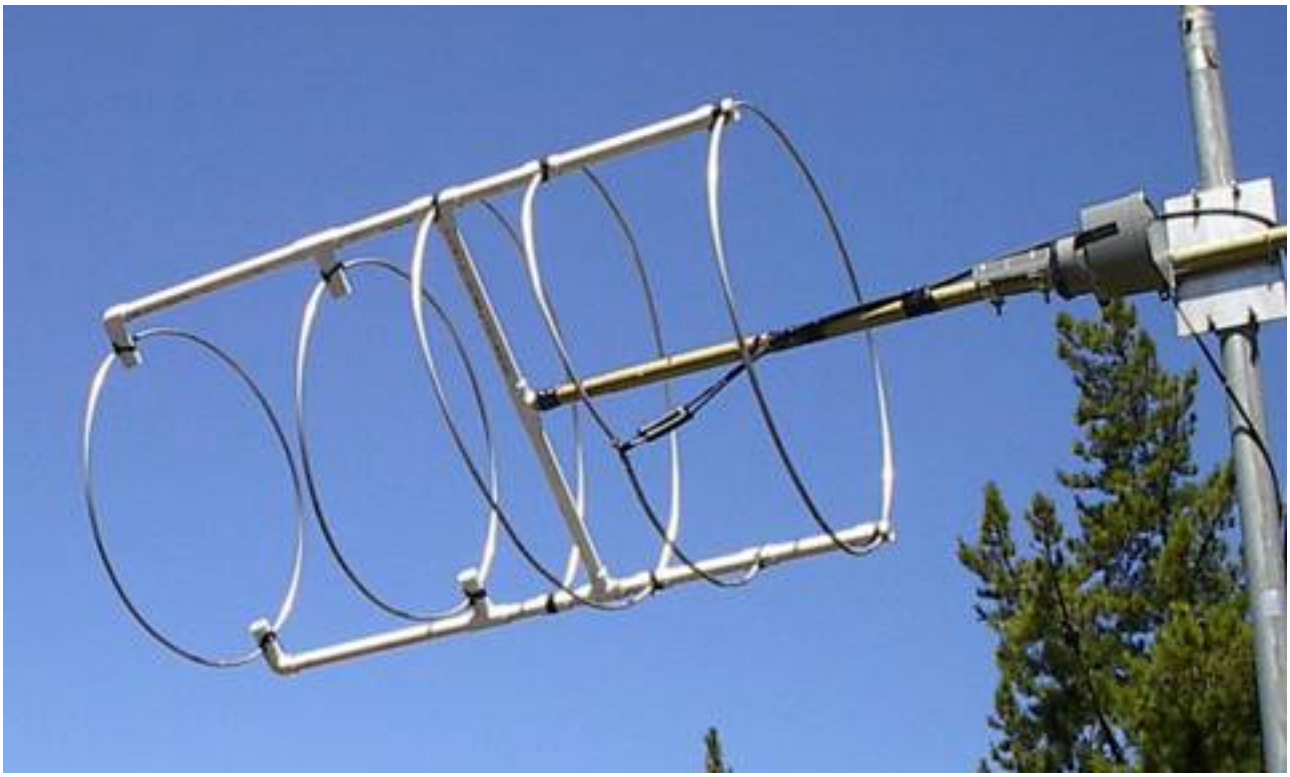
Insulators can be commercial shoulder insulators and keepers or as simple as

heat shrink tubing with the element held in place by hot melt glue or epoxy glue.

The Quadix



The Quadix is a circularly polarized parasitic array, a hybrid between a helix and a quad (or loop yagi). As is the case with other yagi type parasitic arrays, it has a reflector and as many directors as desired. A two turn helix is used as the driven element. The helix is driven ¼ turn from the end of the helix closest to the reflector. Its impedance is a nearly constant 300 ohms across a wide band for a conductor size of 3/8 inch. As with off center fed antennas, the feed point is not balanced, so a current balun is required. A tv/fm balun works well. Or there are many other balun possibilities (see below). I will now describe a 4 element 2 meter quadix.

Its bandwidth exceeds 144 – 148 MHz. Over the 144 – 148 MHz band, its free space gain is simulated to be about 10.5 dBi, and axial ratio less than 2 dB. The SWR is measured to be less than 1.2 when used with an innovative 300 ohm to 50 ohm balun transformer (described below), and axial ratio measured to be less than approximately 1 dB across the repeater output band 145.2 – 147.4 MHz, the source of my test signals.

The support structure is made from 3/4 inch PVC pipe.

The elements are made of 3/8 inch aluminum refrigerator tubing, obtained locally (Sunnyvale, California) from Orchard Supply Hardware. If aluminum refrigerator tubing is not available, you can use copper refrigerator tubing.

The total length of the helix driven element is 179 3/4 inches. Mark it at 44 15/16 inch intervals to show where it passes through the PVC pipe. Also mark it 22 ½ inches from one end. This will be where the balun is attached. The total length of the reflector will be 89 9/16 inches. The total length of the directors is 76 3/16 inches. Mark each of them at the halfway point.

Before assembling the antenna, temporarily connect the ends of each of the elements together and shape them into circles. The driven element should be shaped into a two turn circle.

Assemble the antenna by feeding the elements through the holes drilled in the PVC assembly. The ends of the directors and reflector can be connected together by flattening and securing with bolts, by slotting one end and squishing it down to fit into the other end and securing with a bolt, or by fitting a sleeve over the two ends and securing with a pipe clamp. If one of the overlap methods is chosen, don't forget to allow for this when cutting the tubing.

Before assembling the helix driven element, cut out a ½ inch section of tubing at the feed point and replace by an insulating material. An insulator fashioned from a piece of PVC coupling works well. For right hand circular polarization, feed the helix clockwise through the holes in the PVC assembly as shown in the picture. Secure the elements to the PVC structure. Connect the antenna to a boom, and the balun and feed line to the antenna, and you are ready to go. If you want to measure the axial ratio against a friend's linear polarized signal (or local repeater signals), you need to attach a small rotator to the boom.

A 300 ohm to 50 ohm quarter wave balun transformer that is simple to make is shown.

It consists of a quarter wave transformer made from RG-58 and RG-59 in series. The impedance of the quarter wave transformer is 53 plus 73 equals 126 ohms, which transforms 300 ohms to 53 ohms. The balun action comes from the fact that the two sides of the 126 ohm transmission line (the center conductors of the coaxes) are isolated from each other. The balun is improved by puting approximately 8 ferrite beads onto each line. It has been pointed out to me by BB that there should be a few beads also on the 50 ohm line near where it connects to the balun.

THE SPERRTOPF ANTENNA FOR THE TWO-METER BAND

By ON4CFC, Pascal Veeckmans ~ Translation by Jef Verborgt

To read the PDF, you must have ***Adobe Acrobat Reader 4.0*** installed to download and read the article. If you don't have Acrobat Reader **4.0** installed, it's available free for download at http://www.adobe.com/acrobat

Due to the complexity of this article, we have chose to present it in PDF form. Although the loading is a little slower (overall), some of the many advantages of the PDF format is it contains all of the article's intended formatting allowing ***proper printing*** of the article as seen on the screen. Further, it has the ***fonts embedded*** into the article, especially important when using a character set that may not be on the reader's computer, such as the ***Greek symbols*** used for equations. So, the reader can ***save and print*** the PDF article totally intact exactly as it was originally intended.

Other important features are, with Acrobat Reader, the reader can ***magnify*** (zoom in or out) the article to many different levels so that those superscripts or subscripts can be seen with total clarity. And if the reader wants to, the article can be ***rotated*** making it easy to view diagrams from different angles!

For those who have slower Internet connections, or prefer, we have also provided a copy of the PDF article in a compressed ZIP file. The file is much smaller and will take less time to download. Also, you will be viewing the article from your hard disk and navigation of the article will be faster than over the Internet. Further, for those who choose to load the PDF online, you may also save it to hard disk and view offline as well. To unzip the ZIP file, you need a program like ***WinZip*** or comparable available for free trial download at: www.winzip.com

Cheap Yagi Antennas for VHF/UHF

by Kent Britain, WA5VJB
edited by John Maca, AB5SS

[***Editors notes:*** *The antennas described in this article were built as the result of several discussions between Kent and a Cuban radio operator. While there are plenty of high performance antenna designs, most of the parts required to build them are not available in Cuba. There just isn't an EPO or Radio Shack available in Cuba. Kent accepted this as a challenge to design a really good antenna that could be built with little more than ground wire, coax and a wooden boom. Using the latest antenna design software, he has developed several variations for 144 thru 1296 MHz. Apparently, the designs work very well... Kent entered the 432 MHz version in a recent antenna contest and lost by 0.2 dB to a Midwest ham who had copied his design. Though disappointed in losing, it did prove to Kent that the antennas can be easily replicated with consistant performance.*]

If your planning to build an EME array, don't use these antennas. But, if you want to put together a Rover station with less than $500 in the antennas or just want a good antenna for the home, read on.

These antennas are relatively small, easily constructed from common materials/tools and have surprising performance. The feed method is greatly simpified by directly soldering the coax to the driven element. No baluns or gamma matches are used in this design. This simplified feed uses the structure of the antenna itself for impedance matching. The spacing of the director and reflector elements from the driven element directly affects the feed point impedance of the antenna. So, the design starts with the feed (driven element) and the elements are built around it. Typically, a high gain antenna is designed in the computer, then you try to come up with a matching arrangement for a 31.9 Ohm feed! For the cost about 0.5 dB of gain, these antennas make some design compromises for the feed impedance, use an asymmetrical feed and make trade offs for a very clean pattern. But, they allow simple measurements, have wide bandwidth, the ability to grow with the same element spacing AND... you can build these antennas for $5!!!!

The booms used for these antennas is 1/2" X 3/4" wood. The elements have been made from silicon bronze welding rod, aluminum rod, hobby tubing and solid ground wire with no change in performance. Since you want to be able to solder to the driven element, silicon bronze welding rod, hobby tubing and #10 or #12 solid copper wire have been used and work fine. A drop of "Super Glue", epoxy or RTV is used to hold the elements in place. A good coat of Polyurethane should be applied to the wooden boom to protect it from the weather. A polyurethane varnished 902 MHz version has been in the air for a year now with little deterioration in performance.

And now for the antenna designs. These antennas have been carefully designed to have the highest dB's/Dollar ratio of anything around They were designed with YagiMax, tweaked using NEC and the driven elements experimentally determined on the antenna range. The driven element design is the same for all frequencies except for the length (L) and separation (H). See Figure 1 for details on the driven element. All dimensions are in inches.

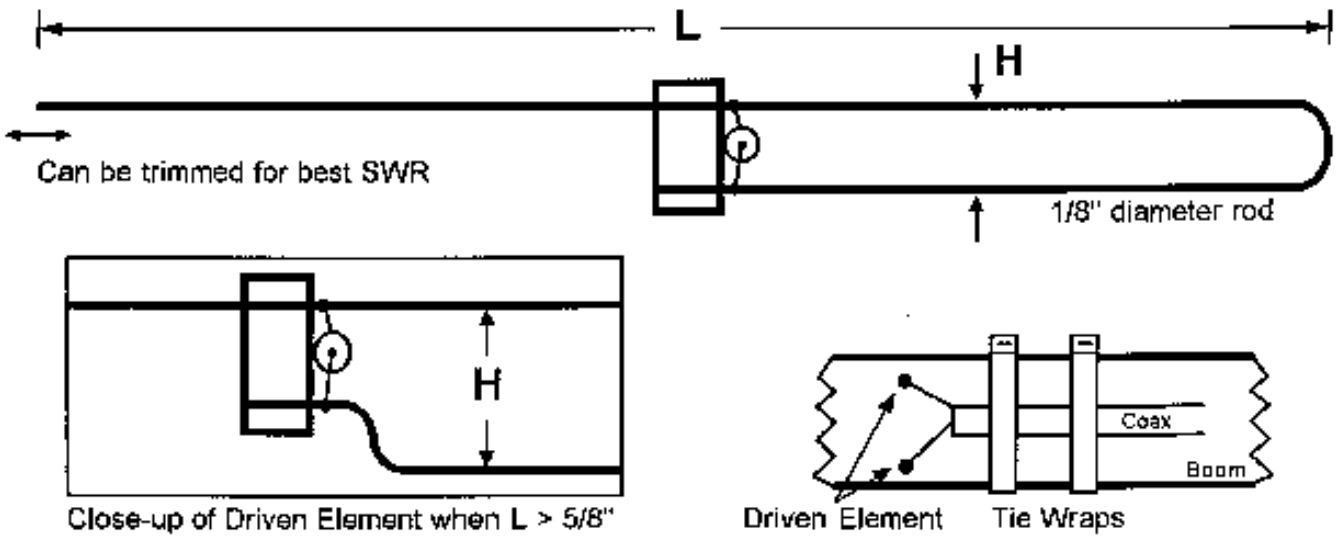
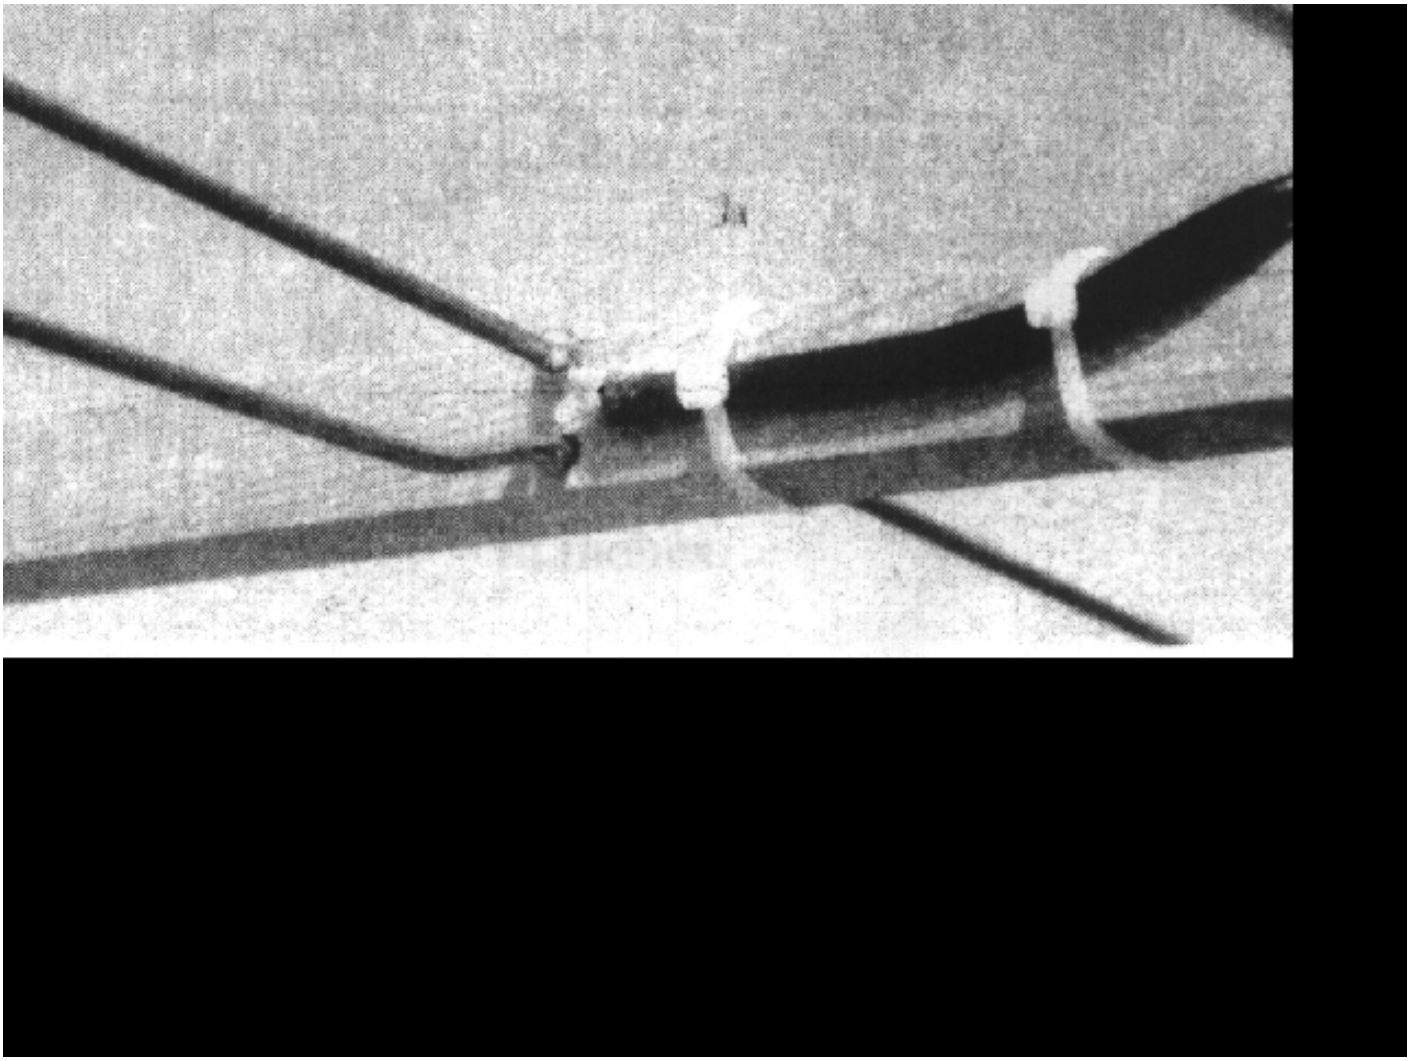
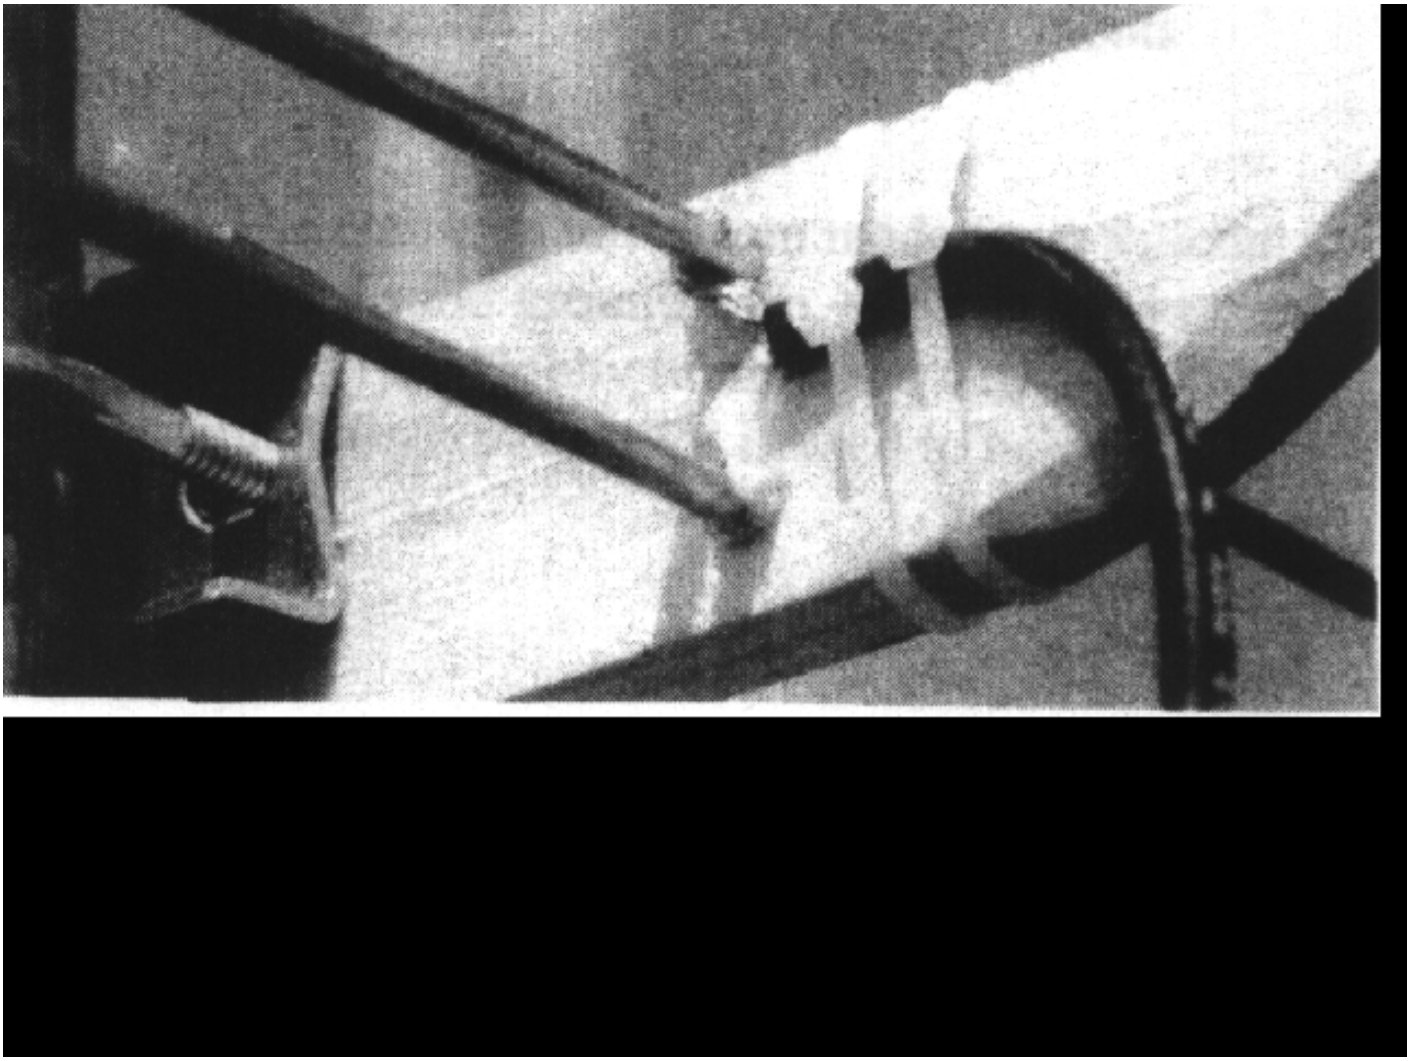
Driven Element Construction (*all versions*)



Close-up of Driven Element when L > 5/8"

Driven Element Tie Wraps





144 MHz. This antenna is peaked for 144.2 MHz but performance is still good at 146.52 (emergency use only!) Driven element dimensions are L = 38.5" and H = 1.0" Elements are 1/8" diameter.

144 MHz		**REF**	**DE**	**D1**	**D2**	**D3**	**D4**
3 Element	Length Spacing	41.00 0.00	8.50	37.00 20.00			
4 Element	Length Spacing	42.00 0.00	8.50	37.50 19.25	33.00 40.50		
6 Element	Length Spacking	40.50 0.00	7.50	37.50 16.50	36.50 34.00	36.50 52.00	32.75 70.00

222 MHz. This antenna is peaked for 222.1 MHz but performance bearly changes at 223.5 MHz. Driven element dimensions are L = 24.5" and H = 1.0" Elements are 3/16" diameter.

222 MHz		**REF**	**DE**	**D1**	**D2**	**D3**	**D4**
3 Element	Length Spacing	26.00 0.00	5.50	23.75 13.50			

4 Element	Length Spacing	26.25 0.00	5.00	24.10 11.75	22.00 23.50		
6 Element	Length Spacing	26.25 0.00	5.00	24.10 10.75	23.50 22.00	23.50 33.75	21.00 45.50

432 MHz. This antenna is peaked for 432.1 MHz. At this frequency, this antenna is getting very practical and easy to build. Driven element dimensions are L = 13.0" and H = 3/8" Elements are 1/8" diameter.

432MHz		**REF**	**DE**	**D1**	**D2**	**D3**	**D4**	**D5**	**D6**	**D7**	**D8**	**D9**
6 Element	Length Spacing	13.50 0.00	2.50	12.50 5.50	12.00 11.25	12.00 17.50	11.00 24.00					
8 Element	Length Spacing	13.50 0.00	2.50	12.50 5.50	12.00 11.25	12.00 17.50	11.00 24.00	12.00 30.75	11.25 38.00			
11 Element	Length Spacing	13.50 0.00	2.50	12.50 5.50	12.00 11.25	12.00 17.50	12.00 24.00	12.00 30.75	12.00 38.00	11.75 45.50	11.75 53.00	11.00 59.50

902/903 MHz. This was the first antenna I built using the antenna to control the driven element impedance. The 2 1/2' length has proven practical, so I haven't built any other versions. Driven element dimensions are L = 5.7" and H = 1/2" Elements are 1/8" diameter.

902/903 MHz		**REF**	**DE**	**D1**	**D2**	**D3**	**D4**	**D5**	**D6**	**D7**	**D8**
10 Element	Length Spacing	6.20 0.00	2.40	5.60 3.90	5.50 5.80	5.50 9.00	5.40 12.40	5.30 17.40	5.20 22.40	5.10 27.60	5.10 33.00

1296 MHz. This antenna is the veteran of several "Grid Peditions" but I have yet to actually measure the gain. Dimensions must be followed with great care. The driven element is small enough to allow 0.141 semi-rigid coax to be used instead of RG-58. Silicon Bronze welding rod was used for the elements but any material can be used. Driven element dimensions are L = 4.0" and H = 1/2" Elements are 1/8" diameter.

1296 MHz		**REF**	**DE**	**D1**	**D2**	**D3**	**D4**	**D5**	**D6**	**D7**	**D8**
10 Element	Length Spacing	4.30 0.00	1.70	3.90 2.80	3.80 4.00	3.75 6.40	3.75 8.70	3.65 12.20	3.60 15.60	3.60 19.30	3.50 23.00

OTHER VERSIONS

421.25 MHz ATV. 421 MHz Vestigial Sideband video is popular in North Texas for receiving the FM video repeaters. The driven element for these antennas is designed for an impedance of 75 ohms. So RG-59, or an `F' adapter to RG-6, can be directly connected to a cable TV converter/Cable Ready TV on channel 57. Driven element dimensions are L = 13.0" and H = 1/2" Elements are 1/8" diameter.

Spacing is the same for all versions.

421 MHz ATV		REF	DE	D1	D2	D3	D4	D5	D6	D7	D8	D9
6 Element	Length	14.00		12.50	12.25	12.25	11.00					
8 Element	Length	14.00		12.50	12.25	12.25	12.00	12.00	11.25			
11 Element	Length Spacing	14.00 0.00	3.00	12.50 6.50	12.25 12.25	12.25 17.75	12.00 24.50	12.00 30.50	12.00 36.00	11.75 43.00	11.75 50.25	11.50 57.25

450 MHz FM. Yea, I understand it's FM, but sometimes a newcomber needs a cheap antenna to get into a repeater or give you a simplex QSO during a contest. Driven element dimensions are L = 12.0" and H = 3/8" Elements are 1/8" diameter. Spacing is the same for all versions.

450 MHz FM		REF	DE	D1	D2	D3	D4
6 Element	Length Spacing	13.00 0.00	2.50	12.10 5.50	11.75 11.00	11.75 18.00	10.75 28.50

435 MHz AMSAT. The larger versions have not been fully tested and I appreciate the help and motivation from KA9LNV for these antennas. Updates and performance evaluations are planned for a later edition of the AMSAT Journal. A high Front-to-Back ratio was the major design consideration for all versions. The computer predicts 30 dB F/B for the 6 element and over 40 dB for the others. NEC predicts 11.2, 12.6, 13.5 and 13.8 dBi for the 6, 8, 10 and 11 element respectively. Using 3/4" square wood makes it easy to build two antennas on the same boom for cross- polarized operation. Offset the two antennas 6 1/2" and feed in phase for Circular Polarization. Or, just build one antenna for portable operation. Driven element dimensions are L = 13.0" and H = 1/2" Elements are 1/8" diameter. Spacing is the same for all versions.

435 MHz AMSAT		REF	DE	D1	D2	D3	D4	D5	D6	D7	D8	D9
6 Element	Length	13.40		12.40	12.00	12.00	11.00					
8 Element	Length	13.40		12.40	12.00	12.00	12.00	12.00	11.10			
10 Element	Length	13.40		12.40	12.00	12.00	12.00	12.00	11.75	11.75	11.10	
11 Element	Length Spacing	13.40 0.00	2.50	12.40 5.50	12.00 11.25	12.00 17.50	12.00 24.00	12.00 30.50	11.75 37.75	11.75 45.00	11.75 52.00	11.10 59.50

7-Element-Yagi for the 2m-Band with the 28-Ohm-DK7ZB-Match

This antenna was described in the issue 2/2000 of the magazine "FUNKAMATEUR" , report "Kurze Yagis für das 2m-Band in bewährter 28-Ohm-Technik".

Short data: 11dBd gain, boomlength 3,30m, very good pattern. For the match see: **DK7ZB-Match**

At the webpage "DOWNLOAD" you can load the report as PDF-File (german language!).

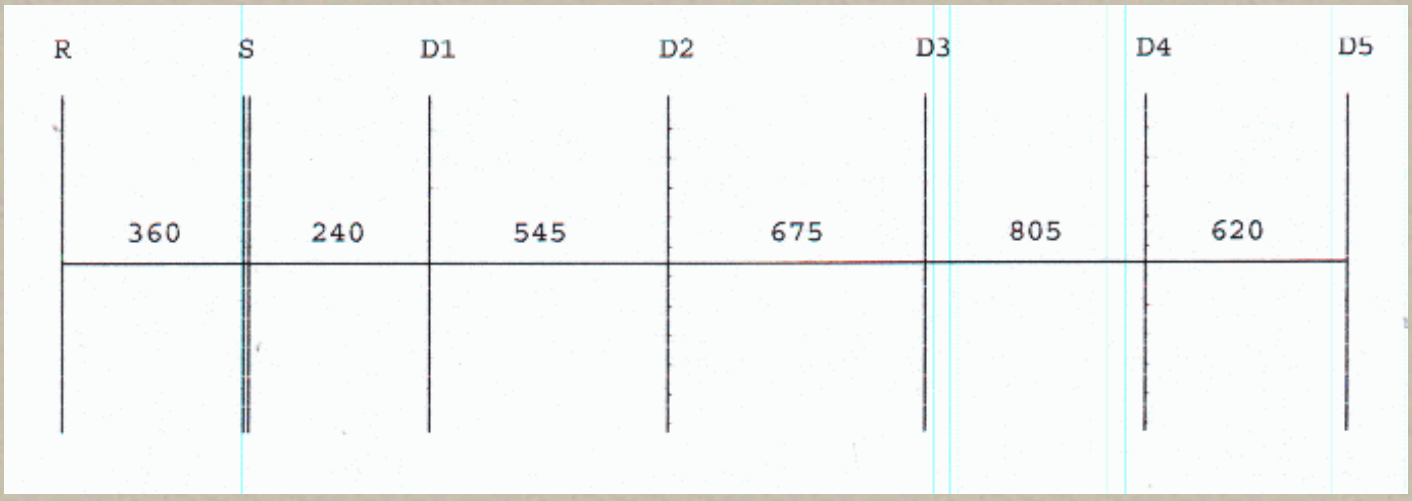


Table of Elements with 4-10mm Diameter

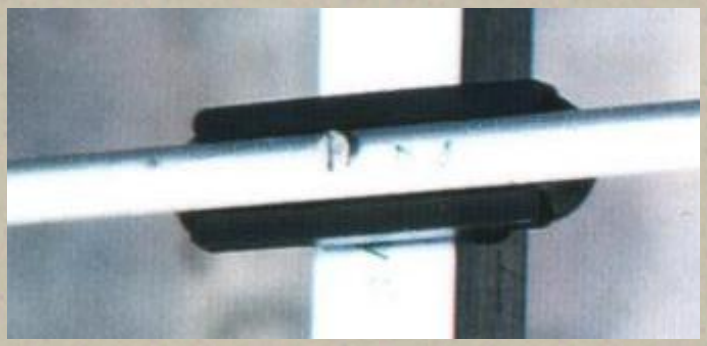
The radiator has always a diameter of 10mm!

El.-Diameter	4mm	6mm	8mm	10mm
Reflector	1019mm	1016mm	1014mm	1011mm
Radiator	978mm	978mm	978mm	978mm
Director 1	959mm	951mm	945mm	940mm
Director 2	933mm	924mm	916mm	909mm
Director 3	916mm	906mm	898mm	891mm
Director 4	915mm	905mm	897mm	890mm
Director 5	904mm	894mm	885mm	877mm



Elements are mounted isolated above the boom with polyamid clamps for TV-Yagis (Konni)

The screw in the center of the element has no influence to the length of the elements!

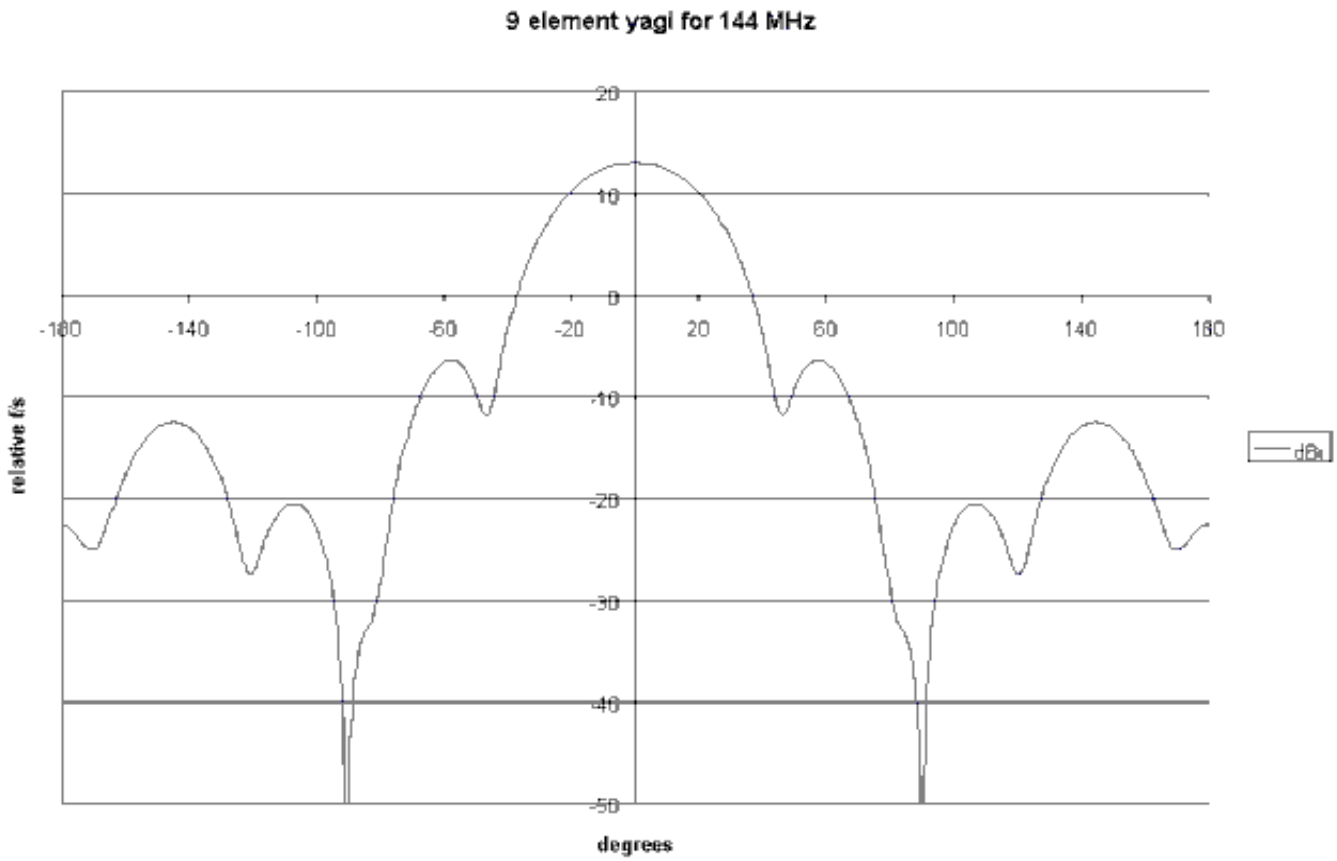
This page is still under construction, but I have more to report on this yagi.

This yagi is based on a design by JM1SZY for 50 MHz that he developed using YO. On 6 Metres, JM1SZY designed this antenna for good gain, fairly wide bandwidth, and a great F/B ratio.

When I scaled it to 2 Metres, it had another quality, it was just a shade over 11 feet in length! I don't know about the rest of the world, but in North America, wood and aluminum tubing is commonly sold in 12 foot lengths. So this antenna could be built with either a single length of 12 foot AL tube, or, if you can find .058" wall aluminum, out of 4 foot sections of tubing. Waste not, want not!

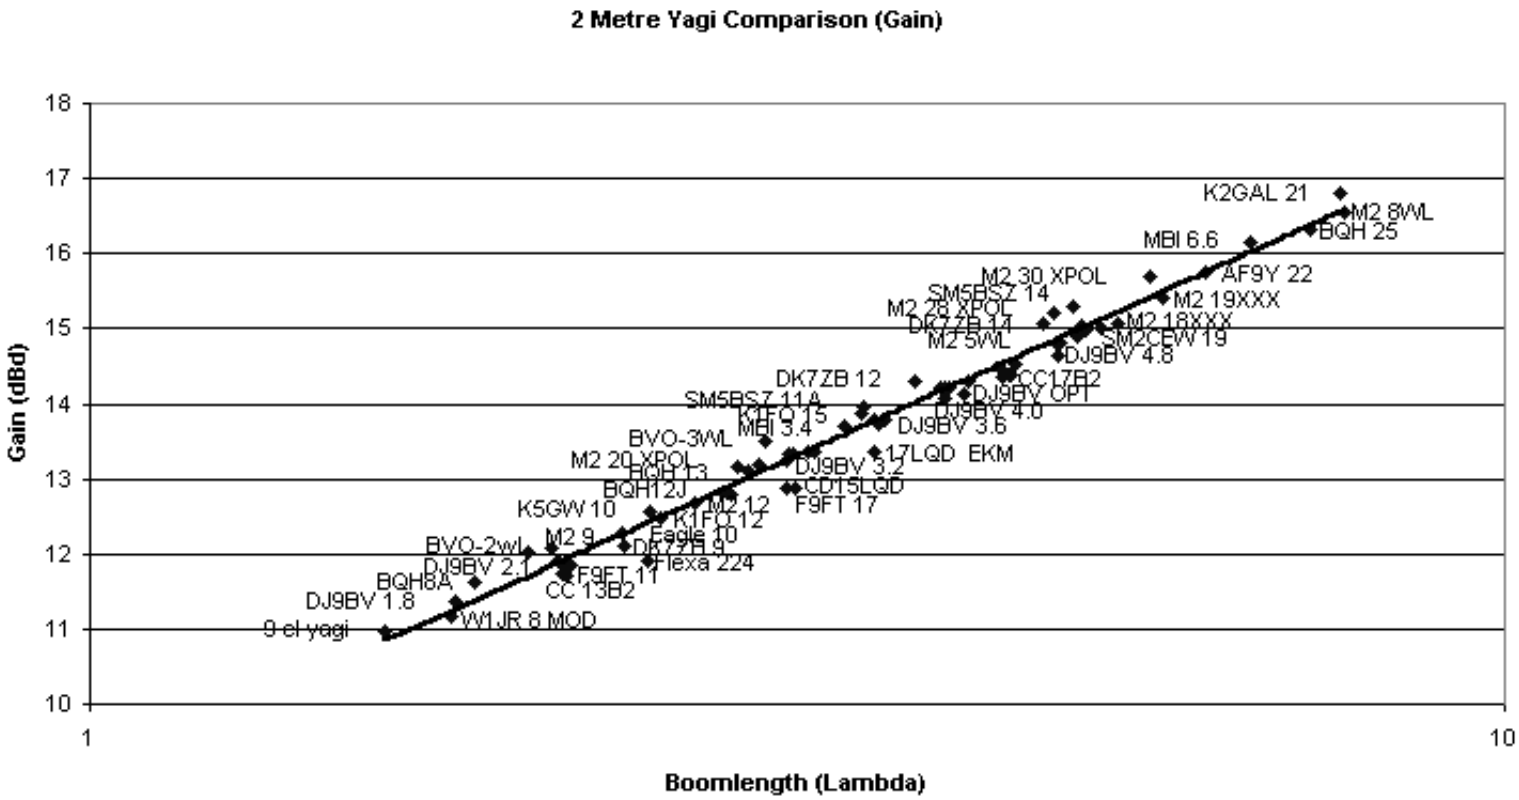
Here's it's free-space pattern on 144.2. It's gain is in line with the DL6WU formula for gain vs. boomlength. It's front-to-back ratio is quite good, IMHO. The far-field data came from NEC2 and was plotted using MS-Excel.



I decided have the gain peak higher up in the band from 144.2. According to K1FO, antennas designed this way are better behaved in a stacked array. I also hope to use it for OSCAR work, so having good gain near 145.9 MHz was a desirable feature, as well.

VE7BQH has done considerable work comparing yagis for 2 Metres. Again, using MS-Excel, I've taken the BQH data, and plotted a trend line showing calculated gain for various antennas. The boomlength axis is logarithmic in scale. Keep in mind, most of these big boys are used for moonbounce, so you'll find the 9 element antenna plotted at the bottom left corner: it is considerably shorter (and subsequently of considerably less gain) than the examples in BQH's table. The data used in this chart can be found at:

http://web.wt.net/~w5un/144gt1.htm



Here's a graph of gain (in dBi), F/B ratio and VSWR vs frequency that was plotted by YagiMax. I'm using a T-match with a half-wave coaxial balun, and the SWR bandwidth is similar to that shown in the graph. The gain is shown in yellow, the F/B ratio in magenta, and the VSWR in green.

Simpleton's Guide to: Quickie Antennas

Brought to you by:

Artsci Publishing

-- Table of Contents -- -- Return to welcome page --

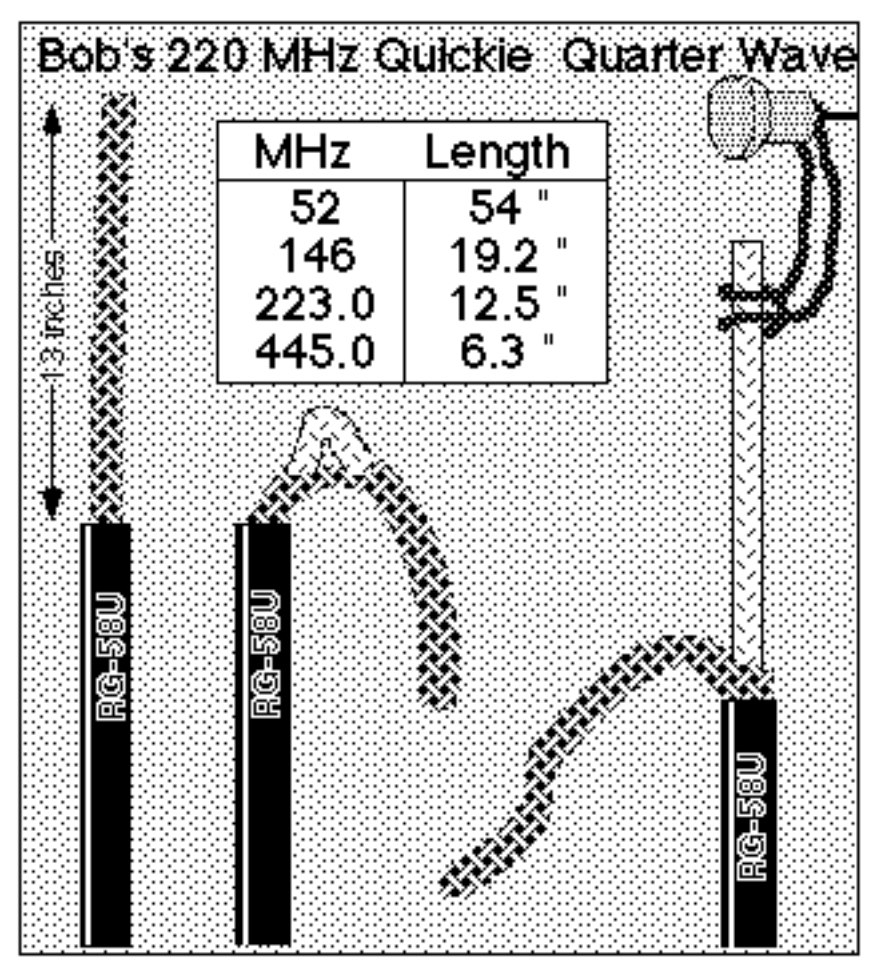
Rebuilding a ham shack after moving into a new home is a very big job. Even if you only have a single VHF radio, running the coax and planting a new antenna system on the roof seems to take more effort each time you do it. Once you get used to drilling holes all the way through a wall for the coax, you are faced with how to support the antenna mast on the roof. If you are only renting the home, you may be tempted to strap the mast on the side of the house and limit the height to just over roof level.

After moving my family into a new home a few months ago, I set aside a weekend to work on my ham shack and antenna system. In my old house, I had an antenna for each band, 2 meters, 220 MHz and 440MHz. Since we are only renting this new home, I wanted to make use of a new multiband antenna. I drilled the holes, built the antenna and mast and bolted it to the side of the house. A triplexer (three port RF splitter) would breakout each band for connection to my three radios. I have used duplexers before, but this would be my first experience with a triplexer.

I was ready to turn the radio on and test my new system. The radios were receiving properly, but my transmitter signal was not making connections to the local repeaters. I connected the antenna to each radio and everything was fine. I connected the triplexer and hooked up a SWR meter and discovered that the SWR through the triplexer was over 5 to 1. I couldn't understand how the receive signals made it through the triplexer but my transmitter could not.

Luckily I had an old duplexer and hooked it up with great success. My 2 meter and 440 MHz radios could now operate properly. The 220 MHz radio was left without an antenna. It was now getting dark, I didn't want to drill another hole for another run of coax and there was no room on the mast for another antenna. I was not going to be defeated by that

malfunctioning triplexer.



I remembered that a 220 MHz quarter wave antenna could be made using a 12 1/2" wire for a radiator and a 13" wire for the ground plane. It was then that the inspiration for a quickie antenna hit me. I had a left over 6 foot piece of coax with a PL connector on one end. I removed 13" of outer insulation and exposed the shield. I measured down 12 1/2 inches and forced open the shield and folded the coax over and pulled out the center conductor with insulation through the hole in the shield.

I now had a 220 MHz quarterwave antenna!! I hung it from the ceiling in my shack with a rubberband and a tack. I hooked it up to the meter and measured the SWR. It was perfect.

This antenna can be built for any frequency you may need.

Just make sure the length of the radiator is correct. If you need to look up the exact length for each band, see the Simpleton's Guide to Quarterwave Antennas. You may attach the radiator to a wood board to help support it.

You must use RG-58 or similar size coax. The larger RG-8 style is much too hard to work with when you attempt to pull out the center insulation. You may be tempted to unbraid the shield instead of opening a hole and pulling out the center insulation. Try unbraiding the wire and you'll get so frustrated with the braid tangling in themselves, you'll cut off the work and start over.

Good luck and remember to have fun when you work on the hobby we call Amateur Radio.

J Pole Antenna

The N6ZAV J-Pole makes a great (but not so hidden) transmitter antenna.

Using the above table, cut the tubing to the size shown for the desired band. The only section where size is not critical is the mast section. Use any size you desire for mounting purposes.

Use steel wool to clean the copper and solder the antenna together as you would with normal copper tubing. Pay close attention to keep the joints straight and snug while doing this. Soldering this together takes quite a bit of heat and a propane torch is the tool of choice.

After the antenna has had a chance to cool, you can attach the coax. Strip the end of the coax that you are going to connect to the antenna and make sure that there is just enough to span the distance between the elements. The cable should be centered between the elements. Strip the center conductor and tin it with solder if it is multi-stranded. Do the same for the braided shield. Using the stainless steel hose clamps, attach the center conductor to the "B" side of the antenna and the shield to the "A" side. Start with the connections about 3" to 5" above the bottom of the "J" and tune with an SWR meter. That's about it! See you on-the-air!

73 de Marty, N6ZAV

```
Parts List:
 1 10' length of 1/2" copper
   tubing schedule "L" or "M"
 1 1/2" copper tubing "T" fitting
 1 1/2" copper tubing elbow
   fitting
 2 1/2" copper end caps
 2 small stainless steel hose
   clamps
 1 50 ohm coax cable with
   connector for radio.

How to build a high gain vertical antenna for the UHF amateur or CB bands

You can use low-cost coaxial cable to make a simple, high performance, omnidirectional vertical antenna that is ideal for both home station and portable applications.

THE collinear antenna has been around a long time. Various versions enjoyed popularity on the amateur VHF and UHF bands in the eras before and after World War II. But the collinear fell out of favour when the Yagi array became popular since the late '50s. The Yagi's popularity is attributable to its feature of giving the 'best bang for the buck'. But it is a beam which requires rotating.

With the rise in popularity of FM operation on the VHF and UHF bands since the '70s, the proliferation of commercial amateur rigs, and the development of repeater networks around the country, the demand for omnidirectional antennas grew apace. A lot of FM activity is mobile, with a degree of base or home station operation, too. For the latter application, an omnidirectional antenna with gain offers distinct advantages, particularly where comparatively low-powered mobile rigs are used at home.

The growth of UHF CB has followed a similar path, boosted by the availability of locally-manufactured transceivers selling alongside imports. Open access repeaters helped the growth of UHF CB, too.

A home-constructed antenna can save you big bucks. Many constructors make up a simple *groundplane* or *coaxial dipole*, which have the advantage of simplicity. However, something that offers a respectable amount of gain and can be assembled with little more effort is a bonus.

The collinear antenna to be described offers considerable gain and improved bandwidth over the conventional groundplane, coaxial dipole, 'Slim Jims' or similar antennas. It is simple to construct and erect since it does not require tuning or pruning, and uses cheap, commonly available 'quarter-inch' RG58 coax.

The word *collinear* means 'in line', the elements of the collinear antenna being placed in line, end to end. Two half wave dipoles placed end to end and fed out of phase make the simplest two-element collinear.

A collinear from coax

To make a collinear antenna from coaxial cable, a number of elements, each an *electrical* half wavelength long, are joined together with the inner conductor and the shield braid transposed at each joint, as illustrated in Figure 1. An even number of elements is required. By transposing the coax's inner and outer conductors at each join, each half wave element is fed out of phase.

I first ran across this form of the collinear in a scientific publication in the early '70s. The published paper described a *monstrous*, 400 metre long, 104 element array used for a

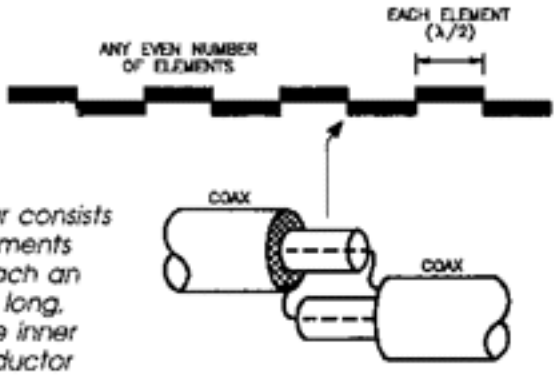

Figure 1. A coaxial collinear consists of an even number of elements made of coaxial cable, each an electrical half wavelength long, joined end to end with the inner conductor and outer conductor transposed at each joint.

advantage of simplicity. However,

Page two

Page three

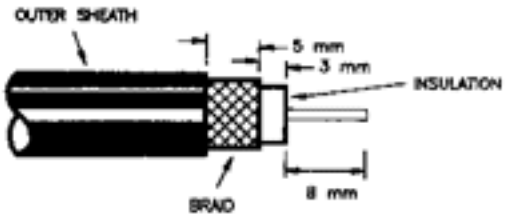

Figure 4. Each element is cut from a piece of RG58 50 ohm coaxial cable and the ends prepared like this.

to any non-conducting support. Dowelling rod from your local hardware store is great for this job and it comes in standard two metre lengths, which is just right. Choose 12.7mm or 19mm diameter dowel to suit yourself.

Now, go through the following procedure step by step and you'll find your collinear goes together quite easily.

1) The very first thing to do is prepare the collinear's support, using a 12.7mm or 19mm diameter wooden dowel rod. This is cheap, readily available and strong enough for the job. The dowel should be thoroughly sealed with an outdoor wood stain or linseed oil, paying particular attention to the ends. Stand it aside to dry properly.

2) Now for the collinear itself. The 'working' length of each element is the distance between the ends of the *braid*. To simplify matters, and to allow for the odd error, cut eight lengths of RG58, each 250mm long for the 70cm amateur band, or 230mm long for the UHF CB band. These lengths make allowance for cutting and stripping back the ends of the elements to make the joints.

3) Prepare each end of *seven* elements, and only one end of the eighth element, as detailed in Figure 4. The eighth element will become the 'top' element of the antenna.

Cut the coax's outer sheath 16mm back from the end using a blunt penknife or hobby knife. It should be blunt so as to avoid nicking the shield braid here. *Do not* unravel the shield braid.

4) Now cut the braid, this time using a sharp knife, 8mm back from the end. Take care not to cut through the dielectric to the centre conductor. Combined use of a sharp knife and sharp, pointed sidecutters can be effective and result in a neat cut.

for a few seconds to heat it, then apply the solder. Use thin gauge, resin-cored solder. But remember to only apply enough solder to lightly 'wet' the conductors.

7) Now to solder the elements together. First slip a 35-40mm length of 9.5mm or 12.7mm diameter heatshrink on each element. Solder the elements together, end to end, as shown in Figure 5. With each joint, after it has cooled, apply silicone sealant to the area of the joint to seal it, then, while the silicone is still plastic, slip the heatshrink tubing over the joint and apply a blast of hot air (hair dryers are great for this). But don't overdo the hot air, though, or you're likely to soften the outer sheath of the coax and possibly damage it.

8) The top element needs to be sealed. Apply a dob of silicone sealant to it, slip on a 30-40mm length of 6.4mm heatshrink while it's still soft, then apply a short blast of hot air to shrink it in place.

9) The next step is to attach what you've just completed to its support. Plastic zip-up cable ties are great for this, as are the plastic zip-lock ties that come with packets of garbage bags. Tie the collinear to the dowel, starting with the top element, putting a tie either side of each joint. The top element should be tied about 50mm below the top end. The other elements should be near the joints.

While the collinear should be laid straight when tying it to the dowel, don't

mechanical support, its prime purpose is protection.

10) Now for the feedpoint and groundplane. You'll have a short length of RG58 left over. Attach a suitable in-line connector, such as a BNC male, to one end and prepare the other end as per Figure 4.

Measure back along the cable, from the end of the shield braid, a quarter wavelength (this time, 'free space' wavelength). For the 70cm amateur band, this is 170mm; for the UHF CB band, 155mm. Mark this point.

Using a blunt knife, or carefully using a sharp knife, make two cuts around the cable's outer sheath, each a few millimetres either side of this point. Slit the sheath between the two cuts and remove the section to expose the shield braid. Using a hot iron, quickly and lightly tin the braid. Slip two 30-40mm lengths of 6.4mm diameter heatshrink down the cable, placing them either side of the exposed shield braid.

11) Cut two lengths of tinned copper wire or brazing rod to size: each 360mm long for the 70cm amateur band, and 330mm long for the UHF CB band (see Figure 3). If you're using tinned copper wire, straighten it first. This can be done by clamping one end in a vise, grasping the other end with a pair of pliers and giving it a good tug. It will bow a bit after you take it out of the vise, but then you can straighten it easily by hand. Tin the centre of each groundplane element.

12) Now attach the prepared cable to

Combined use of a sharp knife and sharp, pointed sidecutters can be effective and result in a neat cut.

5) Next, cut back the dielectric 8mm back from the end to expose the centre conductor. Do this carefully so you don't nick the stranded centre conductor wires. Otherwise, later you may get a break in the centre conductor, or a stray strand may short the joint. Either way, your antenna won't work properly.

6) With the ends of all the elements prepared as per Figure 4, now tin the exposed centre conductor and shield braid on each. Use a hot iron, preferably a temperature controlled type. A flat-faced ('spade') tip is best for this job. Apply the tip to the part to be tinned near the joints.

While the collinear should be laid straight when tying it to the dowel, don't apply too much tension to avoid fracturing the soldering at the joints. Don't depend on the heatshrink for

can straighten it easily by hand. Tin the centre of each groundplane element.

12) Now attach the prepared cable to the feedpoint, making a joint as per Figure 5. Seal it and cover it with heatshrink. Put a tie either side of the

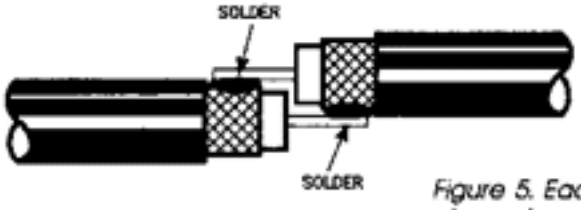

Figure 5. Each joint between the elements, and the joint at the feedpoint, is made like this.

Page four

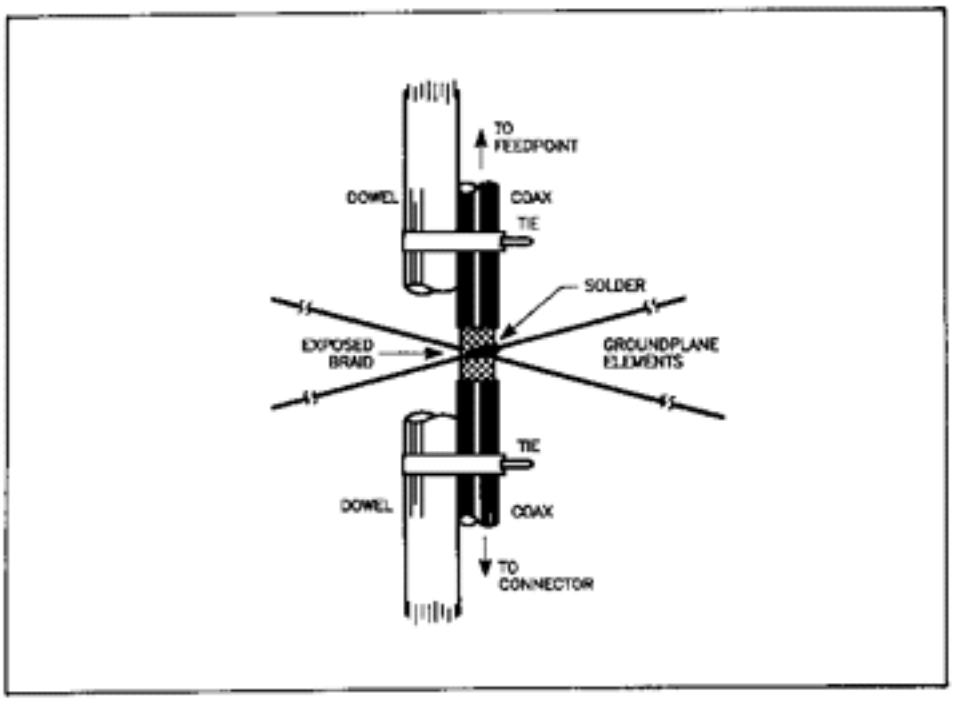

Figure 6. You make the groundplane in this manner. Be sure to thoroughly seal the area of the exposed braid, as described in the text.

though, it's better to pay more and get a cable with the lowest-loss. Belden 9913 is the best of the flexible half-inch cables around and it's stocked by Dick Smith Electronics. You're next best choice would be 'RG213 foam', which is also available from Dick Smith Electronics.

You must mount the collinear well clear of other vertical structures, particularly if they're metallic. The antenna described is readily mounted on a standard TV chimney mount, or even a barge-board mount.

joint to hold it securely to the dowel.

Now, temporarily tie the coax to the dowel near the exposed shield braid. This will secure it while you attach the groundplane elements. Position each groundplane element on the exposed braid and solder them in place at right angles to each other. Take care to solder them properly but not to damage the coax, either (a hot iron with a spade tip is best for this).

13) When the joint is cool, take off the temporary ties and apply a little silicone sealant around the groundplane joint. While the silicone is still plastic, slip the two pieces of heatshrink tubing along to cover the groundplane joint and apply a blast of hot air. Afterwards, cover the joint thoroughly with silicone sealant (you don't want water getting into the coax).

14) Put ties around the dowel and coax, either side of the groundplane, then another tie a little below the groundplane to secure the flying lead, leaving a slack 'kink' in the cable so that

Performance

An eight element array like this has 9dB of gain over a dipole. Your 10 watt rig will sound like an 80 watt rig on a Slim Jim, or like a 100 watt rig on a groundplane – it's cheap gain! A transistor power amp to take your rig's output from 10W up to 80- or 100 watts will cost you $2 per watt, or more. So this collinear costs about one-tenth the price of a power amp. So, how much power will it take? As much as you're legally allowed to run 'up the stick.'

If you live in a valley and hope this antenna will 'get you out', expect the unexpected. It may make things worse because of its low radiation angle. The gain is achieved by compressing the vertical radiation angle. Try it. If you don't get the improvement expected, chop off the top four elements and try

PARTS LIST

Two metres of RG58CU (MIL-C-17F preferred)
500 mm of 9.5 or 12.7 mm diameter heatshrink
100 mm of 6.4 mm heatshrink
in-line coax connector to suit (BNC suggested)
800 mm of 18 gauge tinned copper wire or brazing rod
Two metre length of 12.7 mm or 19 mm diameter dowel
Five or six cable ties
Silicone sealant
Solder
Outdoor wood stain or linseed oil

TOOLS YOU'LL NEED

Sharp penknife or 'hobby' knife
Sharp, pointed sidecutters
Soldering iron, preferably temperature controlled
Small shifting spanner
Pair of needle-nose pliers

groundplane to secure the flying lead, leaving a slack 'kink' in the cable so that any tension is taken by the bottom-most tie.

15) Last of all, put some sort of cap over the top end of the dowel and seal it to prevent it weathering. A damp dowel degrades the collinear's performance, so use a rubber furniture bung of the right size. Or, a short length of heatshrink tubing of the right diameter, tied off and shrunk in place.

That completes the construction. Now to erect it. As individual circumstances vary widely, I'll just give a few hints and tips.

The bottom end of the dowel can be clamped to the top of a mast using hose or muffler clamps that are tightened with a worm-drive mechanism. Use two clamps spaced apart a little to properly support the dowel.

The feedline from your collinear to your rig should be a good quality, low-loss coax. The large diameter 'half-inch' variety is readily available, and affordable. For these frequencies, vertical radiation angle. Try it. If you don't get the improvement expected, chop off the top four elements and try again. It sounds weird, but I know of one constructor who successfully performed this operation, to his surprise, but not mine!

I have made various versions of coaxial collinears over the years, for both temporary, permanent and portable applications. A portable collinear is easily made by tying or taping the coax elements and lead cable to a length of hemp rope. In use, the top end of the rope is tied off to something suitable, like a tree branch or other form of 'skyhook', and the bottom end is either tied down or weighted so that the array is held vertical. When not in use, just roll it up.

I've made four-element coax collinears for 2m, in both 'fixed' and portable versions, an eight-element centre-fed horizontal monster some 15 metres long for six metres, and UHF versions ranging from a four-element job for mobile use to a 16 element phallic symbol nearly four metres tall. ●

Build A 9 dB, 70cm, Collinear Antenna From Coax

By N1HFX

Recently the RASON technical committee was hard at work at the repeater site repairing our 2 meter repeater antenna. One of the members commented to me that I should write an article about collinear arrays so that we could all build our own. While it is not always feasible to home-brew a commercial quality antenna designed to take hurricane force winds, it is very feasible to built a collinear antenna for average use. This article describes a collinear antenna made from very inexpensive RG58/U coaxial cable and encased in PVC pipe.

Before we start building we need to cover some ground about the characteristics of coaxial cable. First remember that there is something called the velocity factor for coaxial cable. For RG58/U coax it is typically .66. This means that when we calculate the length of ½ wavelength in free space we need to adjust its size by multiplying it by the velocity factory. Simply put, RF slows down by the velocity factor when traveling through coaxial cable. All that aside now, lets calculate the ½ wavelength of RG58/U coaxial cable with a frequency of 444 Megahertz:

½ wavelength of coax = 300 / F / 2 * V

Where F = Frequency in Megahertz

V = Velocity factory of Coax

300 / 444 / 2 * .66 = .2229 meters or 223 millimeters

To allow for cutting the ends of our coax, we will need to add 8 millimeters to each ½ wave length for a total of 231 millimeters.

To get started, we will need 8 half wave lengths (231 millimeters) of RG58/U coaxial cable to be cut and connected in the manner shown in Figure 1. First cut back 4 millimeters of the outer jacket, braid and dielectric exposing the center conductor as in Figure 2. Now cut back the outer jacket another 4 millimeters to expose the braid and push the braid back about a millimeter to prevent it from shorting with the center conductor. It is best to lightly tin the braid with solder at this point. Now solder each half wavelength as shown in Figure 1. Attach a few feet of RG58/U to the bottom of the array as in Figure 1 for feeding the antenna.

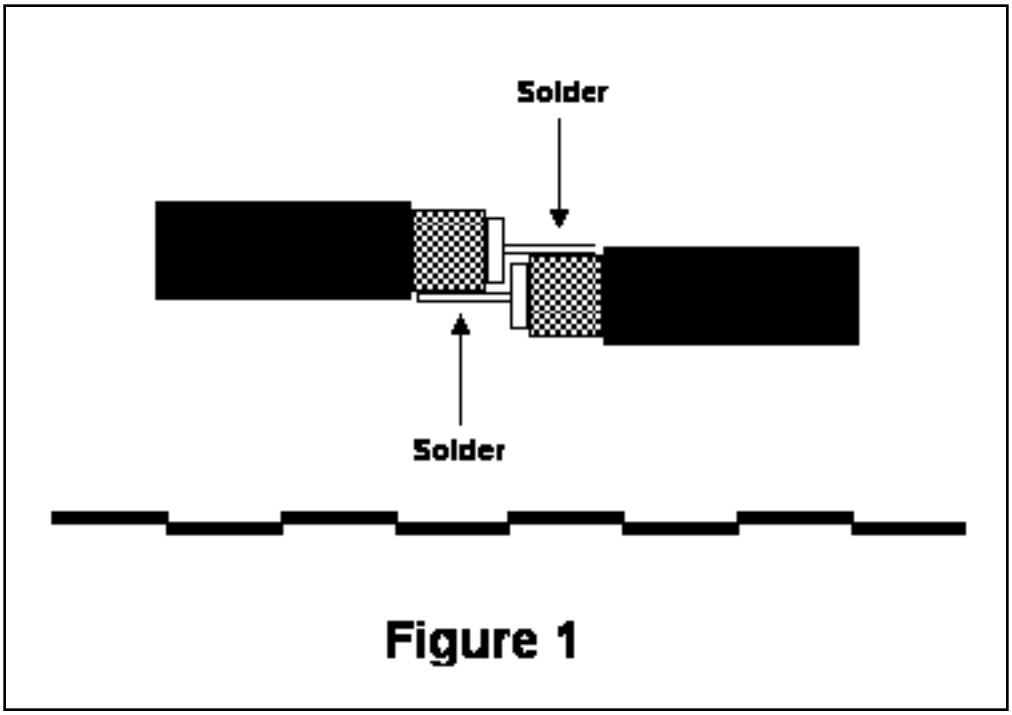

Figure 1

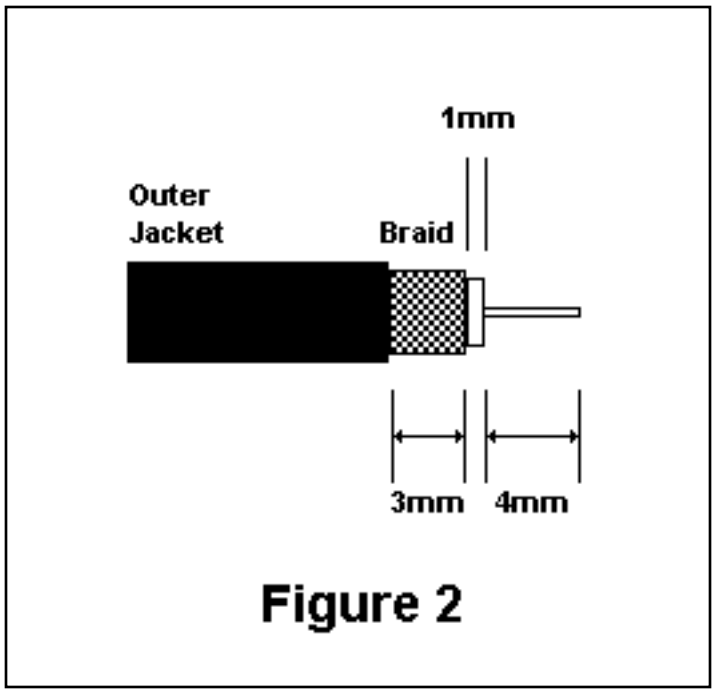

Figure 2

Now its time to add the additional elements to the top and bottom of the collinear array. First add a ¼ wave element to the top of the antenna as shown in Figure 3. Use #16 solid wire or similar and solder it to the center conductor only. The length of the ¼ wave element is calculated as follows:

1/4 wavelength radiator = 300 / F / 4

Where F = Frequency in Megahertz

300 / 444 / 4 = .1689 meters or 169 millimeters

At the bottom of the array we will slide a 5/16 inch aluminum tube over the coax and crimp it to the braid of the antenna feed point only. If copper is used, it is okay to solder. The length of the tube is calculated as follows:

¼ wavelength of tubing = 300 / F / 4 * V

Where F = Frequency in Megahertz

V = Velocity factory of Tubing. (Use .95 for 5/16" tubing)

300 / 444 / 4 * .95 = .1604 meters or 160 millimeters

Because a collinear antenna is hot with RF along the shield of the coax, it is necessary to prevent the RF from coming back through the coax. Slide three FT50-43 or almost any similar sized toroids over the bottom end of the coax as shown in Figure 3. The toroids should be placed about ½ wave length from the bottom of the array. Use the same formula for calculating a half wave length of coax. If you prefer, apply RF to the antenna at this point and slide the toroids up and down until minimum SWR is found. Tape the toroids to the proper point on the coax using electrical tape or similar means.

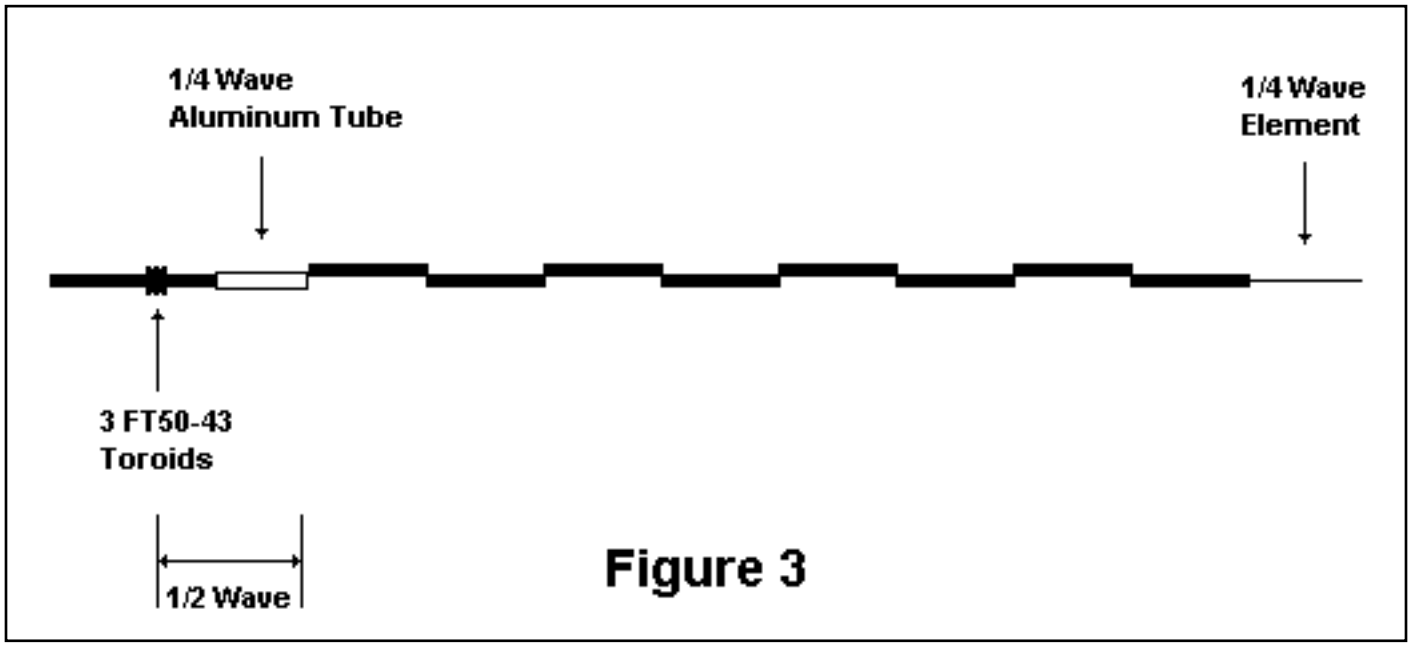

Figure 3

After completing the basic assembly of the collinear antenna, apply a small amount of RF with the antenna on the floor or ground. Relatively low SWR should be observed at this point. The SWR will be much lower once the antenna is mounted in the air. If the SWR is greater than 2 to 1 across the entire band, a connection may separated or a short occurred. It will be necessary to correct the problem before proceeding. After good SWR is obtained, place heat shrink tubing along all connections or wrap tightly with electrical tape.

For final mounting, attach the antenna to a ¼" wooden dowel using tie wraps about every 3 inches. It may not be possible to obtain a wooden dowel for the complete length so attach two dowels together by using a 1 inch sleeve of 5/16" tubing and crimping the tubing at each end. Check SWR again to insure that no connections have separated or shorted. Carefully insert the coax and dowel assembly into several feet of ¾" PVC pipe for final mounting. Because of the tie wraps, it is not necessary to use spacers but may be necessary if larger size piping is used. Drill a hole for the coax at the bottom end cap and place an end cap on the top of the PVC. Do

not cement end caps until the SWR has been doubled checked. Cement end caps and water proof coax opening on the bottom. Use whatever type of coaxial connector is desired on the bottom of the coax end but do not use RG58/U for your complete feed line. Use a low loss coax such as RG8/U for the main feed line to the transceiver. Don't forget to water proof all coax connectors.

If the eight ½ wave coaxial elements result in an antenna too long for your liking (over seven feet), then it is okay to use four ½ wave coaxial elements but the SWR may be slightly higher (Attach four ¼ wave vertical ground radials at the antenna feed point to help lower SWR.). If 9 dB gain is still not enough for you then increase the number of coax elements from eight to sixteen. You will probably need to attach guy lines to the antenna. Although only a 70 CM antenna was described in this article, the formulas can be easily calculated for the 6 meter, 2 meter or 1¼ meter bands. Millimeters were used for many of the measurements but can be converted to inches by dividing millimeters by 25.4 for those who are not familiar with the metric system. After installing one of these antennas, be prepared to hear stations and repeaters that you never heard before.

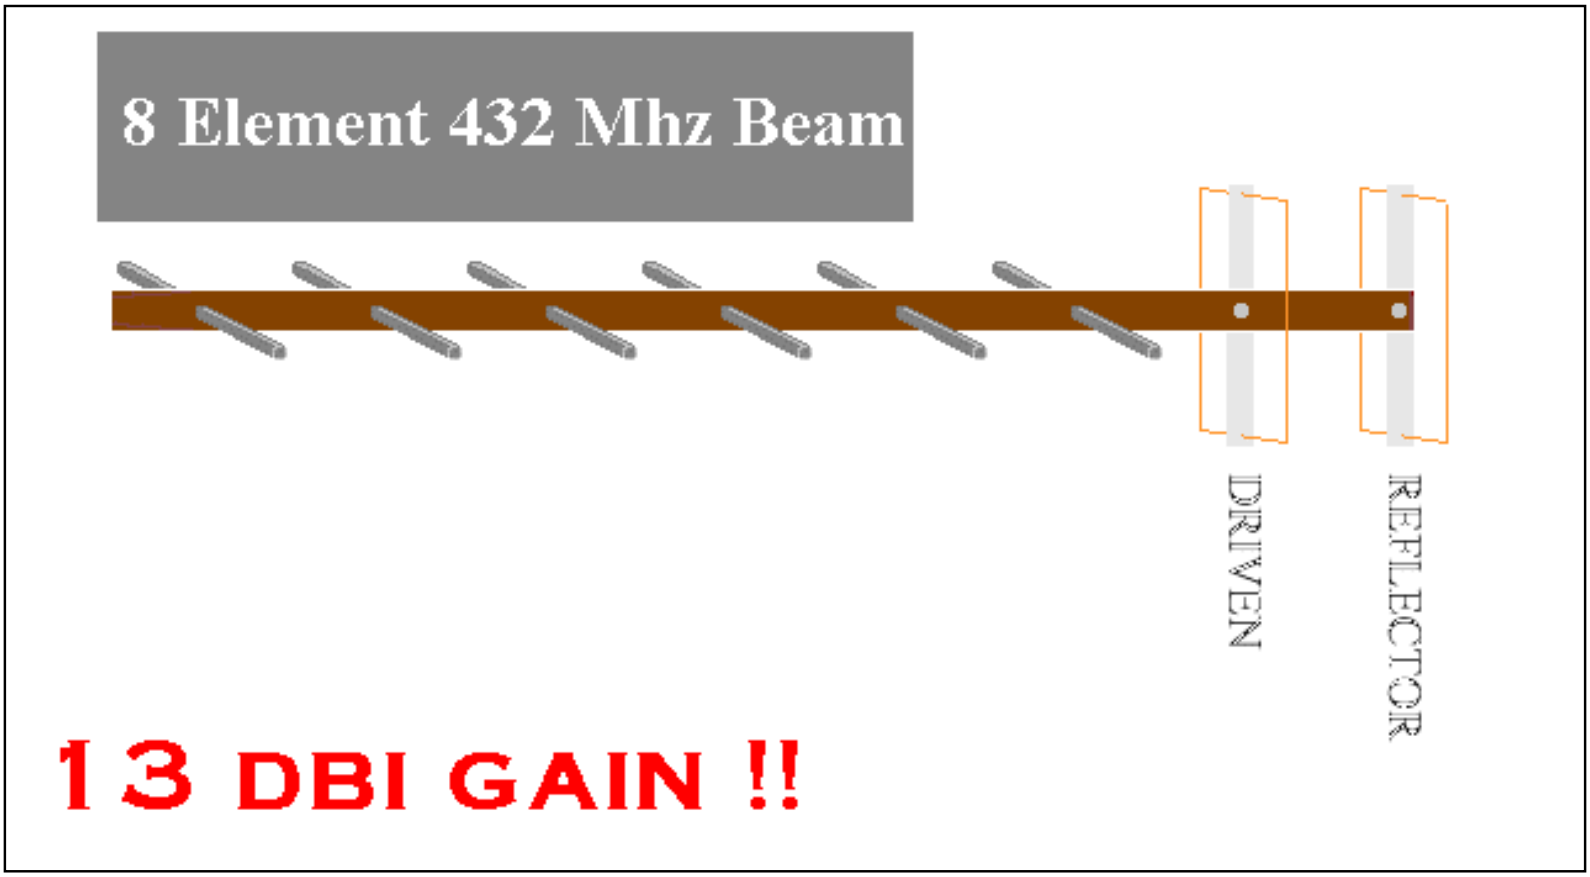
432 8 Element Quagi Antenna



How to build a 432 Mhz Quagi

The boom is made from wood.*{Do not use any type of metal for this.}* Ths boom length is 61 inches and 1/2 inch thick. Mark the boom as to where the elements are to be spaced and drill a 1/8 inch hole in the center of the boom material.After you have done all this apply a few coats of stain.This will preserve the wood from the abuse of the weather.
Use #12 wire to form the quad elements. Cut the wire to the correct lenghts *(see chart below)*. The quad elements are supported at the top and bottom of the element with a Plexiglas strip with a hole centered at both ends. The bottom of the quad being the feedpoint. Apply a little epoxy to where the wire passes through the support holes.This will secure the wire so it will not move around.
Next solder one end of the wire to the center of an type-N conector feed it through the holes in the Plexiglas and bend it into shape. Then finish the element by soldering the loop closed to the ground tab on the N connector.On the reflector just solder to two ends of the wire together.
The directors are mounted through the boom. Epoxy them as well. They can be made

from any 1/8 inch metal rods. Cut them to the EXACT size *(see chart below...I used stainless steel welding rods which are available at a hardware store)*

NOTE: *At UHF frequencies even 1/8 inch difference in length will make the antenna preform differently.*

Element Lengths	
Reflector Loop	**28"**
Driven Loop	**26 5/8"**
Directors	**11-3/4" to 11-7/16" in 1/16" steps**
Element Spacing

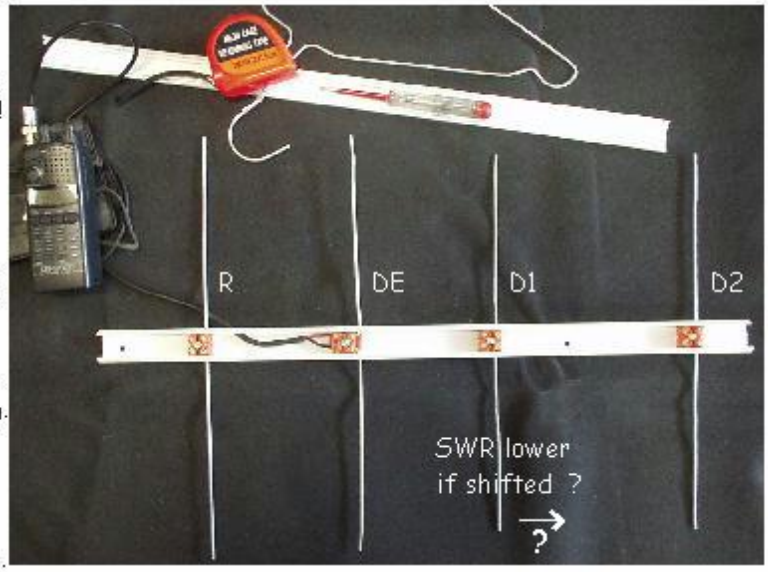
One easy version - uses electrical conduit for boom & galvanised iron coat hanger wire !

Terminal block connector strip makes for great element securing, & neatly connects coax. feed to the 2 parts of the dipole driven els. - each 160mm long.

It all dismantles too- no glue or solder- so suits field use/repairs!



Sourced => www.bk.fr/amatech/electronique/radio/antennes/yagi4/yagi4.htm
Designed under antenna simulator software - "MININEC" => www.emsci.com

433 MHz UHF Yagi antenna

- suitable low power LIPD/ISM "fox hunting"

The 433.92MHz " Low Interference Potential Device" (LIPD) licence free band suits utility devices < 25mW power. A simple 4 element Yagi boosts signals ~ 7dB (= ~ range doubling) + direction finding for nearby signals.

Classic antenna theory, sourced from such Ham texts as the ARRL & RSGB handbooks, assigns the driven element as electrical length =1/2 a wavelength (shown here L) . The actual physical length is somewhat reduced however, by a multiplication factor relating to the diameter of the elements & wavelength of signals in use. At UHF it's typically 0.94. Directors are usually 0.43L, with spacing 0.25L, with improved bandwidth resulting from tapering in the direcxtion of the signal. Gain is not appreciably influenced by rear reflector spacing in the range L/8 - L/4, but useful impedance variation occurs. Hence at 433.92 MHz ...

$L = c/f = 3 \times 10^8 / 433.92 \times 10^6 =$ L = 692mm | L/2 = 346mm | L/4 = 173 mm — This is theoretical electrical length

Actual cut lengths × 0.94 these so L= 650mm | L/2 =325mm | L/4 = 163mm — For physical length driven element

It's apparent thus that the design shown is a compacted version, & better performance may result from spacings & element lengths closer to theoretical. Check many further resources via => **http://ac6v.com/antprojects.htm**

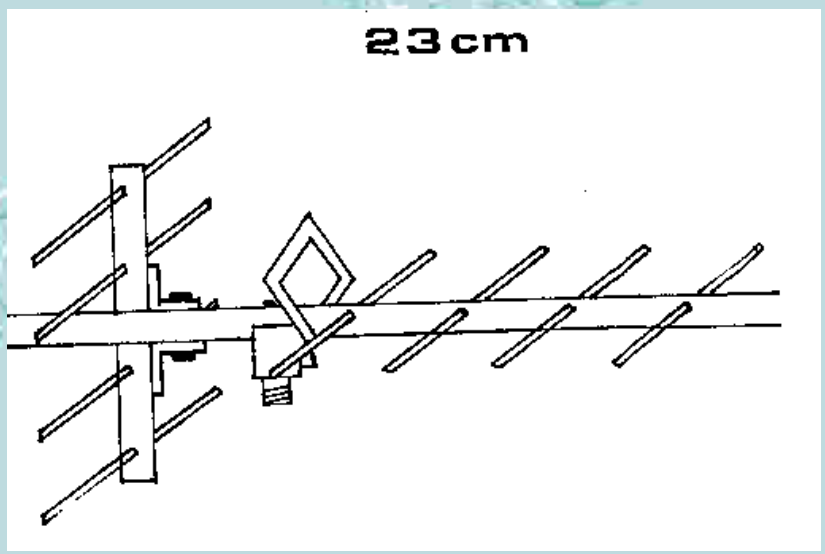
1270Mhz Yagi Antenna

Build your own antenna for the 23cm band (1250Mhz - 1280Mc) using some aluminium and the following simple design.



Due to a large number of reflectors front to back ratio is excellent.

The average gain is about +12 dbd.

Broad bandwith makes this antenna the optimal choice for ATV (television)

SardineCanAntenna

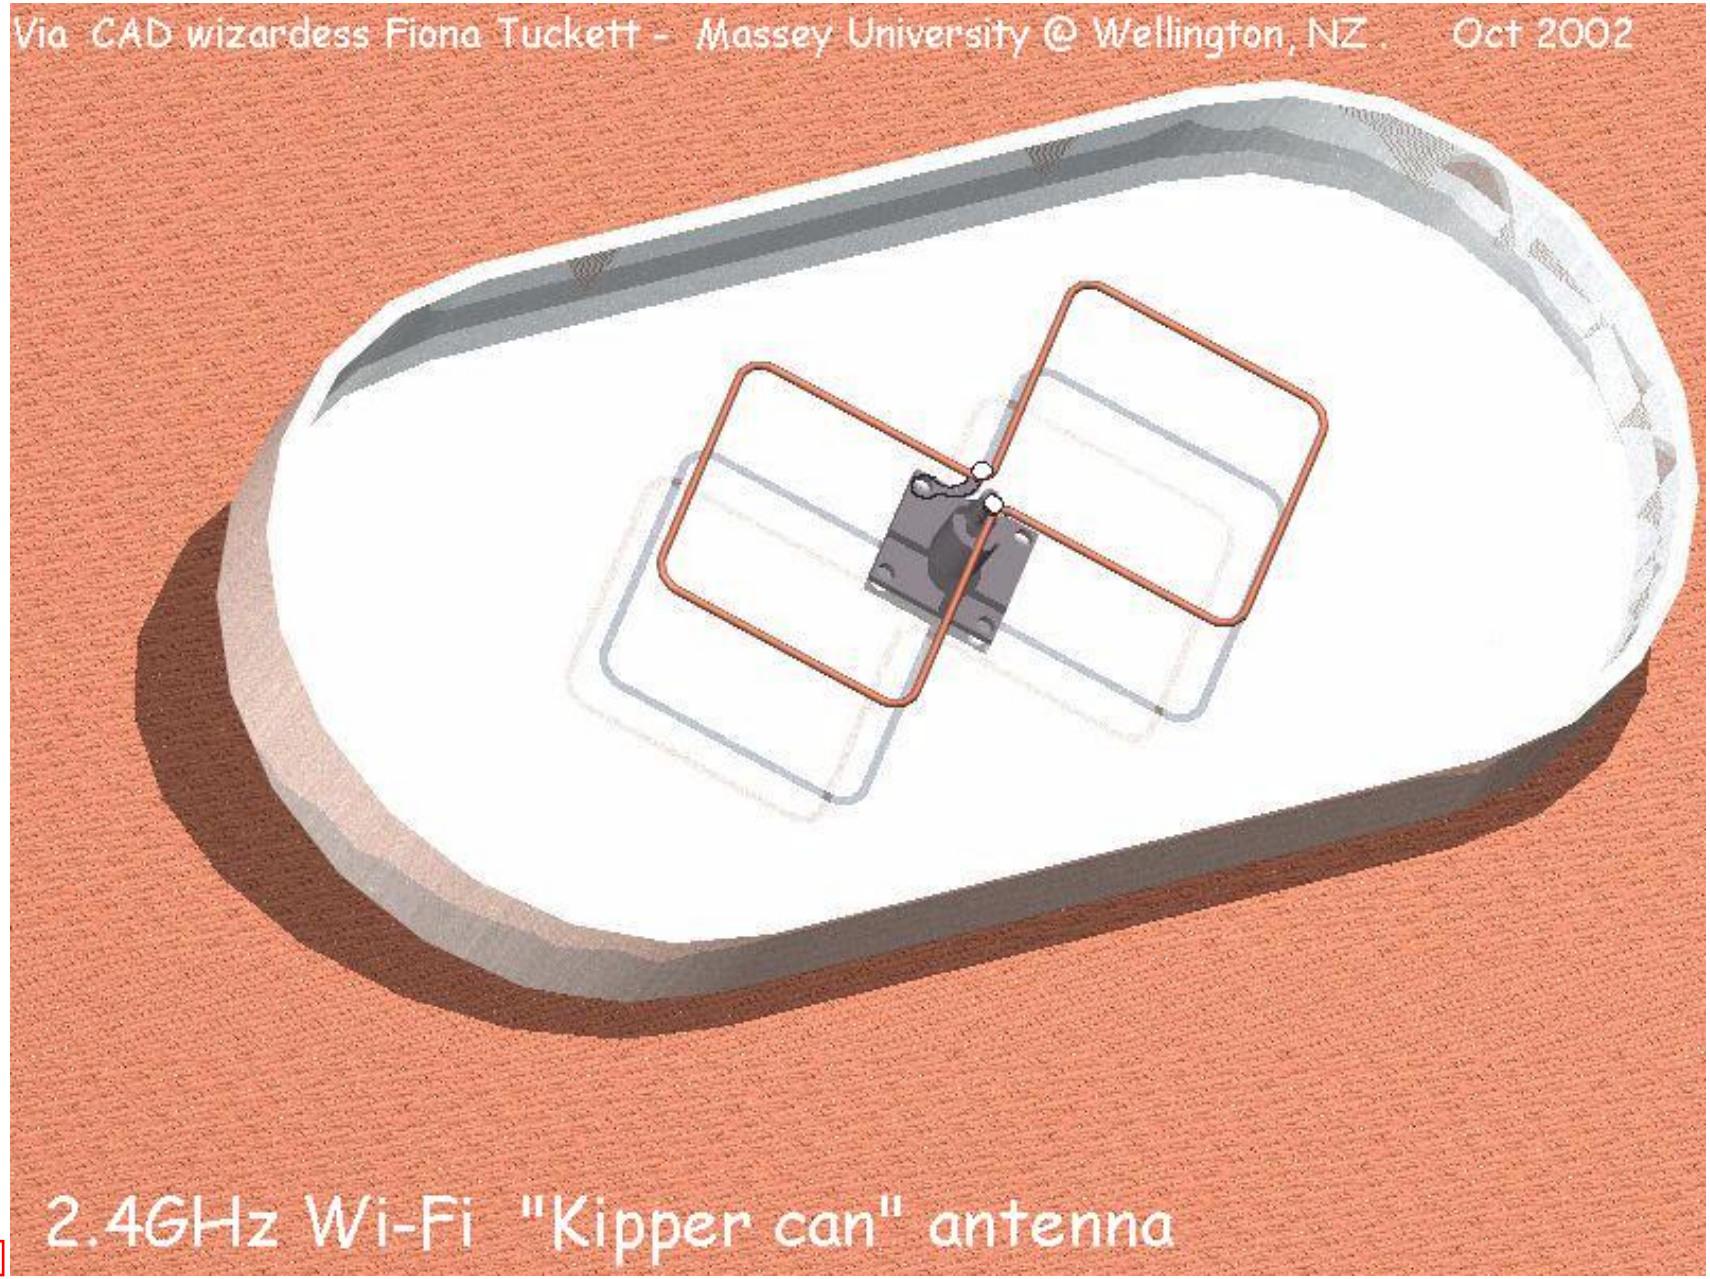
<-- Back to **AntennaHowTo**

Sardine Can Antenna. is a BiQuad or Bi circle - wire length each side (8 x 1/4 waves) 31 mm

Sardine cans have quite standard dimensions around the world, although the oval one shown here is lightweight aluminium & does seem (perhaps by chance ?)to have enhanced directivity compared with more normal steel Canadian "Brunswicks " etc. It's an ex. Latvian RICHTER "Smoked RIGA SPRATS" & perhaps first received publicity in the Nov. 2002 Australian "Silicon Chip" monthly (author Stan. SWAN => s.t.swan@massey.ac.nz), when it was first called a "Kipper Can". (For those readers who don't recall Monty Python, Kippers are smoked herrings http://www.deliaonline.com/ingredients/ingredientsatoz/i_0000000135.asp. See refs & further construction dimensions/views/insights => http://www.manuka.orcon.net.nz <= Even an old CD can act as the reflector, exploiting the metalised layer of course, but the sardine version prooved far superior, no doubt due to the focusing side walls.

The hot melt glue shown here is not really needed if a rigid N connector is used, although a recent enhancement has been to form the radiating bow tie as tracks on a small PCB secured via nylon spacers. Gain is great -typically 10dB (links to 10km LOS made & typically 2km more normal built up areas !).

Need a quickee antenna ? Got 10 minutes & simple tools ? You won't get a simpler, cheaper or more compact design. The unit can be neatly hidden in a pencil case or plastic bag beside your road warrior notebook so it's not intimidating for field use. It's directional enough to even pin point the signal location (using NetStumbler etc)in a multilevel building. RECOMMENDED !



Double Quad "Bow Tie" antenna for 2.4 GHz Wi-Fi range extension

Gain: (relative to half-wave dipole)

El diseño de esta antena se basa en otros encontrados en internet y sobre todo en los datos obtenidos con el programa de G6KSN loopyagi.exe antes alojado aqui y que sirve para calcular antenas loop-uda-yagi para cualquier frecuencia. Las dimensiones y la forma de construirla se han cambiado levemente para adaptarnos a los materiales que teníamos a nuestro alcance. Es una antena muy direccional y con ganancia bastante alta, 14dbi. La polarización horizontal o vertical depende únicamente de la posición en que fijes la antena.

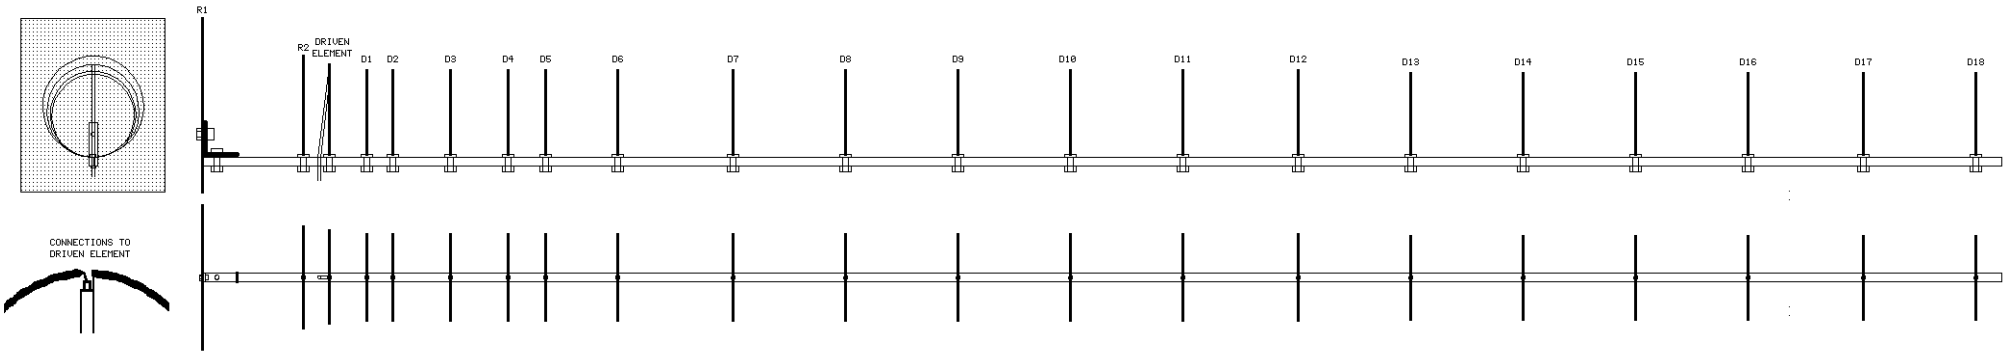

Figura 1: Esquema de la antena original de G6KSN

Los resultados obtenidos con loopyagi.exe para una frecuencia de 2441Mhz son los siguientes :

Elemento	Dimensiones	Distancia desde el reflector1
reflector 1	123mm diametro	0 mm
reflector 2	135mm circunferencia	42 mm

alimentador	123mm circunferencia	55 mm
director 1	114mm circunferencia	70 mm
director 2	114mm circunferencia	81 mm
director 3	114mm circunferencia	105 mm
director 4	114mm circunferencia	129 mm
director 5	114mm circunferencia	146 mm
director 6	114mm circunferencia	177 mm
director 7	114mm circunferencia	225 mm
director 8	114mm circunferencia	273 mm
director 9	114mm circunferencia	321 mm
director 10	114mm circunferencia	369 mm
director 11	114mm circunferencia	417 mm
director 12	114mm circunferencia	465 mm
director 13	110mm circunferencia	513 mm
director 14	110mm circunferencia	561 mm
director 15	110mm circunferencia	609 mm
director 16	110mm circunferencia	657 mm
director 17	110mm circunferencia	705 mm
director 18	110mm circunferencia	753 mm
director 19	110mm circunferencia	801 mm
director 20	110mm circunferencia	849 mm
director 21	106mm circunferencia	897 mm
director 22	106mm circunferencia	945 mm

El radomo (palo al que van soldados el resto de los elementos) es un tubo de cobre, usado en fontanería, de 12mm de diámetro. Los elementos en forma de anilla están hechos a partir de un alambre de cobre de 1.5mm de diámetro.

Dependiendo de la ganancia que queramos conseguir tendremos que hacer la antena mas o menos larga, aquí damos las instrucciones para hacer una de aproximadamente 1 metro de longitud y 22 directores, que da una ganancia aproximada de 14Dbi. Si se quiere hacer una antena de menor ganancia basta con acortarla hasta donde desees, por ejemplo, una antena de 50cm y 11 directores tiene una ganancia de aproximadamente 11Dbi. Como orientación decir que en las pruebas realizadas se obtuvieron ganancias de 7db (la de 22 directores) y 4db (la de 11 directores) por encima de los resultados obtenidos con una antena tipo bote (de 8.7 cm de diámetro y 16.5cm de longitud).

Empezaremos haciendo las anillas, quitamos la funda aislante del cable de cobre, y a continuación enrollamos el alambre sobre un trozo de tubo de cobre de 35mm de diámetro, hasta hacer 12 vueltas completas. Fijamos el alambre con alguna cinta adhesiva y con una cuchilla, dando varias pasadas, hacemos una marca a todas las anillas. Soltamos la cinta, retiramos el alambre del tubo de cobre y vamos cortando cada anilla por las marcas que hemos hecho. Se manipulan las anillas hasta conseguir que formen un círculo completamente cerrado. Estas doce anillas serán los primeros alimentadores numerados del 1 al 12.

El paso anterior lo repetimos enrollado el cable sobre un tubo de 34mm de diámetro, (nosotros utilizamos un tubo de una aspiradora). Sobre este tubo hacemos ahora otras 10 espiras, las marcamos y cortamos. A dos de éstas les cortamos 4 mm, para utilizarlas como directores 21 y 22, las restantes 8 anillas serán los directores del 13 al 20.

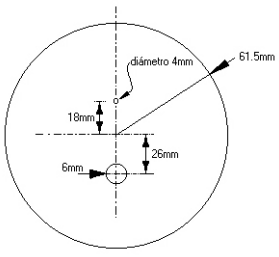
Medimos dos trozos de alambre de cobre, uno de 123mm y otro de 135mm para hacer el Alimentador y el Reflector 2 respectivamente. Les daremos también forma circular enrollándolos sobre un tubo de 40mm de diámetro y rematando la forma a mano.

Cortamos el tubo de cobre que formará el radomo, la longitud depende del número de directores de la antena que nos propongamos hacer. Para la de 22 directores lo cortaremos a 102 cm, es decir, 7.5cm mas largo que la medida que nos indica la tabla (Director 22 945mm).

A continuación sujetamos, con alguna herramienta o cinta adhesiva, una cinta métrica al tubo de cobre y le hacemos las marcas en las que irán soldados los distintos elementos. Comenzamos haciendo una marca a 7cm de uno de los extremos. Esta marca la tomamos como origen o "cero" para le resto de las medidas, o sea, en ella irá soldado el Reflector1. A 42 mm del "cero" haremos la marca para el Reflector2, a 55 mm del "cero" haremos la marca para el Alimentador, a 70 mm del "cero" la marca para el Director1, a 81mm la del Director2 y así hasta llegar al Director22.

Ya sólo nos queda soldar cada elemento en su sitio. Empezaremos por el último director, el 22. Para esto hemos preparado una herramienta o pinza que se puede desplazar por el tubo de cobre y tiene unos brazos que permiten sujetar firmemente una arandela en su posición correcta mientras la soldamos. La soldadura la hacemos con soplete de fontanero, aplicando previamente decapante o flux en las piezas a unir. Tanto los directores, como el Reflector2 se sueldan con la abertura de la anilla en contacto con el tubo de cobre, de modo que al soldar la anilla al tubo queden también unidos los extremos de la anilla.

El Director se suelda de forma que la ranura quede diametralmente opuesta al punto de unión de la arandela al tubo. En los extremos sueltos del Alimentador soldaremos posteriormente el cable coaxial, la malla a uno de los extremos y el vivo al otro. Soldamos a continuación el Reflector 2.



El Reflector1 es un círculo de 123mm de diámetro de chapa de latón de 0.5mm de espesor. Se marca con compás o plantilla y se corta con la tijera para chapa. En este reflector hacemos dos agujeros, uno con centro a 26mm del centro del reflector, y de 12mm de diámetro, en este agujero soldaremos el radomo. Hacemos otro agujero, de 4mm de diámetro y con centro a 18mm del centro del reflector. En este agujero soldaremos un trozo de tubo de latón de 4mm de diámetro y de 60mm de longitud. Por el interior de este tubo se introduce el cable coaxial RG-316, soldamos el cable coaxial al Alimentador y en el otro extremo del cable le colocamos el conector apropiado, dependiendo a que aparato Wifi vayamos a conectar la antena.

Herramientas que necesitas:

- Un cortatubos o un arco de sierra para metales.
- Unas tijeras para cortar chapa.
- Unas tenazillas para cortar los cables, la tijera de chapa puede servir.
- Un soplete, estaño y flux.
- Estaño y un estañador, si es de 100watios mejor que el de 40watios.
- Un tornillo de banco para sujetar las piezas mientras las sueldas.
- Tubos de diferentes diámetros para enrollar las anillas (35mm, 34mm, 40mm)

Donde conseguir los materiales:

- El cable de cobre de 1.5mm de diámetro en cualquier tienda de material eléctrico.
- El tubo de cobre de 12mm de diámetro en cualquier almacén de material de fontanería o inculso en grandes superficies dedicadas a bricolage.
- La chapa de latón la he comprado en Suministros Azán, en el polígono de Argales en Valladolid. Cuesta unos 28 euros una plancha de 100x60cm aprox.
- El tubo de latón de 4mm y la varilla de latón de 4mm de diámetro o similar (para hacer la pinza para sujetar las arandelas) en grandes superficies de bricolage o en tiendas dedicadas a maquetas y modelismo, como Biplano al lado de San Benito, en Valladolid.
- El RG-316 se encuentra en amidata en Madrid, en bobinas de 25 metros.

- El conector N macho para soldar a cable (para rg-58, no se encuentra para cable mas fino) en cualquier tienda de componentes electrónicos, en Valladolid en Oseca, en la carretera de circunvalación. También en Oseca la abrazadera para sujetar la antena a un mástil.
- La chapa perforada para hacer el soporte de la antena se compró en AKI en el Camino Viejo de Simancas, pero puede servir cualquier otra chapa de 2mm de grosor y tamaño 7cmx15cm.

"But I Never Agreed to That!"

Covenants, Conditions and Restrictions in the Amateur Service

By Chris Imlay, W3KD
ARRL General Counsel

From December 1995 *QST*

PRB-1 · Regulatory Information Branch

- How Do Covenants Differ From Zoning Ordinances?
- So Who Enforces These Covenants?
- Antenna Covenants
- How About PRB-1?
- What's in the Future?

Jim Rich, WD6CJB, woke up one morning to find that, during the night, someone had accidentally crashed a car through his fence. That wasn't much of a problem all by itself--the insurance company would cover the fence repair--the unfortunate part was that Jim's multiband HF dipole antenna that was mounted on the inside of the fence, was destroyed. The dipole had not been effective for what Jim Rich wanted to do in Amateur Radio--emergency and public service work--so he figured that it was time to put up something better anyway. That decision began the nightmare that Jim didn't have the night before.

Jim And CC&Rs

Jim went to the zoning authorities for the City of Foster City, a group of subdivisions in a planned community south of San Francisco, and asked for a building permit for a 35-foot crank-up antenna support and a small triband Yagi antenna. He was promptly denied such; the mayor and council members went out of their way to keep this "scourge" out of the neighborhood. They were not successful, because the zoning ordinance in Foster City was plainly preempted by

the FCC's Amateur Radio Preemption policy.[1] The thing about Foster City, though, was that when it was first formed, there was not any zoning ordinance (or local government) in the town. Instead, all of the subdivisions had identical declarations of covenants--often called deed restrictions, or "CC&Rs" (covenants, conditions and restrictions)--that governed land use in each subdivision. When the town adopted zoning ordinances to deal with land use details, the homeowner's associations in the Foster City subdivisions gradually faded away. They were no longer necessary.

The covenants, although dormant, were still in place, and they bound each successive purchaser of land in Foster City. The covenants provided, as do most, that any home-owner could enforce them against any other homeowner. And in Foster City, the CC&Rs prohibited all antennas of every type that are outside the house, above the roof, and not under the eaves. The restriction is absurd, as a practical matter--there are television antennas on numerous houses. When the City of Foster City found out that it couldn't prohibit Jim Rich's modest antenna system, Jim got his building permit. However, the municipal government did all it could to encourage the formation of a group of neighbors (most of whom can't even see Jim's antenna) to enforce the long-dormant and unenforced covenants against Jim. Thus began about four years of litigation. Jim's case ate up thousands of dollars of Jim's money, caused untold emotional impact on Jim and his wife, and resulted in many hundreds of hours of donated time by two very dedicated and talented ham lawyers in northern California [2] in the efforts to protect Jim's ability to install and keep a modest 35-foot crank-up antenna.

How Do Covenants Differ From Zoning Ordinances?

Many hams are not aware of the differences between zoning ordinances and covenants. The two are radically different in terms of their legal status and how they are likely to affect an amateur. It is useful to understand covenants not only from the viewpoint of the ham who appears to be at the mercy of his or her neighbors, but as well as from the point of view of the real estate developer, who has created the problem for the radio amateur in the first place.

Suppose you are a real estate developer, who looks forward to a financially successful subdivision development project. Financing a subdivision and the construction of houses requires that you borrow money from a bank. You then acquire the land for the subdivision, file a subdivision plat with the county or city, and begin construction of houses. Your interest is in getting your houses built and sold quickly, so you can pay off the bank, pocket your profits, and move on to the next project. The process of selling off the houses in your subdivision, however, may not go as fast as you would like, and perhaps you have to keep a few houses for some time. Since the last few houses sold represent, for the developer, the profit in the subdivision project (the bank has to be paid off first), what you don't want is for one of the earlier purchasers of a house in the subdivision to paint pink camels on the front of his house before you can sell off all remaining houses. Some potential home buyers might find the camel paintings unattractive. That would make it difficult for you to sell the last few houses. But what can you do to prevent the pink camel painting? You already sold the painter his house. It isn't yours anymore, and the zoning ordinances don't address pink camel painting.

The answer comes from the old English common law, from where have derived our law and procedures for property ownership and land transactions. Covenants have been placed on land for many years, and have evolved as a means of private land use restriction. Some covenants, in addition to regulating the use of the land itself, seek to regulate even the behavior of those who own the land.[3] Covenants are created when the developer files, with the land records, and usually together with his or her subdivision plat at the time land is subdivided for development, a declaration of covenants. These restrictions on the use of land are applicable to all parcels of land in the subdivision. So, just by buying the land, a buyer becomes subject to the restrictions applicable to the property bought.

Simply stated, covenants are promises that the buyer of land makes as a condition of purchasing the land in the first place, from either a developer or a previous owner. Because the covenants are filed with the land records in the county or city where the land is located, and because they are referred to in your deed, you aren't even required to be fully aware of the specifics of the covenant restrictions when you go to closing on the land.[4] Since they show up in the "chain of title" to your land, the buyer of the land has what is called "constructive notice" of the covenants, and therefore he or she is charged with the knowledge of them. In other words, you are expected to know what is in the covenants, even though you may not have actual knowledge of the restrictions in them. In many states, this is enough all by itself to require that the buyer comply with all of their provisions. The situation is another expression of the concept that "ignorance of the law is no excuse."

So Who Enforces These Covenants?

Initially, the developer retains the rights to enforce the covenants, since they are to his or her benefit in the first place. Remember that the developer wants the homes in the subdivision to pretty much stay the same, in terms of appearance, until he or she can sell off all the houses and take his or her profit and go on to the next development project. After that, the normal provision is for the enforcement authority to be delegated to a homeowner's association or an architectural control board formed by the declaration of covenants. Sometimes these associations exist for a while and then disappear. If there is no association, does the enforcement authority disappear as well? Sadly, no. In most states, individual homeowners, who are supposedly benefited by the covenants, also have the right to enforce the covenants as well.

Antenna Covenants

Covenants regulating antennas come in various forms. According to studies commenced by creative communications lawyer and professor Wayne Overbeck, N6NB, antenna covenants take three typical forms: (1) covenants that prohibit all outdoor antennas, (2) covenants that prohibit all radio transmitting devices on the premises, and (3) those that require, prior to installing any "structure" outside the house, the approval of the homeowner's association.

Suppose you buy a house in a subdivision subject to CC&Rs and then become a ham and want to put up an antenna. If you can't get the approval of the association to do so, what do you do? Simply putting up an antenna in violation of the covenants is not necessarily a good plan, because many homeowner's associations, funded by regular, mandatory dues from homeowners in the subdivision (as provided in the declaration of covenants) are charged with the enforcement of the covenants, and are financially able to bring a lawsuit against you to do just that. Indeed, if they don't bring an enforcement suit against you, other neighbors might sue the association for failing to do its job. The worst part about it is that, if you are sued by the association and lose the case, or if you sue the association and lose, attorney's fees incurred by the association (and occasionally, fees incurred by individual home-owners) are, according to many covenants, assessed against you. If you don't pay the fees, the debt continues to haunt you in the form of a lien on your property.

There are common-law defenses against covenants, but they are not used very much, and their effectiveness has been reduced over the years. However, if there are multiple violations of an antenna covenant in a neighborhood (such as the unchallenged existence of other amateur antennas, CB antennas, satellite dishes, or television antennas), then that is good evidence that the covenants prohibiting antennas are abandoned or waived. If you are told by the association that an antenna installation will be acceptable, that approval, if you can prove that it was given, makes enforcement of the antenna covenant difficult for the association later. And if you have an antenna up for a number of years in violation of the covenant, and if it is visible and obvious to others during that time, it is unlikely that the covenant could be enforced at a later date. But beware of these defenses, as they are not absolutely available. Jim Rich noted in

his case that there were antennas in the neighborhood, but the judge decided that they were minimal by comparison to his 35-foot crank-up tower and standard triband Yagi, and did not constitute a waiver or abandonment of the covenants.

How About PRB-1?

Nor does the FCC's PRB-1 preemption order apply to covenants. It specifically disclaims any application to covenants, which FCC describes as "private contractual agreements." It said that "Such agreements are voluntarily entered into by the buyer or tenant when the agreement is executed and do not usually concern this Commission."[5]

Why would the FCC conclude that PRB-1 did not apply to covenants, while it did apply to zoning ordinances? Surely, covenants that preclude antennas have the exact same effect on the strong Federal interest in promoting Amateur Radio communication as do zoning ordinances. Remember, though, that zoning ordinances are actions of local government, imposed to protect the health, safety and general welfare of the public. State and local laws may be preempted by the Federal law, where the state laws conflict with the Federal law, according to the Constitution of the United States. Covenants, on the other hand, are not governmental actions. They are, in theory, private "agreements" between a buyer and a seller of land. Therefore, they are insulated against intrusion by the Federal government.

There are exceptions to this, however. Racial covenants were declared invalid in 1948 in a famous Supreme Court case called Shelley v. Kraemer.[6] There, the Supreme Court said that where the state courts were called on to enforce a covenant, those covenants that violate a fundamental right should be held invalid. If the FCC had said nothing about covenants in the preemption policy of PRB-1, it might be argued that the "strong Federal interest" in amateur communication is sufficient to support preemption of covenants. However, the Commission's disclaimer of an interest in covenant preemption has made that argument difficult.

The FCC explained its rationale for avoiding the preemption of covenants in PRB-1 by saying that "Purchasers or lessees are free to choose where they wish to reside where such restrictions on amateur antennas are in effect or settle elsewhere." Is that so? Tell that to a person attempting to purchase a home in any of hundreds of other cities in the United States. Studies by Overbeck, N6NB, and others showed that virtually all new housing developments in metropolitan Los Angeles, for example (most less than 20 years old), were subject to antenna covenants. The assumption of the FCC (and of the courts that routinely enforce covenants now) is that it is possible to purchase a home without covenants, so the purchase of a home with covenants is a voluntary act. The assumption fails, however, where the covenants cannot be avoided, subjecting the amateur to having to purchase a house with covenants, or else endure a two-hour commute to work each morning in order to pursue Amateur Radio. There simply is no choice in most metropolitan areas these days, and the situation is getting worse all the time.

What's in the Future?

FCC is now reevaluating its land use preemption policies. It is looking at satellite dish preemption again, and soon will consider preemption of local restrictions on cellular and PCS antennas. FCC has promised to revisit its amateur preemption policies at the same time. It would be reasonable in that context for the Commission to state that it has no less interest in the effective performance of an amateur station merely because it is regulated by covenant restrictions rather than zoning, and at least allow the amateur to make his or her own argument, in the courts, that certain covenants may be preempted.

Until then, the best solution to the covenant problem is to avoid purchasing a house with deed restrictions, or make your offer on the house contingent on your ability to install a reasonable antenna. Put the burden of getting that

approval on the seller. If you are already in a subdivision with deed restrictions, get on the board of the home-owner's association and use some politics. Meanwhile, the League will continue to work for some regulatory reform to deal with antenna covenants and other deed restrictions. If you have a covenant problem, let the Regulatory Information Branch at Headquarters know about it.

And What Happened to Jim Rich?

Just before press time, and after over seven years' struggle, Jim's antenna case is finally over. A settlement was reached on October 10, whereby Jim will pay the plaintiffs $6,000 of the $13,000 in fees awarded by the trial judge, both sides will dismiss their appeals, the plaintiffs will release the lien they had on Jim's home, and plaintiffs will not complain about the wire antenna Jim has strung along his fence at a height of five feet.

The trial judge determined that the FCC had the ability to deal with the CC&R issue, but that they had ducked the issue with a footnote in PRB-1. The judge concluded that is was not appropriate for the court to overturn well-settled land law use to address something the FCC itself was unwilling to address.

Rusty Epps, W6OAT, who supplied this late-breaking information, commented that "No one is happy with the settlement terms, so that probably means that it's a pretty good compromise solution!"

Notes

[1] See, PRB-1, 101 FCC 2d 952 (1985), codified at 47 C.F.R. §97.15(e). See also, Chris Imlay, N3AKD, "PRB-1, Seven Years Down the Road," *QST*, Oct 1992. pp 35-37.

[2] The trial law skills of Kip Edwards, W6SZN, and Rusty Epps, W6OAT, and their amazing tenacity and generosity, are stories in themselves.

[3] A good example of this is the prohibition of parking recreational vehicles or boats, or even cars with antennas, in the driveways of houses in subdivisions with CC&Rs.

[4] This is changing by statute in many states; now, it is often required that a buyer of land be given a copy of the CC&Rs prior to closing, at least when buying from a developer.

Welcome! I have been searching the net for months now, looking for legal resources that hams can use for that "tower project". I have all the documents contained in the ARRL "legal packet", and was hoping to find them posted somewhere. With the exception of PRB-1, I have not. As a service to fellow amateurs, I have decided to post them here. Some of my own ramblings and experiences can also be found here. I welcome your comments, suggestions, questions, and answers. If relevant, they will also be posted here on a regular basis.

-Good luck with that tower project! 73, de Gregg, K3QK

CC&R Survival Series

Bill Fisher (W4AN) on January 8, 2001
View comments about this article!

I would like to propose the start of a series of articles from people who are still able to be active hams while living within restrictive covenants. I happen to be one of those people, and I am on the air daily on several bands with good signal reports and long QSOs. I am currently writing an article on an antenna that I am building and hope to have it posted in a week or two.

If you are successfully operating the radio under restrictive covenants and have advice or interesting success stories, please take a few minutes to pass them on the rest of us. If you know someone else who is surviving CC&R's, please drop me a line with their email address and I will contact them about writing an article for us.

Interesting topic. One item to include with CCR solutions would be how RF exposure issues are resolved; for example, it would be very difficult to have an antenna radiating 1.5 KW (say in the 10 meter band)located in the atic with an operator located close by and still meet the FCC RF exposure requirements.

I live in a college dorm apt complex, with blanket antenna restrictions. I have (so far) gotten away with a run of magnet wire from my 2nd floor window to some trees about 50 feet away for SWL work, and I put a 2M groundplane on top of a homebrew T shaped PVC assembly with some pipe hangers and hung it off the gutter outside my window. The restrictions in our housing contract are written so broadly, that they could technically ban cordless phones, cell phones, stereos, clock radios, TVs, walkmans, etc.. (of course this was not the intent I'm sure).

RE: CC&R Survival Series Reply
by W4AN on January 8, 2001 Mail this to a friend!

BTW, I was hoping we could have some articles from you survivors and not just comments posted to this article.

When I was in college, I snuck a piece of coax out the dorm room window up on to the roof. Luckily I was on the top floor. I put up a 40 meter dipole antenna off of the TV antenna mast. Antenna was probably a good 100' off the ground and worked VERY well.

Of course, my buddies with the stereo gear didn't appreciate it. But they were none the wiser of my being a ham. :)

A distinction that would be interesting to understand in each situation is whether the operation is OVERT or COVERT. Is your setup known to management and approved, known to management but not approved, or unknown to management? By separating situations into these categories, a variety of interesting strategies can be devised.

I only operated 2fm from my dorm room in college - and my mag-mount 1/4-wave vertical was confiscated more than once. It was an engineering school. We had a nuclear power lab on campus. We had biotech engineers cloning each other. Didn't management have anything better to worry about than my 2m whip? Good thing we had a great ham station and I was eventually the Station Manager.

I chose, and my wife accepted, a home with trees and undeveloped space close behind the house. If you have such "natural antenna supports" on your property, it makes getting on the air in stealth mode much easier.

The end-fed antenna is 130' of #26 black insulated wire in the trees, worked against a single ground rod. The system is matched using the great SGC-230 remote antenna tuner. By using a wire that's a multiple of a half wave at 80, 40, 20, 15 and 10, the feedpoint impedance is relatively high so ground losses from using just the single ground rod are relatively low.

The SGC is fastened to the "back side" of a tree trunk just above ground level, and disguised by setting some broken limbs alongside it to break up its outline. The coax and 12 volt power cables are buried in a shallow trench to the point where they are routed up a deck support post and into the basement

through the sill plate. I laid out and buried the cables one evening when I knew the nearest neighbor was away.

The antenna wire is very difficult to see against the trees, even when you're looking for it. At a previous, rented QTH, I ran this kind of wire from the second story of my townhouse across the parking lot and into a tree. None of the neighbors ever noticed it until one neighbor had a visitor who was a ham. The ham pointed it out, but since my QRP operation hadn't been causing any QRM, the neighbor didn't raise any kind of fuss.

A slingshot with a 1 oz lead sinker can fire 10 lb test line a remarkable distance up and out. I use a fluorescent green line to make finding the far end easier. Cut off the sinker, tie the antenna wire to the line, reel it in from your launch point, and you're well on your way to stealth hamming.

Hello Bill,
Sure I will comment. I am currently buying a house in Texas. It has a deed restriction and I think I can beat it. At least I am going to try because the Homeowner's association does not charge any dues. The restriction is poorly worded too. I am going to first speak with attourney buddies to see what I can do about having it removed from the deed (when I get that as I have not yet seen it.) The land size is nice, about an acre and well treed. I think I can easily hide wires in the trees. A tower is the big question.
I will keep you informed.

We had our house built in a very restrictive neighborhood. I particularly hate the restriction against growing a vegetable garden. However, the covenant against antennas is vague, reading "no unsightly structures" which eliminates towers of course.

I planned ahead. I selected a lot with dense woods extending over 300' behind the house. Then I borrowed a plane-table, a fairly simple surveying device, and mapped all the significant trees growing there. With this done, I selected trees to support my dipoles, out of sight, and was lucky enough to have a large maple tree, 150 feet back in the forest, with the main truck forming an arch at about forty-five degrees. Throwing a line over this "limb" and clearing all growth underneath, I pulled a full wave two-element Lighting brand quad wired for five bands up off the ground eight feet. I then poured a 24X24 inch pad with a pipe flange secured to its surface with spikes, screwed a 3 foot galvanized pipe into it, mounted a CDE rotor on the pipe, and used a telescoping Radio Shack mast to connect to the boom. The limb holds the weight and the rotor works great. I painted the poly arms green and brown, and you really have to make an effort to see the setup. (we are in the lowest elevation on the subdivision, and I still compete successfully in the pileups, 5BDXCC, 5BWAS, etc. Not as easy as with a tower at a higher elevation of course, but I still enjoy good DXing)

by WA4CNG on January 10, 2001 Mail this to a friend!

I am still surviving after making Y2K-DXCC in October last year with my Attic Antennas (Article posted here). You and I live less than 15 miles apart in Alpharetta Ga. I have made some changes up there, got rid of the Square Loops, added a 6 meter dipole. Hamshack and shop is now in the Terrace Level, added an Amertron Al-811H amplifier, feeding the antennas with 1/2 inch hardline in the attic via the conduit I had installed by the builder. I am still working on getting 75 meters to work. I am having mixed results, mostly not, from the DX-SA Antenna I

installed for 75/20 meters. VHF/UHF is great with the ground elevation of 1140FT, plus 35 feet into the attic. That is nearly 1200 Feet ASL in Atlanta Ga, where the average terrain is 1000 feet, like having a 200 ft tower in the backyard.

My subdivision bans antennas. I am taking a two prong tact: First, I volunteered for the architectural review board and wound up as chairman. This gives me a lot of "inside influence" especially when convincing others that new PRB-1 actually applies to ham antennas in CC&Rs. Second, I applied a loophole that allows "satellite antennas" (intended for tv of-course) and called my 6 meter rotatable dipole a "satellite antenna" who knows, it might pick up a satellite signal! Since we have some trees, I can keep things low profile until I get bolder...so I put up a MARTIN HOUSE (you know - for Purple Martins) on a 15 foot steel pole. I have a radial system below it on the ground. I dont feed the pole, I have thin black wires attached at the top and coming down to feed point at the bottom (I use a remote switch to change antennas) these form inverted Ls on 160-10 meters. I had to bend the 160 L (more of a W than L)around my small yard a lot. I can run up to 700 watts...never a complaint from neighbors. I work the world on 100 watts including a lot of dx on 160. This stealth stuff is almost as much fun as working dx from a tower/beam...like the WWII resistance/spy novels I liked as a kid.

I'll let you know if I can get more overt.

I,m anonymous because of my insider position!

by K0MU on January 13, 2001 Mail this to a friend!

The previous poster mentioned that satellite antennas are allowed. Any HF antenna that covers 10 and 15 meters is a "satellite antenna." RS12 has uplink on 15 and downlink on 10. Therefore any HF antenna / beam should be allowed. The satelite industry did us a favor!!! Is this a loophole?

I appreciate all the posts about the CC&R's..... When i first started reading about it back in like sept-octish, I thought oh whats the big deall..... you know... then I started checking into it more and started understanding why its a big topic. Well, I'm finally getting my first apartment next month, and I'm pretty sure I'm not going to be able to erect anything like an antenna on top of the building for my radio working fun. So, basically I just want to thank you all that have posted on this and it has helped me with ideas and ways to get around this problem. Thanks once again guys.

Maybe I'm nuts, but if I saw a development that actually had a CC&R against a VEGETABLE GARDEN, I'd go look somehwere else. Antennas or no antennas.

It is most important to be on good terms with the HOA Board, join it if you can. I obtained approval by writing a letter to the Board explaining the benefits from emergency communications that I can provide the community in times of emergency. I mentioned in my letter that one such antenna could be treated as a special case in any community without creating a precedent for others. I compared the profile of my R6000 vertical in sq ft to a DBS dish. I stated that I would assist any homeowner who encountered problems but stopped short of saying that I would fix any problem.

They asked questions about RF health and I responded by saying my power was controlled by my FCC licence and is about the same as a lightbulb. They also asked questions about the installation and I explained my method of attachment to the apex of my roof and could quote the EIA requirements for grounding.

Jonathan (KD5LJH):

I'm an apartment dweller and have lived in several apartments. I think the most important thing you can do is *ask your landlord* about antennas *before* you put them up. If you explain the purpose of the antennas and amateur communication, the proposed installation procedure, and the safety measures in place regarding the antennas you might be surprised how willing they are to work with you. I have an A99 (17' tall) and a Diamond X50A (6' tall, on a 15' mast) both mounted on my balcony and the landlord doesn't have a problem with them because I asked first and did not damage the apartment installing them. 73

At one time, I had a wife who was adamant about NO ugly towers, and No ugly antennas on the house. Our house was on 1 arce with many trees in the back, where the majority of land was. One day while she was a way, I put up a 1/4 wave GP for 40 meters made out of brown wire and a SO239 (I didn't know then that a delta loop would have been better. I used a pine tree to pull the fishing line up to hold the verticle wire, and fishing line to tie the radials to other trees. The radials were 6 feet off the ground, along with the feed point. The verticle portion wasn't totally verticle, it sloped front the feed point that was about 5 feet away from the pine tree. About 18 months later, we were on the back porch watchin a sunset through and over the trees in the back, and my wife wondered what that shiny thing was hanging in the air about 30 feet away from the house (my SO239) I had tons of fun with that antenna and a SB220 amplifier. And, yes, the antenna stayed up, after the shiny "free floating" thing was observed. You had to look very carefull in the winter time when there weren't leaves on the trees to find the antenna.

I remember one time when I was single and in a crowded housing development, my neighbor asked me why I had a brick and an arrow hanging from a tree in my front yard He didn't see the brown verticle wire from the top of the tree to the ground). The arrow and brick got caught in the tree when they were thrown or shot over the tree and the fishing line got caught in the tree. I explained I had used them, and they got caught in the tree, to pull a thin wire in the tree to use for my nightly SWL.

Hmm... Looks like I'll have to start on the one I was working on doing back in early October of last year after I arrived out here in Chicago. I've had to be pretty creative, but so far things are working very well. I will however be very happy to return to sunny & warm Arizona where I have much less restrictions, actually there are some where I currently live out there, but I did get around them... :^)

Anyway Bill look for an article submission by me in a few weeks. I've been so busy with computer consulting and my business on the 'net that I haven't had time to do any free-lance writing (for anyone), in the past four months. I think that I still have the framework for that article on my HD and a few of the pictures that I took of a couple of my antenna setups as well. It's not much, but it works. I'm betting that we can really learn from one another on this subject...

I am in a college dorm at an engineering school. Due to the fact that my dorm has a "grounded" chicken wire network in all the walls under the plaster and I cannot remove the screen at all, there is little hope of a signal getting out. I use a twin-lead J-pole (I know it isn't the best, but no where to put a mag mount) in the window frame itself. I am able to get into the close, local repeaters and on packet (2m FM) without too much trouble, but since I am chief op at the local Ham Club, I can use that equipment if necessary with all the outdoor antennas. All in all, I live in a pandora's box that eats signals and am just lucky that I can get anything out at all. The neighbors don't like the intermod through the computer speakers though, hihi. If I was able to remove the screen and get an antenna out into the tree outside of my antenna, I would have get better signal reports and my pbbs wouldn't time everyone out.

I bought my house about 6 years ago in a now 20 year old neighborhood (San Jose CA). CC&R's are clear and legal. No antennas, no basketball hoops no, can't work on cars in driveway, keep garage doors closed.... Then there is reality.

When I was considering the the house I plotted. Seeing the conditions in the neighborhood I could see the CC&R's were not being enforced, no gross violations but RVs are here etc.

My house is next to the end of culdesac and backs on to a freeway. That means no backyard neighbors. With a streetlight on my curb first up was a 133' dipole from the streetlight to the backyard. Used phylistrand and no insulator on the street end. It is almost invisible. That was good for 40 & 80 now what about a beam?

I bought a 40' tubular tower (used) with the rotor at the base. That with a Force12 C3-S (12' boom no traps no rotor at the top) made for the lowest profile cleanest installation one could think of. The tower went up about 2 years after the dipole and been up exactly a year and the folks are peaceful.

Our current QTH does not have CC&R's which was a major factor in our decision to purchase the property. Our previous residence was a gated community with strict CC&R's and an overly-nosey property management firm. One easy way to beat restrictions is to operate MOBILE from your vehicle. I used to sit out in the driveway operating HF with a screwdriver-type antenna while the jerk manager just stood there raising his blood pressure. It's a great feeling knowing there's nothing they can do about it.

Hello,
My family and I live in graduate and family housing at Western Illinois University (WIU)and any outside antennas are strictly prohibited. So I go to my wife's minivan and operate mobile (stationary). For some silly reason the state of Illinois is very reluctant to grant a driver's license to a legally blind individual. hi hi. I usually run 100 watts from my Icom 706MkII through a hustler mobile antenna. So far I've worked 7 foreign countries and about half of the states on 40m. Since Sequoia my Leader Dog is usually with me I can get away with saying "we" while operating.hi hi. although for the most part I try to avoid using hambabble on the air. One of these days I'll get up to courage to "run with the big dogs" and operate CW. A friend from my former hometown loaned me a non J-38 antique straight key- it had been used in World War two by the Army.
Some of the reasons I like working mobile (stationary)are:
1.) My five year old daughter isn't being exposed to RF.
2.) My wife can't complain about wires being run all over the apartment.
3.) Fellow hams seem to be more willing to talk to a "Mobile" station... hi hi hi

Her is one for the books as to Deeds and restrictions here where I live, Maybe we can get something done as to this fracture I have found.

IN my meighborhood there are SIX(6) differant deed systems which ALL but ONE doesnt allow antennas.

I live at the end of the street,4th house form the corner NOW the side streets, and house's behind me behind my back yard can HAVE antennas but no higher than 10 feet above the roofline. HOWEVER my street for a quarter of a block is in the DEEDED company that doesnt allow for any antennas.

When I first moved in The antenna could be spotted and got a notice to take it down which I did, and then put up another one that couldnt be seen from the front of the house.

SO FAR in 10 yrs I have not gotten a notice, to take it down. I have a six element antenna and going to get a smaller one 3 element, beam. I have been lucky im a disabled person and this is what I do to stay active as a Disabled Veteran is be a ham and help during flods and disasters. About 2 yrs ago on all the houses here on my block I have spotted satelitte antennas, and everyone I have talked to said they could put them up, SO I DONT KNOW if this blows out the ALL NO ANTENNA DEED RESTRICTION-- since they have let in one type of antenna. ALSO to my DISBELIEF is everyone has BEEN HIJACKED as to TV here, due to not being able to put up a tv antenna, we have to have cable tv installed, which to me takes away my rights to Television and putting up a antenna, WISH we could get these B******S as to HIJACKING rights.

IT is a shame that in all the areas around me people have antennas outside and this one small quarter of a blovk who is under HOUSING PROPERTY MANAGENT wont let any antennas be had and everyone else does.

LOVE DISCRIMINATION here as to what I have to live with. About a year ago I wrote a long letter to the ARRL< about how this is here to see if in the future the FCC who has NO BACKBONE anymore full of

POLITICINS turn their backs on the very HAMS who might be the only communications due to terrorism today in the US.

Thanks for reading

I decided to follow the rules and apply for the antennas through normal channels. I was turned down at first and went before the board to state my case. After some muscle flexing by the board and some ego stroking by me, they approved the installation of my Hustler 4-BTV. I also use a Webster Bandspanner mounted on the ground, but this one is short enough that it doesn't fall under the rules. For two meters, I have an Isopole 144 mounted to the back of the chimney. Since it is not visible for anyplace but my backyard, it is not a problem either.
In my case, an unexpected ally turned out to be the manager of the Management Company. She explained to the board that during times of disaster, having a ham in the neighborhood is invaluable. I cannot wait for some legislation to assist hams with their antenna issues, but in the interim, I would advise hams to at least try to follow the rules and be reasonable in their request. I have no doubt that they would have turned me down completely if I had asked for "forgiveness" instead of "permission". I want to mention though, that I was going to use my 4-BTV even if I had been turned down. A wing nut at the bottom would have made it easy to remove from the ground mount, so that I could have taken it down when I wasn't using it. A pain in the neck, but better than nothing and not against the rules. Unfortunately not everyone's antennas lend themselves to this type of solution.

how about we just refuse to buy houses where there are c&r and hoa-i just found an older house on one acre no c&rs no hoa i can have antennaes ,poultry and horses!

tell all your friends not to buy houses with c&rs!

RE: CC&R Survival Series Reply
by KC4UAI on August 4, 2004 Mail this to a friend!

Not Buying a house with CCNR's is becoming more and more difficult. Most newer homes will have CCNRs, and the remaining older homes are either too expensive, or are in undesireable locations.

I checked in my local area and found that about 90% of the houses that I could afford had CCNRs. I suspect that this percentage would be less in a more rural area, but one has to live where they can earn a living.

I was wondering... Has anybody conducted a formal study to determine the % of houses that have CCNRs, verses the % that don't. Would not the same argument that the FCC used to justify state and local preemption, be valid for CCNR's if the percentage of homes availble was very small?

I would suspect that the % of available houses w/o CCNRs has been drasticly reduced since the PRB-1 rules where put into effect, and I sometimes wonder if the FCC would listen to that argument. I suppose it's wishful thinking, so we can hope that the CCNR bill makes it through congress..

FEDERAL COMMUNICATIONS COMMISSION

FACT SHEET

May 2001

Over-the-Air Reception Devices Rule

Preemption of Restrictions on Placement of Direct Broadcast Satellite, Multichannel Multipoint Distribution Service, and Television Broadcast Antennas

Quick Links to Document Sections Below

- Questions and Answers
- Links to Relevant Orders and the Rule
- Guidance on Filing a Petition
- Where to Call for More Information

As directed by Congress in Section 207 of the Telecommunications Act of 1996, the Federal Communications Commission adopted the Over-the-Air Reception Devices Rule concerning governmental and nongovernmental restrictions on viewers' ability to receive video programming signals from direct broadcast satellites ("DBS"), multichannel multipoint distribution (wireless cable) providers ("MMDS"), and television broadcast stations ("TVBS").

The rule is cited as 47 C.F.R. Section 1.4000 and has been in effect since October 14, 1996. It prohibits restrictions that impair the installation, maintenance or use of antennas used to receive video programming. The rule applies to video antennas including direct-to- home satellite dishes that are less than one meter (39.37") in diameter (or of any size in Alaska), TV antennas, and wireless cable antennas. The rule prohibits most restrictions that: (1) unreasonably delay or prevent installation, maintenance or use; (2) unreasonably increase the cost of installation, maintenance or use; or (3) preclude reception of an acceptable quality signal.

Effective January 22, 1999, the Commission amended the rule so that it also applies to rental property where the renter has an exclusive use area, such as a balcony or patio.

On October 25, 2000, the Commission further amended the rule so that it applies to customer-end antennas that receive and transmit fixed wireless signals. This amendment became effective on May 25,

2001.

The rule applies to viewers who place antennas that meet size limitations on property that they own or rent and that is within their exclusive use or control, including condominium owners and cooperative owners, and tenants who have an area where they have exclusive use, such as a balcony or patio, in which to install the antenna. The rule applies to townhomes and manufactured homes, as well as to single family homes.

The rule allows local governments, community associations and landlords to enforce restrictions that do not impair the installation, maintenance or use of the types of antennas described above, as well as restrictions needed for safety or historic preservation. In addition, under some circumstances, the availability of a central or common antenna can be used by a community association or landlord to restrict the installation of individual antennas. In addition, the rule does not apply to common areas that are owned by a landlord, a community association, or jointly by condominium or cooperative owners. Such common areas may include the roof or exterior wall of a multiple dwelling unit. Therefore, restrictions on antennas installed in or on such common areas are enforceable.

This fact sheet provides general answers to questions that may arise about the implementation of the rule, but is not the rule itself. For further information or a copy of the rule, call the Federal Communications Commission at 888-CALLFCC (toll free) or (202) 418-7096. The rule is also available via the Internet by going to links to relevant Orders and the rule.

Q: What types of antennas are covered by the rule?

A: The rule applies to the following types of video antennas:

(1) A "dish" antenna that is one meter (39.37") or less in diameter (or any size dish if located in Alaska) and is designed to receive direct broadcast satellite service, including direct-to-home satellite service, or to receive or transmit fixed wireless signals via satellite.

(2) An antenna that is one meter or less in diameter or diagonal measurement and is designed to receive video programming services via MMDS (wireless cable) or to receive or transmit fixed wireless signals other than via satellite.

(3) An antenna that is designed to receive local television broadcast signals. Masts higher than 12 feet above the roofline may be subject to local permitting requirements.

In addition, antennas covered by the rule may be mounted on "masts" to reach the height needed to receive or transmit an acceptable quality signal (e.g. maintain line-of-sight contact with the transmitter or view the satellite). Masts higher than 12 feet above the roofline may be subject to local permitting requirements for safety purposes. Further, masts that extend beyond an exclusive use area may not be covered by this rule.

Q: What are "fixed wireless signals"?

A: "Fixed wireless signals" are any commercial non-broadcast communications signals transmitted via wireless technology to and/or from a fixed customer location. Examples include wireless signals used to provide telephone service or high-speed Internet access to a fixed location. This definition does **not** include, among other things, AM/FM radio, amateur ("HAM") radio, Citizens Band ("CB") radio, and Digital Audio Radio Services ("DARS") signals.

Q: Does the rule apply to hub or relay antennas?

A: The rule applies to "customer-end antennas" which are antennas placed at a customer location for the purpose of providing service to customers at that location. The rule does not cover antennas used to transmit signals to and/or receive signals from multiple customer locations.

Q: What types of restrictions are prohibited?

A: The rule prohibits restrictions that impair a person's ability to install, maintain, or use an antenna covered by the rule. The rule applies to state or local laws or regulations, including zoning, land-use or building regulations, private covenants, homeowners' association rules, condominium or cooperative association restrictions, lease restrictions, or similar restrictions on property within the exclusive use or control of the antenna user where the user has an ownership or leasehold interest in the property. A restriction impairs if it: unreasonably delays or prevents use of; (2) unreasonably increases the cost of; or (3) precludes a person from receiving or transmitting an acceptable quality signal from an antenna covered under the rule. The rule does not prohibit legitimate safety restrictions or restrictions designed to preserve designated or eligible historic or prehistoric properties, provided the restriction is no more burdensome than necessary to accomplish the safety or preservation purpose.

Q: What types of restrictions unreasonably delay or prevent viewers from using an antenna?

A: A local restriction that prohibits all antennas would prevent viewers from receiving signals, and is prohibited by the Commission's rule. Procedural requirements can also unreasonably delay installation, maintenance or use of an antenna covered by this rule. For example, local regulations that require a person to obtain a permit or approval prior to installation create unreasonable delay and are generally prohibited. Permits or prior approval necessary to serve a legitimate safety or historic preservation purpose may be permissible.

Q: What is an unreasonable expense?

A: Any requirement to pay a fee to the local authority for a permit to be allowed to install an antenna would be unreasonable because such permits are generally prohibited. It may also be unreasonable for a local government, community association or landlord to require a viewer to incur additional costs

associated with installation. Things to consider in determining the reasonableness of any costs imposed include: (1) the cost of the equipment and services, and (2) whether there are similar requirements for comparable objects, such as air conditioning units or trash receptacles. For example, restrictions cannot require that expensive landscaping screen relatively unobtrusive DBS antennas. A requirement to paint an antenna so that it blends into the background against which it is mounted would likely be acceptable, provided it will not interfere with reception or impose unreasonable costs.

Q: What restrictions prevent a viewer from receiving an acceptable quality signal?

A: For antennas designed to receive analog signals, such as TVBS, a requirement that an antenna be located where reception would be impossible or substantially degraded is prohibited by the rule. However, a regulation requiring that antennas be placed where they are not visible from the street would be permissible if this placement does not prevent reception of an acceptable quality signal or impose unreasonable expense or delay. For example, if installing an antenna in the rear of the house costs significantly more than installation on the side of the house, then such a requirement would be prohibited. If, however, installation in the rear of the house does not impose unreasonable expense or delay or preclude reception of an acceptable quality signal, then the restriction is permissible and the viewer must comply.

The acceptable quality signal standard is different for devices designed to receive digital signals, such as DBS antennas, digital MMDS antennas, digital television ("DTV") antennas, and digital fixed wireless antennas. For a digital antenna to receive or transmit an acceptable quality signal, the antenna must be installed where it has an unobstructed, direct view of the satellite or other device from which signals are received or to which signals are to be transmitted. Unlike analog antennas, digital antennas, even in the presence of sufficient over-the-air signal strength, will at times provide no picture or sound unless they are placed and oriented properly.

Q: Are all restrictions prohibited?

A: No, many restrictions are permitted. Clearly-defined, legitimate safety restrictions are permitted even if they impair installation, maintenance or use provided they are necessary to protect public safety and are no more burdensome than necessary to ensure safety. Examples of valid safety restrictions include fire codes preventing people from installing antennas on fire escapes; restrictions requiring that a person not place an antenna within a certain distance from a power line; and installation requirements that describe the proper method to secure an antenna. The safety reason for the restriction must be written in the text, preamble or legislative history of the restriction, or in a document that is readily available to antenna users, so that a person wanting to install an antenna knows what restrictions apply. Safety restrictions cannot discriminate between objects that are comparable in size and weight and pose the same or a similar safety risk as the antenna that is being restricted.

Restrictions necessary for historic preservation may also be permitted even if they impair installation, maintenance or use of the antenna. To qualify for this exemption, the property may be any prehistoric or

historic district, site, building, structure or object included in, or eligible for inclusion on, the National Register of Historic Places. In addition, restrictions necessary for historic preservation must be no more burdensome than necessary to accomplish the historic preservation goal. They must also be imposed and enforced in a non-discriminatory manner, as compared to other modern structures that are comparable in size and weight and to which local regulation would normally apply.

Q: How does the rule apply to restrictions on radiofrequency (RF) exposure from antennas that have the capability to transmit signals?

A: All transmitters regulated by the Commission, including the customer-end fixed wireless antennas (either satellite or terrestrial) covered under the amended rule, are required to meet the applicable Commission guidelines regarding RF exposure limits. The limits established in the guidelines are designed to protect the public health with a large margin of safety. These limits have been endorsed by federal health and safety agencies, such as the Environmental Protection Agency and the Food and Drug Administration. The Commission requires that providers of fixed wireless service exercise reasonable care to protect users and the public from RF exposure in excess of the Commission's limits. In addition, as a condition of invoking protection under the rule from government, landlord, and association restrictions, a provider of fixed wireless service must ensure that customer-end antennas are labeled to give notice of potential RF safety hazards posed by these antennas.

It is recommended that antennas that both receive and transmit signals be installed by professional personnel to maximize effectiveness and minimize the possibility that the antenna will be placed in a location that is likely to expose subscribers or other persons to the transmit signal at close proximity and for an extended period of time. In general, associations, landlords, local governments and other restricting entities may not require professional installation for receive-only antennas, such as one-way DBS satellite dishes. However, local governments, associations, and property owners may require professional installation for **transmitting** antennas based on the safety exception to the rule. Such safety requirements must be: (1) clearly defined; (2) based on a legitimate safety objective (such as bona fide concerns about RF radiation) which is articulated in the restriction or readily available to antenna users; (3) applied in a non-discriminatory manner; and (4) no more burdensome than necessary to achieve the articulated objectives.

For additional information about the Commission's RF exposure limits, please visit http://www.fcc.gov/oet/rfsafety or call the RF Safety Information Line at 202-418-2464.

Q: Whose antenna restrictions are prohibited?

A: The rule applies to restrictions imposed by local governments, including zoning, land-use or building regulations; by homeowner, townhome, condominium or cooperative association rules, including deed restrictions, covenants, by-laws and similar restrictions; and by manufactured housing (mobile home) park owners and landlords, including lease restrictions. The rule only applies to restrictions on property where the viewer has an ownership or leasehold interest and exclusive use or control.

Q: If I live in a condominium or an apartment building, does this rule apply to me?

A: The rule applies to antenna users who live in a multiple dwelling unit building, such as a condominium or apartment building, if the antenna user has an exclusive use area in which to install the antenna. "Exclusive use" means an area of the property that only you, and persons you permit, may enter and use to the exclusion of other residents. For example, your condominium or apartment may include a balcony, terrace, deck or patio that only you can use, and the rule applies to these areas. The rule does not apply to common areas, such as the roof, the hallways, the walkways or the exterior walls of a condominium or apartment building. Restrictions on antennas installed in these common areas are not covered by the Commission's rule. For example, the rule would **not** apply to prohibit restrictions that prevent drilling through the exterior wall of a condominium or rental unit.

Q: Does the rule apply to condominiums or apartment buildings if the antenna is installed so that it hangs over or protrudes beyond the balcony railing or patio wall?

A: No. The rule does not prohibit restrictions on antennas installed beyond the balcony or patio of a condominium or apartment unit if such installation is in, on, or over a common area. An antenna that extends out beyond the balcony or patio is usually considered to be in a common area that is not within the scope of the rule. Therefore, the rule does not apply to a condominium or rental apartment unit unless the antenna is installed wholly within the exclusive use area, such as the balcony or patio.

Q: Does the fact that management or the association has the right to enter these areas mean that the resident does not have exclusive use?

A: No. The fact that the building management or the association may enter an area for the purpose of inspection and/or repair does not mean that the resident does not have exclusive use of that area. Likewise, if the landlord or association regulates other uses of the exclusive use area (e.g., banning grills on balconies), that does not affect the viewer's rights under the Commission's rule. This rule permits persons to install antennas on property over which the person has *either* exclusive use *or* exclusive control. Note, too, that nothing in this rule changes the landlord's or association's right to regulate use of exclusive use areas for other purposes. For example, if the lease prohibits antennas and flags on balconies, only the prohibition of antennas is eliminated by this rule; flags would still be prohibited.

Q: Does the rule apply to residents of rental property?

A: Yes. Effective January 22, 1999, renters may install antennas within their leasehold, which means inside the dwelling or on outdoor areas that are part of the tenant's leased space and which are under the exclusive use or control of the tenant. Typically, for apartments, these areas include balconies, balcony railings, and terraces. For rented single family homes or manufactured homes which sit on rented property, these areas include the home itself and patios, yards, gardens or other similar areas. If renters do not have access to these outside areas, the tenant may install the antenna inside the rental unit. Renters are not required to obtain the consent of the landlord prior to installing an antenna in these areas. The rule

does not apply to common areas, such as the roof or the exterior walls of an apartment building. Generally, balconies or patios that are shared with other people or are accessible from other units are not considered to be exclusive use areas.

Q: Are there restrictions that may be placed on residents of rental property?

A: Yes. A restriction necessary to prevent damage to leased property may be reasonable. For example, tenants could be prohibited from drilling holes through exterior walls or through the roof. However, a restriction designed to prevent ordinary wear and tear (*e.g.*, marks, scratches, and minor damage to carpets, walls and draperies) would likely not be reasonable provided the antenna is installed wholly within the antenna user's own exclusive use area.

In addition, rental property is subject to the same protection and exceptions to the rule as owned property. Thus, a landlord may impose other types of restrictions that do not impair installation, maintenance or use under the rule. The landlord may also impose restrictions necessary for safety or historic preservation.

Q: If I live in a condominium, cooperative, or other type of residence where certain areas have been designated as "common," do these rules apply to me?

A: The rules apply to residents of these types of buildings, but the rules do not permit you to install an antenna on a common area, such as a walkway, hallway, community garden, exterior wall or the roof. However, you may install the antenna wholly within a balcony, deck, patio, or other area where you have exclusive use.

Drilling through an exterior wall, *e.g.* to run the cable from the patio into the unit, is generally not within the protection of the rule because the exterior wall is generally a common element. You may wish to check with your retailer or installer for advice on how to install the antenna without drilling a hole. Alternatively, your landlord or association may grant permission for you to drill such a hole. The Commission's rules generally do not cover installations if you drill through a common element.

Q: If my association, building management, landlord, or property owner provides a central antenna, may I install an individual antenna?

A: Generally, the availability of a central antenna may allow the association, landlord, property owner, or other management entity to restrict the installation by individuals of antennas otherwise protected by the rule. Restrictions based on the availability of a central antenna will generally be permissible provided that: (1) the person receives the particular video programming or fixed wireless service that the person desires and could receive with an individual antenna covered under the rule (*e.g.*, the person would be entitled to receive service from a specific provider, not simply a provider selected by the association); (2) the signal quality of transmission to and from the person's home using the central antenna is as good as, or better than, than the quality the person could receive or transmit with an individual antenna covered by

the rule; (3) the costs associated with the use of the central antenna are not greater than the costs of installation, maintenance and use of an individual antenna covered under the rule; and (4) the requirement to use the central antenna instead of an individual antenna does not unreasonably delay the viewer's ability to receive video programming or fixed wireless services.

Q: May the association, landlord, building management or property owner restrict the installation of an individual antenna because a central antenna will be available in the future?

A: It is not the intent of the Commission to deter or unreasonably delay the installation of individual antennas because a central antenna may become available. However, persons could be required to remove individual antennas once a central antenna is available if the cost of removal is paid by the landlord or association and the user is reimbursed for the value of the antenna. Further, an individual who wants video programming or fixed wireless services other than what is available through the central antenna should not be unreasonably delayed in obtaining the desired programming or services either through modifications to the central antenna, installation of an additional central antenna, or by using an individual antenna.

Q: I live in a townhome community. Am I covered by the FCC rule?

A: Yes. If you own the whole townhouse, including the walls and the roof and the land under the building, then the rule applies just as it does for a single family home, and you may be able to put the antenna on the roof, the exterior wall, the backyard or any other place that is part of what you own. If the townhouse is a condominium, then the rule applies as it does for any other type of condominium, which means it applies only where you have an exclusive use area. If it is a condominium townhouse, you probably cannot use the roof, the chimney, or the exterior walls unless the condominium association gives you permission. You may want to check your ownership documents to determine what areas are owned by you or are reserved for your exclusive use.

Q: I live in a condominium with a balcony, but I cannot receive a signal from the satellite because my balcony faces north. Can I use the roof?

A: No. The roof of a condominium is generally a common area, not an area reserved for an individual's exclusive use. If the roof is a common area, you may not use it unless the condominium association gives you permission. The condominium is not obligated to provide a place for you to install an antenna if you do not have an exclusive use area.

Q: I live in a mobile home that I own but it is located in a park where I rent the lot. Am I covered by the FCC rule?

A: Yes. The rule applies if you install the antenna anywhere on the mobile or manufactured home that is owned by you. The rule also applies to antennas installed on the lot or pad that you rent, as well as to other areas that are under your exclusive use and control. However, the rule does not apply if you want to

install the antenna in a common area or other area outside of what you rent.

Q: I want a conventional "stick" antenna to receive a distant over-the air television signal. Does the rule apply to me?

A: No. The rule does not apply to television antennas used to receive a distant signal.

Q: I want to install an antenna for broadcast radio or amateur radio. Does the rule apply to me?

A: No. The rule does not apply to antennas used for AM/FM radio, amateur ("ham") radio, Citizen's Band ("CB") radio or Digital Audio Radio Services ("DARS").

Q: I want to install an antenna to access the Internet. Does the rule apply to me?

A: Yes. Antennas designed to receive and/or transmit data services, including Internet access, are included in the rule.

Q: Does this mean that I can install an antenna that will be used for voice and data services even though it does not provide video transmissions?

A: Yes. The most recent amendment expands the rule and permits you to install an antenna that will be used to transmit and/or receive voice and data services, except as noted above. The rule will also continue to cover antennas used to receive video programming.

Q: I have already installed an antenna that is used solely for the purpose of receiving video programming. Am I affected by this amendment?

A: Persons who have already installed, or who plan to install, an antenna designed to receive only video programming are not affected by this amendment. The purpose of the amendment is to permit persons to install antennas that may be used for voice and data services, as well as for video programming services. The rules concerning restrictions on the placement of video antennas will apply equally to antennas that are used for voice and data services.

Q: I'm a board member of a homeowners' association, and we want to revise our restrictions so that they will comply with the FCC rule. Do you have guidelines you can send me?

A: We do not have sample guidelines because every community is different. We can send you the rule and the relvant orders, which will give you general guidance. (See list of documents at the end of this factsheet. Some communities have written restrictions that provide a prioritized list of placement preferences so that residents can see where the association wants them to install the antenna. The residents should comply with the placement preferences provided the preferred placement does not

impose unreasonable delay or expense or preclude reception of an acceptable quality signal.

Q: What restrictions are permitted if the antenna must be on a very tall mast to get a signal?

A: If you have an exclusive use area that is covered by the rule and need to put your antenna on a mast, the local government, community association or landlord may require you to apply for a permit for safety reasons if the mast extends more than 12 feet above the roofline. If you meet the safety requirements, the permit should be granted. Note that the Commission's rule only applies to antennas and masts installed wholly within the antenna user's exclusive use area. Masts that extend beyond the exclusive use area are outside the scope of the rule. For installations on single family homes, the "exclusive use area" generally would be anywhere on the home or lot and the mast height provision is usually most relevant in these situations. For example, if a homeowner needs to install an antenna on a mast that is more than 12 feet taller than the roof of the home, the homeowners' association or local zoning authority may require a permit to ensure the safety of such an installation, but may not prohibit the installation unless there is no way to install it safely. On the other hand, if the owner of a condominium in a building with multiple dwelling units needs to put the antenna on a mast that extends beyond the balcony boundaries, such installation would generally be outside the scope and protection of the rule, and the condominium association may impose any restrictions it wishes (including an outright prohibition) because the Commission rule does not apply in this situation.

Q: Does the rule apply to commercial property or only residential property?

A: Nothing in the rule excludes antennas installed on commercial property. The rule applies to property used for commercial purposes in the same way it applies to residential property.

Q: What can a local government, association, or consumer do if there is a dispute over whether a particular restriction is valid?

A: Restrictions that impair installation, maintenance or use of the antennas covered by the rule are preempted (unenforceable) unless they are no more burdensome than necessary for the articulated legitimate safety purpose or for preservation of a designated or eligible historic site or district. If a person believes a restriction is preempted, but the local government, community association, or landlord disagrees, either the person or the restricting entity may file a Petition for Declaratory Ruling with the FCC or a court of competent jurisdiction. We encourage parties to attempt to resolve disputes prior to filing a petition. Often calling the FCC for information about how the rule works and applies in a particular situation can help to resolve the dispute. If a local government, community association, or landlord acknowledges that its restriction impairs installation, maintenance, or use and is preempted under the rule but believes it can demonstrate "highly specialized or unusual" concerns, the restricting entity may apply to the Commission for a waiver of the rule.

Q: What is the procedure for filing a petition or requesting a waiver at the Commission?

A: There is no special form for a petition. You may simply describe the facts, including the specific restriction(s) that you wish to challenge. If possible, attach a copy of the restriction(s) and any relevant correspondence. If this is not possible, be sure to include the exact language of the restriction in question with the petition. General or hypothetical questions about the application or interpretation of the rule cannot be accepted as petitions.

Petitions for declaratory rulings and waivers must be served on all interested parties. For example, if a homeowners' association files a petition seeking a declaratory ruling that its restriction is not preempted and is seeking to enforce the restriction against a specific resident, service must be made on that specific resident. The homeowners' association will not be required to serve all other members of the association, but must provide reasonable, constructive notice of the proceeding to other residents whose interests foreseeably may be affected. This may be accomplished, for example, by placing notices in residents' mailboxes, by placing a notice on a community bulletin board, or by placing the notice in an association newsletter. If a local government seeks a declaratory ruling or a waiver from the Commission, the local government must take steps to afford reasonable, constructive notice to residents in its jurisdiction (*e.g.*, by placing a notice in a local newspaper of general circulation). Proof of constructive notice must be provided with a petition. In this regard, the petitioner should provide a copy of the notice and an explanation of where the notice was placed and how many people the notice reasonably might have reached.

Finally, if a person files a petition or lawsuit challenging a local government's ordinance, an association's restriction, or a landlord's lease, the person must serve the local government, association or landlord, as appropriate. You must include a "proof of service" with your petition. Generally, the "proof of service" is a statement indicating that on the same day that your petition was sent to the Commission, you provided a copy of your petition (and any attachments) to the person or entity that is seeking to enforce the antenna restriction. The proof of service should give the name and address of the parties served, the date served, and the method of service used (*e.g.*, regular mail, personal service, certified mail).

All allegations of fact contained in petitions and related pleadings before the Commission must be supported by an affidavit signed by one or more persons who have actual knowledge of such facts. You must send an original and two copies of the petition and all attachments to: Secretary, Federal Communications Commission, 445 12th Street, S.W., Washington, D.C. 20554, Attention: Media Bureau.

Q: Can I continue to use my antenna while the petition or waiver request is pending?

A: Yes, unless the restriction being challenged or for which a waiver is sought is necessary for reasons of safety or historic preservation. Otherwise, the restriction cannot be enforced while the petition is pending.

Q: Who is responsible for showing that a restriction is enforceable?

A: When a conflict arises about whether a restriction is valid, the local government, community association, property owner, or management entity that is trying to enforce the restriction has the burden of proving that the restriction is valid. This means that no matter who questions the validity of the restriction, the burden will always be on the entity seeking to enforce the restriction to prove that the restriction is permitted under the rule or that it qualifies for a waiver.

Q: Can I be fined and required to remove my antenna immediately if the Commission determines that a restriction is valid?

A: If the Commission determines that the restriction is valid, you will have a minimum of 21 days to comply with this ruling. If you remove your antenna during this period, in most cases you cannot be fined. However, this 21-day grace period does not apply if the FCC rule does not apply to your installation (for example, if the antenna is installed on a condominium general common element or hanging outside beyond an apartment balcony. If the FCC rule does not apply at all in your case, the 21-day grace period does not apply.

Q: Who do I call if my town, community association or landlord is enforcing an invalid restriction?

A: Call the Federal Communications Commission at (888) CALLFCC (888-225-5322), which is a toll-free number, or 202-418-7096, which is not toll-free. Some assistance may also be available from the direct broadcast satellite company, multichannel multipoint distribution service, television broadcast station, or fixed wireless company whose service is desired.

GUIDANCE ON FILING A PETITION

Q: What are the procedural requirements for filing a Petition for Declaratory Ruling or Waiver with the Commission?

A: There is no special form for a petition. You may simply describe the facts, including the specific restriction(s) that you wish to challenge. If possible, attach a copy of the restriction(s) and any relevant correspondence. If this is not possible, be sure to include the exact language of the restriction in question with the petition. General or hypothetical questions about the application or interpretation of the rule cannot be accepted as petitions.

Petitions for declaratory rulings and waivers must be served on all interested parties. An entity seeking to impose or maintain a restriction must include with its petition a proof of service that it has served the affected residents. Similarly, an antenna user seeking to challenge the permissibility of a restriction must include with the petition a proof of service that the antenna user has served the restricting entity with a copy of the Petition.

If you are an antenna user, you must serve a copy of the Petition on the entity seeking to enforce the restriction (*i.e.*, the local government, community association or landlord). If you are a local government, community association or landlord, you must serve a copy of the Petition on the residents in the

community who currently have or wish to install antennas that will be affected by the restriction your Petition seeks to maintain. For example, if a homeowners' association files a petition seeking a declaratory ruling that its restriction is not preempted and is seeking to enforce the restriction against a specific resident, service must be made on that specific resident. The homeowners' association will not be required to serve all other members of the association, but must provide reasonable, constructive notice of the proceeding to other residents whose interests may foreseeably be affected. This may be accomplished, for example, by placing notices in residents' mailboxes, by placing a notice on a community bulletin board, or by placing the notice in an association newsletter. If a local government seeks a declaratory ruling or a waiver from the Commission, the local government must take steps to afford reasonable, constructive notice to residents in its jurisdiction (*e.g.*, by placing a notice in a local newspaper of general circulation). Proof of constructive notice must be provided with a petition. In this regard, the petitioner should provide a copy of the notice and an explanation of where the notice was placed and how many people the notice might reasonably have reached.

Finally, if a person files a petition or lawsuit challenging a local government's ordinance, an association's restriction, or a landlord's lease, the person must serve the local government, association or landlord, as appropriate. You must include a "proof of service" with your petition. Generally, the "proof of service" is a statement indicating that on the same day that your petition was sent to the Commission, you provided a copy of your petition (and any attachments) to the person or entity that is seeking to enforce the antenna restriction. The proof of service should give the name and address of the parties served, the date served, and the method of service used (*e.g.*, regular mail, personal service, certified mail).

If you wish to file either a Petition for Declaratory Ruling or a Petition for Waiver pursuant to the Commission's Over-the-Air Reception Devices Rule (47 CFR Section 1.4000), you must file an original and two copies of your Petition on the following address:

Office of the Secretary
Federal Communications Commission
445 12th Street, S.W.
Washington, D.C. 20554
Attn: Media Bureau

Q: What are the substantive requirements for filing a petition for waiver or declaratory ruling?

A: To file a Petition for Waiver, follow the requirements in Section 1.4000(c) of the rule. The local government, community association or landlord requesting the waiver must demonstrate "local concerns of a highly specialized or unusual nature." The petition must also specify the restriction for which the waiver is sought, or the petition will not be considered.

To file a Petition for Declaratory Ruling, follow the requirements set forth in Section 1.4000(d) of the rule. Set out the restriction in question so that we can determine whether it is permissible or prohibited under the rule. In a Petition for Declaratory Ruling, the burden of demonstrating that a particular

restriction complies with the rule is on the entity seeking to impose the restriction (*e.g.*, the local government, community association or landlord).

We recommend that you include the language of the restriction in question, as well as a daytime telephone number, with your petition.

While a petition for declaratory ruling or waiver is pending with the Commission or a court, the restriction in question may not be enforced unless it is necessary for safety or historic preservation. No fines or penalties, including attorneys fees, may be imposed by the restricting entity while a petition is pending. If the restriction is found to be permissible, the antenna users subject to the ruling will generally have at least 21 days in which to comply before a fine or penalty is imposed.

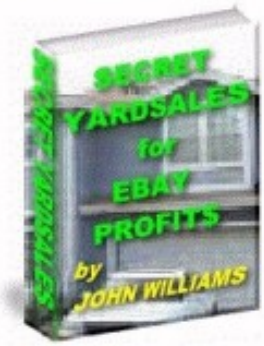
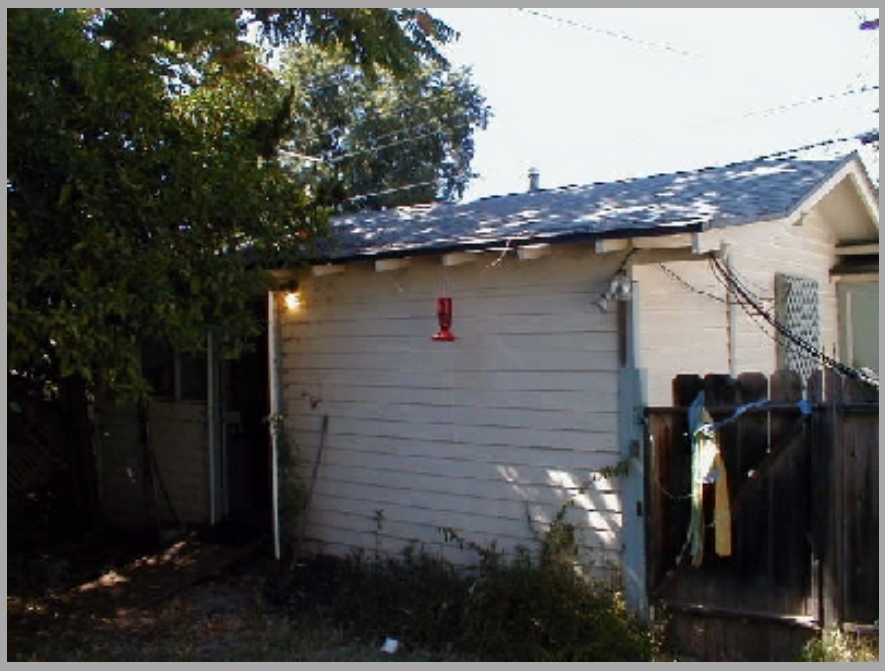
Earn a Living on eBay with Secret Yard Sales



Hide your antenna in something else. Extreme Measure for the most severely restricted environment. When NOBODY can know you have a transmitter. For apartment Balcony, Great working! Hanging "HUMMINGBIRD FEEDER" bird feeder 10-40m HF Antenna Instructions. This hides the outside loading coil so your random wire will tune up on 10-40m. Puts substansial portion of your radiated RF outside your apartment-condo. Here is a brief description until I put up a page: Buy a plastic hummingbird feeder with standard glass syrup jar. Replace syrup bottle with a 2 liter soda bottle. Threads of soda bottle match feeder bottom perfectly, plus plenty of room to put a large COIL inside. Cut bottom 5" of bottle off. Save it to slide back over remainder later after you instal a 80-100 turn air or ceramic core coil. No plastic cores. Can get hot! on some freqs. Coil turn spacing min= space of same wire diameter as gap between turns. Larger gaps ok. Solder 10',(or more), wire to top of coil, run through bottle end to hang. Use a foot or two to hang and run remainder painted, hidden behind eves etc. horizontally for "INVERTED L" capacity hat. Solder a random wire to bottom of coil to exit out of bottom of feeder to your tuner (tune with tuner as a random wire. use a counterpoise, a real or artificial ground.) Small guage Black insulated wire is hardest to see. Best to hide most of feed wire, but do not run parallel next to other parallel metal objects,(ok to cross metal. just don't run along lengths of metal rails, sliding doors, extension cords, etc.). If ask what is "THAT" wire for, say, "It is a special ultrasonic LARGE bird repeller" and it only repells one foot from my feeder. Tell them how safe it is. Make up details, go on and on about technical details etc. They are sorry they ask and leave. This always works for me. Paint soda bottle fire engine red to hide coil and match rest of feeder. The longer the feed

wire the better. The more turns and diameter of coil the better. You want to increase your chances of a "PEAK CURRENT POINT" occuring somewhere, (that is why so many turns), in the coil for lowest angle radaition possible under such compromised conditions. (sorry no more syrup). Safe for birds. Works great and even the most snoopy manager neighbor will never suspect a pirate like antenna. This description and photos will get you started. You can easily improvise until I post more construction photo details.



10-40m Hummingbird feeder antenna in use

LOOK AT THESE 10-30m and 40m balcony antennas. 10-30m is an AEA Isoloop magnetic loop, (MFJ type loop), and a 40m hamstick bundled with fishing poles to hide. Stick is tuned with wire tuner and artificial ground counter poise. Loop is covered with plastic tarp to hide. I get average 559 sig reports. Loop works DX on CW! I can't say enough about these loops. They really perform. Hamstick equals a 100w moblie for performance. It,s fun and I get to keep my hobby where not allowed.

ARRL Offers On-Line "Antenna Restrictions 'How To' Chart"

NEWINGTON, CT, Jan 7, 2002--The ARRL Regulatory Information Branch has made available what might be called a "triage center" for amateurs facing the prospect of dealing with various roadblocks to erecting an antenna system at their residence. The new "Antenna Restrictions 'How To' Chart" page offers three separate outlines that help the user to logically work through issues involving local government zoning restrictions; deed covenants, conditions and restrictions (CC&Rs); or rental/lease restrictions relating to antenna structures.

The prime focus is on dealing with local zoning restrictions to putting up an antenna structure and how to make the best possible case at a local regulatory board hearing. Some of the advice there also applies to CC&Rs and rental/lease situations too.

"Remember: at the hearing, your presentation will be 80% of the battle, and 100% of the basis for any record, if the case ends up going to court," the "Important Notice" on the page advises.

Each "how to" outline is structured around a series of questions--much like a logic or flow chart. Depending on the answer, the user is referred to specific information or additional resources. The page also offers some step-by-step suggestions. For example, the local government zoning outline suggests 10 steps to those seeking to change an overly restrictive local amateur antenna ordinance. One of them is to obtain the ARRL book *Antenna Zoning for the Radio Amateur* ($49.95; order Item 8217 from ARRL via the Online Store or order by calling toll-free

ARRL Products: Digital Communications (More)

The ARRL Image Communications Handbook -- Use Amateur Radio to see and talk with other hams! Enjoy the imaging modes: NBTV, ATV, SSTV and WEFAX.

802.11 Wireless Networks: The Definitive Guide -- Creating and administering wireless networks.

Digital Signal Processing Technology -- Essentials of the Communications Revolution. An understandable presentation and reference on DSP in contemporary communications technology.

Practical Digital Signal Processing -- **Now Shipping!** -- Gain a working knowledge of DSP applications, including

888-277-5289), which offers detailed information on working with local governments. Written by attorney Fred Hopengarten, K1VR, the book describes proven techniques and strategies that amateurs can employ in efforts to obtain an antenna-structure permit.

As the page emphasizes up front, however, neither this book nor the outlines on the "Antenna Restrictions 'How To' Chart" page are intended as substitutes for advice from an attorney.

communications and process control.

ARRL's HF Digital Handbook -- **Now Shipping!** -- 3rd edition. Use your computer to talk to the world!

The local government zoning outline also asks, "Has your state codified PRB-1?" and, if the answer is no, offers suggestions and information for amateurs who would like their legislature to incorporate the limited federal preemption known as PRB-1 into their state's laws. So far, only 13 states have done so, but bills are still in the works in a few others.

The page offers limited guidance to those confronting CC&Rs--an issue facing more and more amateurs these days--and to those who rent or lease their homes and still want to be able to install an antenna--a situation where PRB-1 does not apply. In both instances, affected amateurs are advised to develop and present logical and persuasive cases for being allowed to install an antenna system--much as they would have to do when dealing with a local government.

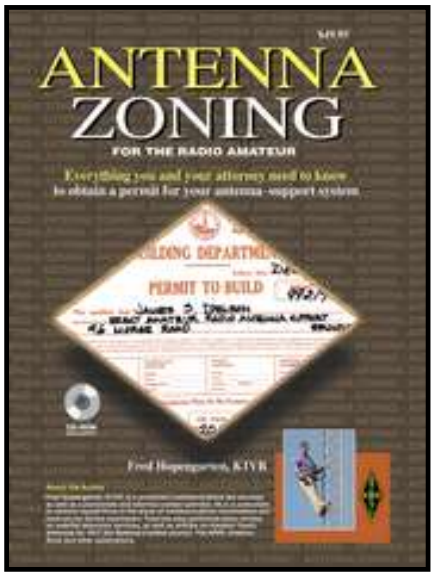
Antenna Zoning for the Radio Amateur

-- By Fred Hopengarten, K1VR



Everything you and your attorney need to know to obtain a permit for your antenna-support system.

Don't let the confusing tangle of ordinances and by-laws keep you from installing the antenna you need in order to communicate effectively! In recent years, many cities and towns have enacted ordinances designed mainly to regulate cellular antenna structures. Unfortunately, hams have sometimes been caught in the backlash of regulatory overkill. This book describes proven techniques and strategies that a ham and his or her attorney can use to obtain an antenna-structure permit (also includes material on Canadian law and regulation).

Contents

- Introduction: Why This Book Was Written
- 1: Principles That Will Help You Win
- 2: The Process in a Nutshell
- 3: Your Winning Team
- 4: Basic Preparations
- 5: Getting to Know the Players
- 6: Possible Objections
- 7: Preparing the Permit Application
- 8: Public Hearings—Your Big Moment in the Spotlight
- 9: Deliberations and Decisions
- 10: Now, Get the Permit and Build Your Antenna
- 11: Awkward Post-Permit Situations

- 12: Appeals
- 13: Tower and Antenna Regulation in Canada [by Tim Ellam, VE6SH]
- 14: Bibliography
- Appendix A: The Law
- Appendix B: Drafting a Bylaw, or Redrafting a Bylaw
- Appendix C: Lawsuits

CD-ROM included containing case law, customizable forms and additional legal reference material. Windows and Macintosh compatible.

Online Special $40 (was $49.95)

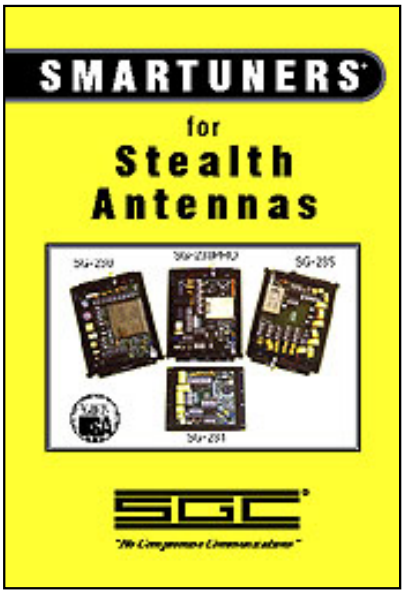
Smartuners for Stealth Antennas

Download your copy today! See Brochures and Publications.



ARE YOU INSTALLING A NEW ANTENNA SYSTEM?
Get your facts from the professionals in the newest SGC publication!

A book about theory and installation of effective HF antenna systems. For novice to experienced HF users, "Smartuners for Stealth Antennas" shows you antenna installations tried and proven using SGC Smartuners. Dozens of illustrations actually show you how to set up your very own practical *and* "hidden" HF antenna system.

Chapters include:

- Tuner, Coupler, what is the difference?
- Why an antenna coupler?
- Basic antenna theory
- Antenna types
- Practical Installations
- Ground systems
- Indoor antennas
- Construction techniques

Hide your antenna in something else. Extreme Measure for the most severely restricted environment. When NOBODY can know you have a transmitter. For apartment Balcony, Great working! Hanging "HUMMINGBIRD FEEDER" bird feeder 10-40m HF Antenna Instructions. This hides the outside loading coil so your random wire will tune up on 10-40m. Puts substansial portion of your radiated RF outside your apartment-condo. Here is a brief description until I put up a page: Buy a plastic hummingbird feeder with standard glass syrup jar. Replace syrup bottle with a 2 liter soda bottle. Threads of soda bottle match feeder bottom perfectly, plus plenty of room to put a large COIL inside. Cut bottom 5" of bottle off. Save it to slide back over remainder later after you instal a 80-100 turn air or ceramic core coil. No plastic cores. Can get hot! on some freqs. Coil turn spacing min= space of same wire diameter as gap between turns. Larger gaps ok. Solder 10',(or more), wire to top of coil, run through bottle end to hang. Use a foot or two to hang and run remainder painted, hidden behind eves etc. horizontally for "INVERTED L" capacity hat. Solder a random wire to bottom of coil to exit out of bottom of feeder to your tuner (tune with tuner as a random wire. use a counterpoise, a real or artificial ground.) Small guage Black insulated wire is hardest to see. Best to hide most of feed wire, but do not run parallel next to other parallel metal objects,(ok to cross metal. just don't run along lengths of metal rails, sliding doors, extension cords, etc.). If ask what is "THAT" wire for, say, "It is a special ultrasonic LARGE bird repeller" and it only repells one foot from my feeder. Tell them how safe it is. Make up details, go on and on about technical details etc. They are sorry they ask and leave. This always works for me. Paint soda bottle fire engine red to hide coil and match rest of feeder. The longer the feed

wire the better. The more turns and diameter of coil the better. You want to increase your chances of a "PEAK CURRENT POINT" occuring somewhere, (that is why so many turns), in the coil for lowest angle radaition possible under such compromised conditions. (sorry no more syrup). Safe for birds. Works great and even the most snoopy manager neighbor will never suspect a pirate like antenna. This description and photos will get you started. You can easily improvise until I post more construction photo details.

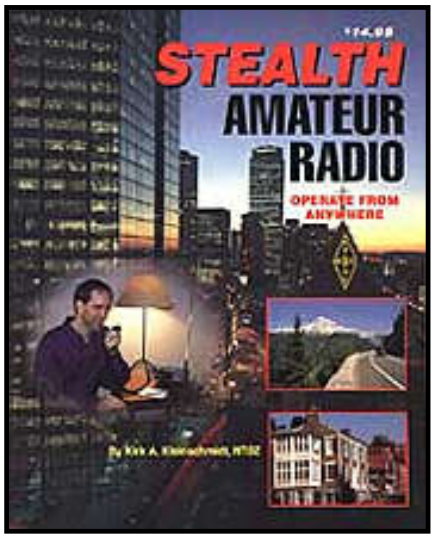
Stealth Amateur Radio

-- Operate From Anywhere

by Kirk A. Kleinschmidt, NT0Z.



Adventure into the world of hidden stations and invisible antennas! Set up and operate a station without calling attention to yourself. Successfully operate a low power (QRP) station. Install safe antennas, including indoor antennas. Build invisible antennas. Install and operate a mobile station, to "get away" from radio-forbidden locations. Operate a portable station from a campground, motel room, picnic area, mountaintop or other location. Handle interference from your station to nearby consumer electronics devices as well as to your station from other nearby devices. Use this book and enjoy operating from just about anywhere!

First edition, second printing, 2001. © 1999-2001, The American Radio Relay League, Inc. (ISBN: 0-87259-757-1) #7571 -- $14.95

Clif's Ham Radio Page

Welcome to Clif's ham radio connection. On this page you'll find links to other interesting sites. It is not my intention to create the end all page with links to everywhere but I've included a few of the ones that I think are most pertinent.

My particular area of interest is in high frequency (HF) antennas in less than optimal conditions. Most of the available programs used to analyze antennas today assume that the antenna is mounted in free space or mounted a uniform distance above ground - conditions that unfortunately many hams can get nowhere near achieving. Since the software tools are somewhat limited in what can be simulated I'm instead looking for the apartment dwellers, condo owners and other restricted antenna users with any experience. Your experience level is not important - what you did and what the results were are more important. It doesn't matter if what you tried didn't work, just let the rest of us know so we might learn from your experience. I'm collecting data - not to analyze but rather to show empirically what works and what doesn't. Send me all your details, in particular try to provide the following information:

- description of the antenna
- where and how it was mounted such as in the attic, under the eaves, in the middle of a group of trees etc.
- Typical transmitter power
- Contacts made
- Anything else you think might help another ham

I'll make the data available here as case studies. I've included the results of my own experiences to give you an idea. Got comments or questions? Ideas of how to make this site better? Email me!
As more data becomes available, the format of this page may change, however it will remain the entry point into the database with the same name and location so go ahead and bookmark it.

Summary of experience with restricted space antennas

First and foremost hams faced with restrictive antenna constraints should not lose faith. You still can operate sucessfully although you will never be able to out-slug the hams running linears into beams mounted high up on towers. If you build a hidden outdoor antenna you will probably be limited to 100 watts or less due to the wire sizes and insulator types. If the antenna is mounted indoors, your power will still be restricted due to health hazards to yourself or other family members (arcing or RF energy) or due to interference with televisions, computers, VCRs, telephones, etc. However the QRP hams continue to show us that QSOs can and do happen with regularity at low power outputs. In general you should strive to build an antenna as high and as close to full size as your situation allows. If elements need to be bent to fit the space thats ok - just try not to have them double back on themselves. An antenna tuner is a must have item with almost any antenna you will build. Almost anything metal can be made to radiate RF

energy so don't despair! If you meet with sucess, drop me some email so we can share it with others. Some other common approaches are the flagpole vertical, the magnetic loop and slinky dipole. Another approach I want to try is to build a St. Louis Vertical which is a portable antenna that works 10m to 40m and only erect it when I'm on the air.

Case 1: 10m dipole in attic

Antenna type

Full size dipole made with #24 gauge magnet wire and ceramic insulators. Oriented approximately NNW by SSE. Actual elevation above ground was approximately 25 to 30 feet.

Structure

Two and a half story condominium unit. Shack was in upper level with the antenna mounted in the attic using cord to mount the antenna between rafters. Structure was wood frame with a stucco exterior and a composite shingle roof. Also under one half of the dipole was a forced air furnace made of galvanized steel. This heater was about 2.5 feet below the wire of the dipole. Shack was located in Southern California.

Rig Details

Icom IC725 running average of 50 watts. Coupled to antenna through RG58/U coax. Used MFJ-941E tuner to match rig to antenna.

Performance Summary

When the 10m band opened, 50 watts and my attic dipole did quite well. Most signal reports were 55 to 59. Contacts were made to Indiana, Alabama, Louisiana, Texas, Wisconsin, Kansas, Minnesota, Mississippi, Pennslyvania, North Carolina, New York, Rhode Island, Hawaii plus a few other states and even Japan!

Comments

This antenna may have done well since it was in a wood structure and the actual antenna height above ground was greater than a half wavelength. The contacts appeared consistent with the orientation of the antenna, that is most of the contact occured broadside to the antenna.

Case 2: 40m twin lead Marconi in attic

Antenna type

This antenna was a twin lead Marconi based on information found in William Orr's **Radio Handbook.** This antenna was also fed with RG-58/U coax. In addition, a half wavelength counterpoise was attached to the coax shield/antenna junction to provide an RF ground.

Structure

This antenna was also mounted in the same attic as case 1. The twin lead was snaked around the perimeter of the attic and held in place by attaching it to the studs with cable ties. The twin lead could not be laid out in a straight line instead it was routed in a shape like a question mark where the bottom of the question mark was the feed point. The first section was about 20 feet followed by a 90 degree bend and the next 10 feet followed by another 90 degree bend and the final 3 or 4 feet. The first section was oriented roughly E-W, the second section N-S and the third section was

again E-W. The counterpoise was snaked in the other direction in a similar shape with the first section of about 25' going N-S, and the remainder going E-W.

Rig Details

Same as Case 1.

Performance Summary

As expected, this antenna didn't perform like a free space 1/4 wave vertical. It took time but the MFJ tuner would get a good match to the transmitter. Normal power used was 50 watts. Contacts ranged all around the western United States with the majority in Oregon, Washington and Northern California. There were also contacts made in Idaho, Utah, Montana, Colorado, Nevada, Alaska, British Columbia and Texas.

Comments

This antenna was used to primarily work 40m CW. On occasion it was used of 15m CW also. Signal reports were average with R's of 4 to 5, S's from 3 to 9 and T's of 9. There were very few reports of 599. The signal was getting out but not very well. Almost all the contacts were broadside to the longest section of the twinlead.

Case 3: Triband inverted V dipole under the eaves

Antenna type

This antenna was constructed as a 40m dipole and a 10m dipole with a common feedpoint. The 10m elements are built using #24 gauge magnet wire and ceramic insulators. The 40m elements are built using #18 gauge hookup wire. The apex of the inverted V is at the high point of the roofline, approximately 18 to 19' above ground. The 10m elements slant downward about 30 degrees below horizontal and remain spaced about 14 inches from the stucco surface of the wall. The 40m elements are secured under the eaves and extend about 30 feet from the apex before reaching the corners of the house where they both make 90 degree bends and continue under the eaves. At this point, the elements are only about 8 feet above ground. The major portion of both antennas are oriented N-S.

Structure

The house is a wood frame, stucco exterior, single story dwelling with a concrete tile roof. The eaves extend about 16 inches beyond the walls of the house. The house is located in Southern California.

Rig Details

Same as Case 1.

Performance Summary

So far it appears that the proximity to the structure make the 40m antenna appear electrically longer than it is physically. Only one QSO has been completed so far and that was with a station in WA. RST report was 469 but WA is off the "end" of the major axis of this antenna. At this time (7/10/97) no contacts on 10m have been completed but the band still appears dead.

Comments

With only one QSO completed, the jury is still out on this antenna. Will update this page as more as information becomes available.

Case 4: 10m dipole in attic

Antenna type

Full size dipole made with #24 gauge magnet wire and ceramic insulators. Oriented approximately NNW by SSE. Actual elevation above ground was approximately 15 to 18 feet. Dipole was not perfectly horizontal, instead it was oriented more like an inverted V with about a 15 to 20 degree slope.

Structure

Single story, single family house. Wood frame, stucco exterior walls with a concrete tile roof. Shack was located in Southern California.

Rig Details

Icom IC725 running average of 50 watts. Coupled to antenna through RG58/U coax. Used MFJ-941E tuner to match rig to antenna.

Performance Summary

No contacts were made. Did manage to hear two or three other stations but all attempts to reach them were unsucessful. Wasn't able to determine how much power the other stations were running or the type of setup used. Also used the antenna as a receive only on 40m, this appears to have worked but without another outdoor antenna that could be switched in, no comparative measurements could be made.

Comments

Data for this case is inconclusive. Band conditions on 10m were very poor so there may not have been any stations there to begin with. Theorized that the concrete tiles could have been interfering with the radiation of energy from the antenna. The antenna has since been relocated outside the house under the eaves - see case 3.

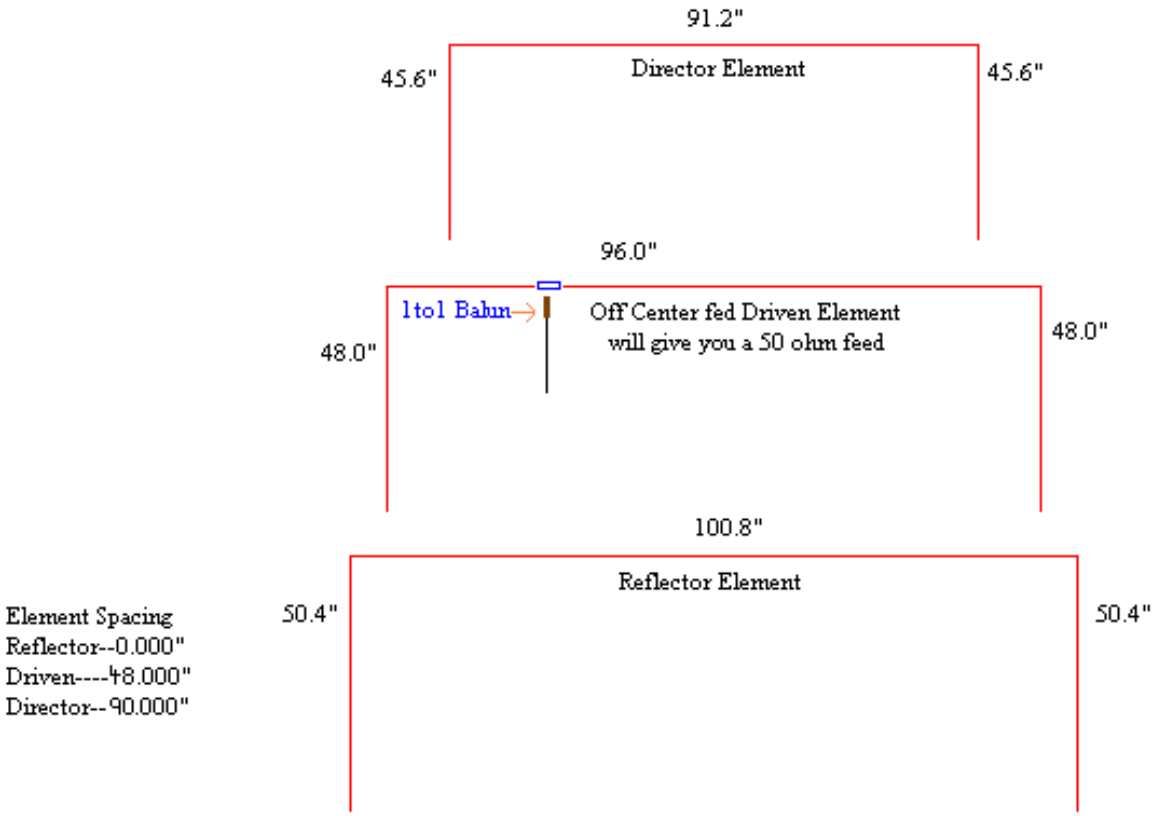
KE4UYP'S

Off Center fed Bent 10m YAGI for attics



Specifications

This is a horzontally polarized three Element Yagi. The bent Elements cause very little performance lose.
When you consider it is only 8ft. 5" wide and 7ft. 6" long and still has 6.2dbi gain and 20db front to back ratio.
And when you off center feed it you get a perfect 50 ohm match to coaxial cables.The SWR is less than 2to1 for 600khz.
Not bad for a Antenna that the neighbors don't even know exist.

The question
HOW MANY INCHES FROM THE CENTER OF THE DRIVEN ELEMENT IS THE FEED POINT?
Is not a simple one, each installation is different there is no set distance from the center. There is too many variables to consider the height above ground is one of them the gauge wire is another all objects that are within 16 feet is one more but there is a simple solution to this problem. If you make each end of the driven element adjustable where you can easily change the length then you can easily off center the feedpoint to the exact spot that gives you the 50 ohm match.
Remember that you want to keep the total length of the driven element 16 feet long so if you shorten one side by one inch you want to lengthen the other side by one inch this will maintain the 16ft. if you make the last 12" of each end of the element where you have a second wire that is wrapped around the element wire and it is also 12" inches long you will be able to lengthen or shorten that wire easily.
So one-half of the driven element would be seven feet long and the other half of the driven element would be 8 feet long and you would be able to lengthen the seven foot element up to 12" inches longer and you would be able to lengthen the eight foot element up to 12 inches longer once you get your perfect match all you have to do then is solder the sliding wire permanently to the element on each end.

Privacy Policy . Info

W3FF Antennas is a manufacturer of a lightweight, versatile hf portable dipole antenna system for amateur radio. This hf antenna is instantly configurable as a vertical dipole or any one of several other shapes including a vee dipole, sloper, or L. The Buddipole dipole antenna is directional and can be converted to a an effective single element vertical antenna (the “Buddistick”) by using either one of the dipole antenna arms and a counterpoise. The Buddipole or Buddistick are perfect for space-restricted covenants such as use as an apartment antenna, hotel antenna or backup marine antenna, or as a compact dxpedition antenna or backpack antenna.

All world rights reserved W3FF Antennas, 2003.
Unauthorized duplication is unlawful.

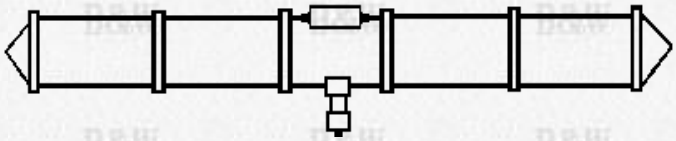
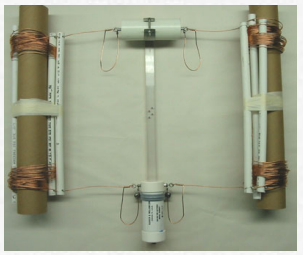
Antennas, Coils and Accessories for HF Radio

ALL PRODUCTS PROUDLY MADE IN THE USA

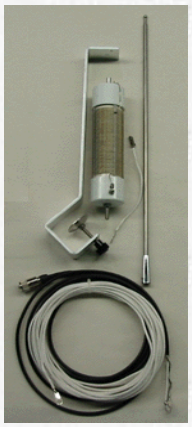


Click Here for our Antenna Review in Popular Communications



Broadband Antennas - Our field proven broadband HF antennas operate *all* frequencies continuously from 1.8 to 30 Mhz *without an antenna tuner*, plus 6 meters. If you are participating in various programs such as MARS, ARES, RACES or CAP these antennas will work all of your frequencies all the time. If your frequencies get reassigned, it does not matter.

Of course, these antennas are not limited to emergency operation. Any radio amateur enthusiast can take advantage of full coverage with one antenna that has a fairly small visual impact. We even have a configuration that can have the ends run down to the ground - *pretty stealthy!*



Other Antennas - Our AP-10A

window/portable antenna lets almost anybody get on the air regardless of covenant restrictions, and is truly portable. For travel it easily fits in a suitcase or briefcase.

Components and Accessories -

Professional and amateur users alike can make use of various products we carry such as our world famous air wound coils, chokes, insulators, wire, cables - just look around the web site for all of your needs.

Antenna restrictions? - Short on Space?

The CliffDweller II Antenna

The CliffDweller II antenna!

The CliffDweller II is the Original variable length HF antenna that adjusts it's size to fit YOUR operating environment. 6 to 80 Mtrs. - QRP to 100 Watts -

Although composed of a full 130 feet of wire (a full half wavelength on 80 mtrs!), the CliffDweller II will operate from a compressed length of only 15 feet to a fully extended length of 50 feet -- or anywhere in between. It fits the space you have available!

Fully compressed the CliffDweller II takes up less than one foot of space. Take it with you anywhere an antenna may be needed! Permanent or portable operation...

CliffDweller II - $39.95 plus $10.95 S&H (U.S. only) - *$2.00 Insurance.
*Not responsible for lost or damaged packages - Please insure your purchase.
(Foreign orders please write for International shipping rates)

See main USA 2Way page for ordering information.

***30 Day Satisfaction Return requires antenna to be in resaleable condition.**

*When using this (or any antenna) indoors for transmitting purposes please use low power and keep the radiating elements as far as possible from humans and animals. RF energy can be harmful.

Amateur Wire Antennas

Par Electronics
End-Fedz
Wire Antennas

back

The **Par End-Fedz** are a full length half wave dipoles, but with an important difference. The coax connector is at one end of the dipole, where it is most needed. These antennas can be mounted horizontally, vertically or as a sloper. No ground plane or counterpoise is needed. Portable operation could not be easier. Simply hang the far end from a tree limb -- the coax is at the bottom. Hang it up in a hotel window or string it up in the attic. End insulators are supplied making suspension easy.

The UV resistant ABS plastic housing encloses an efficient matching network allowing the antenna to be fed with common 50 ohm coaxial cable. All hardware is stainless and the SO-239 connector is silver/teflon. The radiator material is a tough polyethylene jacketed, highly flexible #14 copper wire (41 strands of #30 gauge). One end comes with a #10 solder lug making attachment to the matchbox simple and allowing the radiator portion to be replaced if ever necessary. Power rating is a conservative 200 watts (except EF-20/40). Lightweight (the 20 meter version is only 0.5 pounds), they are ideal for portable work. The all black construction makes them difficult to see. Click here to see an alternate view.

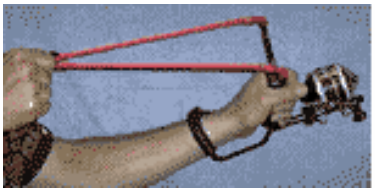
E Z HANG

HANG YOUR NEXT WIRE ANTENNA
THE *EZ HANG™ WAY*

US Patent No. 6,286,495



- **No climbing trees or ladders**
- **No dangerous bow-and-arrow**
- **No tangled string**

The perfect tool when you want to put up a wire antenna easily, quickly and safely.

EZ HANG ™ can be used to "shoot" a line over a tree or other object over 100 feet high.

Tree surgeons and gardeners can use EZ HANG ™ to attach a line to a tree and pull it safely away from a structure in order to cut off branches.

Cable pullers can use EZ HANG ™ to "shoot" a drag-line through a dropped-ceiling/plenum up to 60 feet and avoid using long pull-rods. It cuts installation time and your costs dramatically. Click Here for the Cable Pulling Page.

Remember! SAFETY FIRST! The EZ HANG ™ propels a high velocity projectile. Always use safety glasses or safety goggles when using the EZ HANG ™. Be sure the area is cleared of personnel before using.

EZ HANG's ™ basic construction is steel attached to a reel that is corrosion-resistant plastic and stainless steel. The reel comes with 300 feet of 10-pound-test monofilament line installed, a quick-disconnect clip to release the weight and an easy-to-see "bright yellow" one-ounce lead weight.

Don't be fooled by "rip-off" imitations that use inferior materials and a poor design!

Look for the EZ HANG™ name.

Price: $99.95

Add to Shopping Cart
Download the MFJ-1622 Manual

The MFJ-1622 Apartment Antenna covers 40 through 2 Meters, mounts outdoor to windows, balconies, railings, and works great indoors mounted to desks, tables, and bookshelves!

This Apartment Antenna lets you operate 40 through 10 Meters on HF and 6 and 2 Meters on VHF with a single antenna! Its universal mount/clamp lets you easily attach it to window frames, balconies, and railings. It also works great indoors mounted to a desk, table, or bookshelf. It's not a five element yagi, but you'll work your share of exciting DX!

The highly-efficient air wound 'bug catcher' loading coil and telescoping 5 1/2 foot radiator lets you really get out! The radiator collapses to 2 1/2 feet for easy storage and

Tools and 12 Volt Accessories

MinuteMan 20™ Portable Antennas get you on the air from wherever you are

A complete HF Station in a Briefcase.

From the Park

From the Backyard

From the Mountaintop

The MinuteMan 20 is, we believe, the best performing portable antenna of its type on the market today. It operates on 20-17-15-12-10 Meters without a tuner (in most cases). On 15, 12, and 10 Meters it's a full 1/4-wavelength long. For 20 and 17 Meters, a small bit of High Efficiency loading coil is added. For more information on why efficiency is so important, and why our antenna is better, go to those pesky laws of physics

It fits in any standard briefcase, backpack or airplane carry-on. We designed it to be rugged, lightweight (about 5 lbs.) and field serviceable. It's perfect any time you need a quick set-up antenna.

Why it's better:

- Sets up in 3 minutes or less, with no tools and no supports needed
- Outperforms competitive antennas
- Fits in a briefcase, backpack, carry-on bag, etc.
- Less expensive, and no "extras" needed to purchase

Specifications:

Height: (when fully extended) appx 12'10"
Power: 100 Watts
Weight: appx 5 lbs
Radials: 4 radials included, each 16'8" long
Longest piece: (when disassembled) 17"
Base Size: (when assembled, base is included) 3' x 3'

Electrical Description:

The MinuteMan 20 is a classic 1/4 Wave vertical groundplane antenna on 10-12-15 Meters. A lower element of #14 wire attaches to a 6' telescoping whip. The whip length is adjusted for best SWR match. For 17 and 20 Meters, a small loading coil is inserted between the elements. The coil is oversquare -- that is, larger in diameter than in length. This Hi-Q design provides much lower loss than the long skinny coils that others use.

Four counterpoise radials are included. Each consists of two conductors, one 8'4", the other 16'8". These lengths are approximately 1/4 wavelength on 10 and 20 Meters. This arrangement strikes an ideal balance between portability and ease of use on one hand, and high earth loss on the other.

To download a printable PDF file of the manual, click here.

Pricing

We sell the MinuteMan 20™ for $130, plus $12 shipping and handling. We now accept PayPal.

You may find it more convenient to purchase through one of our authorized dealers. Each dealer sets his or her own retail price and shipping charge.

Hi-Q-Antennas™ by W6HIQ
VE7BOC / HA5CMG

Special Announcement!

Visalia, Dayton and SeaSide Ham Conventions are over and thanks to those customers who took time out to see us and to buy a Hi-Q-Antenna or to order one for later delivery. Our back log is more manageable than last year since we have ramped up our production for the Ham versions and have separated the Military types in production.

We INTENTED to EAT the competitors' LUNCH and NOW we will eat their DINNER as well! Not just by the QUALITY and PERFORMANCE, but by PRICE as well! Please visit our website (and theirs) and COMPARE! ASK them for the RADIATION EFFICIENCY and other technical details that pertain to an HF Mobile antenna, and see what kind of answers you get. Ask if they have Hewlett Packard antenna test equipment to verify radiation Field Strength... ask about the COIL "Q"... and ask if they have US or Foreign PATENTS. As our motto says: Shop around and compare, BUT hold on your wallet until you get to the Hi-Q-Antenna products.

My very 73 to you all,
Charlie Gyenes, W6HIQ (HA5CMG)

Welcome to the Hi-Q-Antennas™ Home Page!

The Hi-Q-Antennas Mission Statement:

Force the competitors to produce a better quality and better performing antenna by LEADING the WAY!

The new, improved, Hi-Q-Antennas™ by W6HIQ / VE7BOC / HA5CMG are the latest, state-of-the-art, 6th generation, stealth design. Hi-Q, Hi-Radiation efficiency is provided by computer design and Mil-Spec materials used in manufacturing.

Remember, the Hi-Q-Antennas design is NOT a cheap copy of the original Don Johnson screwdriver antenna. These Hi-Q-Antennas™ products are the **Highest Radiation Efficient** and **Best Quality** HF Mobile antenna EVER designed and manufactured, and are covered by one or more of the following patents: US 6,275.195 B1 and US 6,496.154 B2. For a more in-depth comparison between the Hi-Q-Antennas design and screwdriver-type designs, click here.

Please use the links to the left to learn more about my **ANTENNAS** and **ACCESSORIES**. Also, be sure to check the **LATEST NEWS** page for new product announcements, hamfest schedules, etc. You may also wish to visit our **MESSAGE BOARD** to ask questions and get advice from other owners of Hi-Q-Antennas products. When you've decided on the right antenna for you, utilize the Secure **SHOPPING CART** to place your order.

If you have any questions, please don't hesitate to contact me. You may also get answers to many common questions by reading the **Hi-Q-Antennas™ INSTALLATION MANUAL** and by visiting the ARRL Automotive RFI web site.

Amateur Radio Ventennas

Specifications

Model	Frequency (MHz)	Gain (dBi)	Length	Feedline	Price
VT-14	144 - 148	2.6	36 in.	3 ft. RG-58	$54.95
VT-22	222 - 225	2.6	19 in.	3 ft. RG-58	$54.95
VT-44	440 - 450	2.6	16 in.	3 ft. RG-58	$54.95
VT-27	144-148 & 440-450	2.6	36 in.	3 ft. RG-58	$84.95
VT-90	900 - 928	4.2	19 in.	3 ft. RG-58	$84.95
VT-12	1270 - 1290	4.2	19 in.	3 ft. RG-58	$84.95
VT-15S	140-172 & 440-512	Receive only	36 in.	3 ft. RG-58	$54.95
VT-SWL	2 - 30	Receive only	36 in.	3 ft. RG-58	$129.95

Note: all feedlines terminated with an SO-239 connector.

The Ventenna is constructed from rugged ABS plastic tubing. As such, it is virtually indesctrucible. It is designed to fit over vent pipe sizes from 1 to 3 inches, and works over metal or plastic vent pipes. The Ventenna is hollow, thus it does not disrupt the vent function in any way.

The normal "ABS Black" color of the outside of the Ventenna may be painted with any non-metallic-based paint. This allows you to match the Ventenna to the other fixtures on the rooftop.

Stealth Base Station Antennas

Restrictive covenants or ordinances got you off the air? Want to put up a very effective antenna that even the XYL will like?

The ultimate in STEALTH! This very efficient disguised antenna looks like (and is) a fully functional WEATHER VANE. The deception is so totally effective that anyone looking for your antenna will have trouble finding it. It is so attractive that the neighbors will want one!

Specifications and performance are the same as the GIA-XXX series antennas. With its great performance and effective disguise, this is the best clandestine antenna available.

Just in case the neighbors want a Weather Vane like yours, there is a special model just for them. It looks exactly like the STEALTHY antenna but is only a weather vane.

Model	Band	Elements	Price	S & H
WVA-146-2	144-148 MHz	1	$59.95	$5.00
WVA-223-2	222-225 MHz	1	$59.95	$5.00
WVA-445-4	440-450 MHz	2	$69.95	$5.00
WVA-NV	Neighbor Version		$29.95	$5.00

Prices are in U.S. Dollars. Foreign orders add $10.00 S & H.

Don Stoner, W6TNS, has an interesting dissertation on the need for hidden antennas on his web site.

All Customer Reviews

Average Customer Review: ★★★★★

Write an online review and share your thoughts with other customers.

★★★★★ **An excellent basic text**, January 29, 2004

Reviewer: "dalmatians2k" (Maine, NY USA) - See all my reviews

It seems that today's amateur radio operator more often than not has a station consisting of manufactured equipment. At the heart of these stations are transceivers so complex that the average ham has neither the equipment nor the ability to fix or modify them. Antennas are, however, something that still attract homebrewers.

RATE THIS BOOK

I dislike it I love it!

1 2 3 4 5

Edit your ratings

If you're going to put up an antenna, why not do it right and get the best performance for the time spent? For a low key yet effective introduction to wire antennas this is a wonderful little book. Nowhere near as long, or complex, as the ARRL Antenna Handbook, this concise volume presents some elementary theory and a number of practical designs for wire antennas. I've lent my copy to new hams several times and from all reports it's been a big help.

This book is highly recommended as a basic reference and a good stepping stone to the next level.

Was this review helpful to you? yes no (Report this)

★★★★★ **Simple low cost wire antennas for radio amateurs**, April 10, 2002

Reviewer: **Javier Carvajal** (Costa Rica) - See all my reviews

That book is full load with prctical information for any ham beginner who wants to learn by doing wire antennas. It is really helpfull, and well oriented

I QSL 100% -- Send Via eQSL Or Snail Mail Or ARRL Bureau

Hi I'm Rod Dinkins living in Oceanside, CA. I started in radio in the late 1940's as an SWL, AM, and Ham band Listener with a Knight Kit OceanHopper - later a Hallicrafters S-40A.

Electronics seemed to be my calling and I had 2 years of vocational electricity and electronics in High School. Four years in the US Navy during the Korean War as an Aviation Electronics Technician - AT1. Also taught electronics at NATTC Memphis, TN - one year.

Four years at Convair Pomona as an instructor of electronics and guided missles. 2 years as a vocational electronics teacher at the Junior college level in Walnut CA. Achieved an AA degree in Electonics under the GI Bill. Over 30 years as an Electronics Technical Writer with aerospace and Hewlett Packard. Licensed in Amateur Radio since 1977.

Today I am Full Time DXing (retired), writing Ham Books and enjoy working on my web pages and being as good an Elmer as I can.

Field Day 2002. 11 Year Old Bryce Kozlowski contacts Australia!

Balun and Transformer Core Selection

[Home] [Up]

Related articles at

Balun Test contains model of "perfect" dipole currents.

Sleeve Balun shows how a sleeve adds impedance, useful for VHF and higher baluns

Receiving Common Mode Noise shows how lack of a balun can contribute to system noise (it applies to transmitting antennas as well)

Longwires, Verticals, and Baluns shows how unbalanced antennas can have similar problems

Transmitting baluns on testing transmitting baluns

Occasionally errors are made regarding core selection. This especially includes baluns, where on occasion some very strange ideas surface. One rather odd but somewhat popular idea is that adding a mixture of core types will allow both high power operation and high choking impedance in baluns by slowly reducing current through a balun. Other misleading claims are that extreme values of core ui, such as values in the 10,000 or higher range, are necessary on 1.8 MHz and higher. Other ideas tend support use of excessively low permeability cores for the same application.

When I recommend a core, the material selection is always based on actual measurements with proper test equipment on a bench as well as in the actual end-application.

Core Material

I mainly use 73 material for receiving applications in ***LOW POWER*** applications between .1 and 30 MHz. 73 and similar core materials generally minimize the turns count required without inducing excessive loss. One of the best indicators of correct core selection is looking at the turns required. You'll notice most of the transformers I use have only one or two turns for every 100 ohms of impedance. My 75 to 450 ohm Beverage transformers, for example, only require two-turn primary and 5-turn secondary windings. ***A low "turns count" is a good indicator the correct core size and***

core material is being used.

For high power applications at HF it is often necessary to use lower permeability cores. There are two reasons for this:

- Lower permeability cores generally are available with higher curie temperatures. They operate at high temperatures without losing their magnetic properties.
- Lower permeability cores have higher Q (lower loss tangent) at a given frequency. This means a larger part of the impedance is associated with *lossless* reactance rather *dissipative* resistance. They turn a smaller percentage of power into heat, and that is very important at high power levels.

Permeability changes with frequency. As frequency is increased from zero eventually core impedance peaks. Above the frequency where impedance peaks the impedance of the core (and the ***effective*** permeability) actually decreases.

A downward slope in permeability with increasing frequency is useful for controlling impedance in broadband transformers, but we should be careful to avoid excessive slope. Excessive initial permeability can easily move the operating area too far out on the downward slope of impedance.

A transformer or inductor operating on the downward slope of a high ui core requires extra turns to maintain critical impedance and often requires more turns than a lower ui core. The upper frequency limit will decrease, and this may reduce useful bandwidth in the desired frequency range.

Using excessive initial permeability means winding becomes more tedious (it takes more turns). The wire has to be smaller and more fragile to fit a given core window. Temperature stability is often reduced while losses increase over an optimum core material selection. In addition, stray capacitance increases needlessly, reducing bandwidth and increasing unwanted stray coupling.

Do **NOT** pick cores solely by considering initial mu, since that value is taken at dc. You should consider ***characteristics measured at the operating frequency!***

Always remember this general guideline. Les wire length (as long as winding impedance is sufficient) results in better transformer bandwidth. The best designs place maximum conductor length INSIDE the magnetic core window, and minimum conductor length OUTSIDE the core window.

Heating

At higher power levels, it is necessary to move to lower loss tangent and higher curie

temperature materials like 65, 61, or (in extreme cases) 43 materials. Even a fraction of a dB loss produces significant heating in small cores when power level is in the kilowatt range. *The loss DIFFERENCE in non-resonant applications between lower and high ui ferrite cores isn't significantly different, but* ***heating*** *can be much less!*

We often assume heat means a core is very lossy or is "saturating", but **t**his often isn't true. We must consider the power level, duty cycle, and ability of the core to dissipate heat and look at the full picture.

Very small cores, such as small thin .5 inch diameter cores used on bead-type choke baluns, can only dissipate a fraction of a watt in open air. It sometimes helps to put temperature in perspective by visualizing how hot a 60-watt light bulb runs in normal operation. When we consider the core's size, it usually has significantly less surface area than the bulb. The core also has poor thermal conductivity, and is often stuffed in a container preventing any type of air circulation.

Consider the construction of a typical bead balun, enclosed in PVC and heat shrink tubing. As little as 20 watts dissipated out of 1500 watts can produce damaging heat in tiny beads enclosed in a PVC tube. 20 watts out of 1500 is less than 0.1dB loss, yet it overheats the core!

The problem is almost always a heating problem, and not a core-loss problem. It is almost never core saturation, unless the core is subjected to very low average power and very high peak power levels. It is best that we worry about heat and the number of turns we use, not actual power loss, when selecting a core.

Core Style

Soft-iron cores (soft magnetically) increase inductance because they increase *flux density* near a conductor for a given current. With only a small amount of flux "concentration", there can not be a large increase in inductance or impedance. We need a significant increase in flux to have a significant increase in impedance.

The area outside the core window does NOT have a closed magnetic path surrounding the conductor. ***The presence of the core has a minimal effect on impedance of any conductor area outside the core window.*** Most of the flux from external wires is in air, rather the core. With only a portion of the flux surrounding the outer conductors cutting the outer layers of the core, the ***useful*** impedance contribution of wire outside the core window to system impedance is minimal. Conductor length outside the core window mostly adds unwanted stray reactance and leakage flux. If we MINIMIZE the wire length exposed outside the core, and we generally have a more effective inductor, choke, or transformer.

This effect can be easily conformed in a simple experiment using an antenna analyzer. Connect a short wire across the output of an analyzer, and measure the impedance. Lay a core against the wire,

and observe the very small impedance increase. Now pass the same wire through the core center, and observe the large impedance change. This illustrates why the winding's wire length on the outside of the core is wasted, mostly contributing to undesired effects.

Core Dimensions

The area inside the winding-window of a soft-iron (soft magnetically, not physically) core is cut by all of the flux lines, and this area has a very large effect on impedance. The core concentrates the magnetic flux surrounding a current-carrying conductor into a very small area, and the thickness of the core moving away from the area of the conductor very rapidly has less effect.

- The additional impedance caused by placing a core over a conductor or conductors is almost entirely proportional to the core's internal length (window depth) paralleling and surrounding the conductor or conductors.
- The core diameter or radial thickness only has a small effect on impedance.

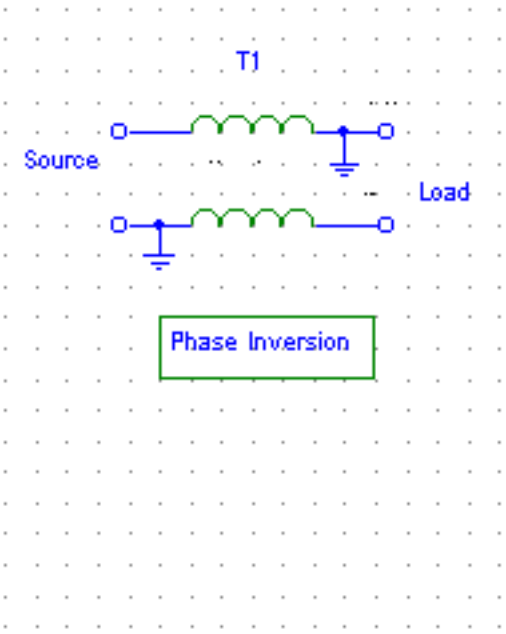
Doubling the core area **parallel** with a conductor roughly doubles winding impedance. The same is NOT true for an increase in core wall thickness, core thickness barely affects impedance.

I prefer binocular cores for most low-power applications and side-by-side stacks of cores (making a large "binocular core") for high power broad-band applications. This type of core arrangement almost always minimizes the amount of conductor hanging "outside the window". With very little conductor hanging "outside" the core window, there is less "needless" wire adding undesired stray capacitance and series resistance. For a given core material and impedance, conductor length can often be reduced to about one-third of a similar impedance choke (or transformer) using a conventional single-hole core or single stack!

Low Power Measurements

Phase Inversion and Choke Baluns

Some of my receiving system designs use phase-inversion transformers. Phase-inversion transformers are identical to (and interchangeable with) choke baluns or line-isolation transformers. For HF receiving applications, 73-material binocular cores are wound with six passes of #26 twisted-pair enameled wire. I use Fair Rite Products 2873000202 cores (about 1/2 inch square and 1/3 inch thick 73 material).

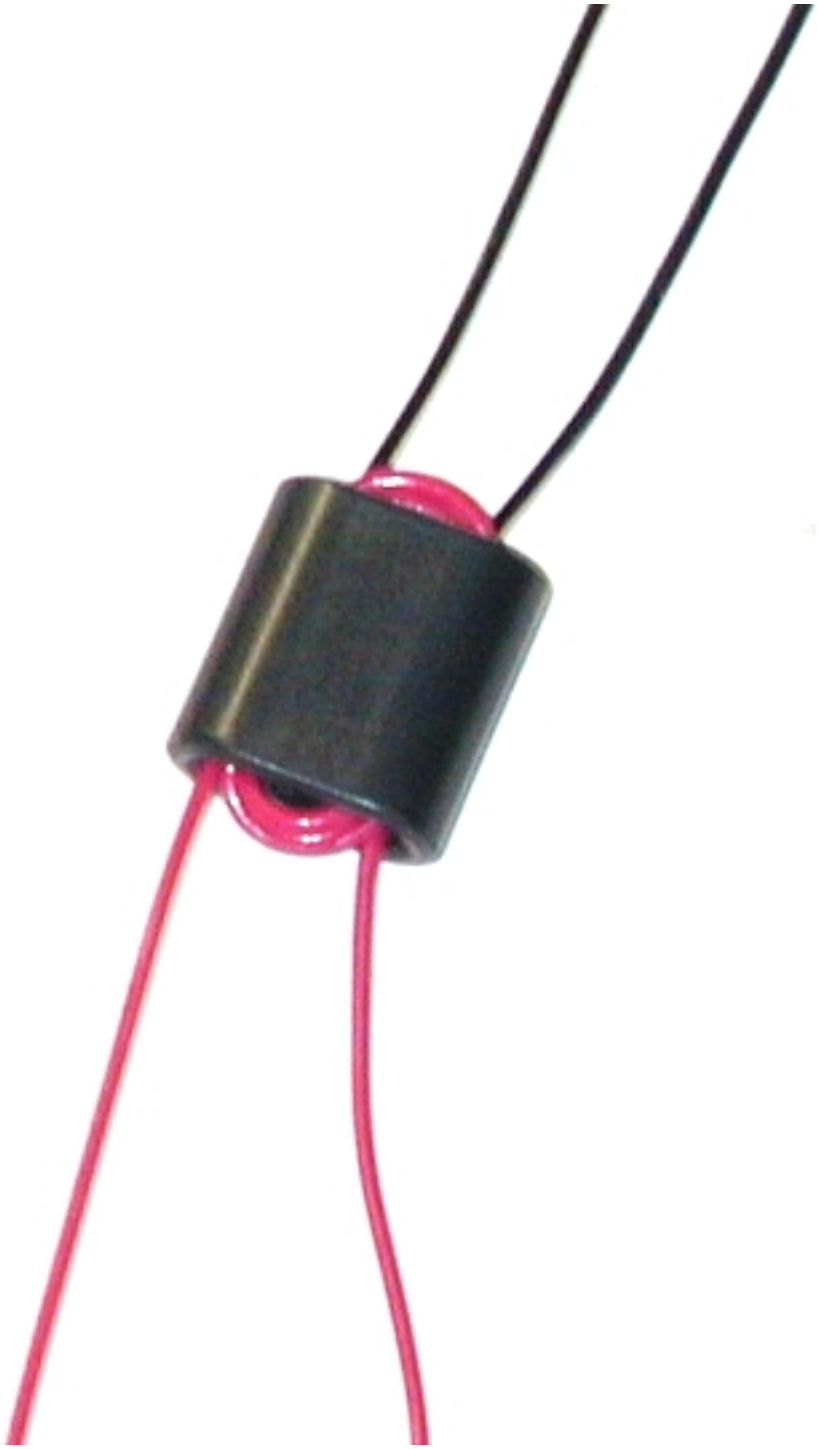


Here are measurements of a sample inversion transformer at 2.5MHz using accurate (and fairly new) commercial equipment:

Load Value (ohms)	Loss (-dB)	Phase Error (degrees deviation from 180)
100	~ 0	<1
33	~ 0	-1.2
10	0.2	-2

This shows inverting transformer construction is good, since even a 10-ohm impedance load works well!

Beverage Matching Transformer



Sometimes I use designs for a long time, and forget how I decided they were OK. I recently received an e-mail questioning the number of turns in my Beverage transformer design, so it seemed like a good time to re-confirm the design.

I retested a 2:5 turn ratio transformer using a single FairRite Products 2873000202 core (about 1/2

inch square and 1/3 inch thick 73 material) two different ways on a generator/ network analyzer/vector impedance test set.

Total loss of two back-to-back transformers was .84dB at 1 MHz increasing, not decreasing, linearly to .98dB at 30MHz. The actual transformer loss would be .42dB at 1MHz increasing to .49dB at 30MHz.

Doubling turns increased the attenuation slope. While 1MHz loss decreased to .69dB per pair, 30MHz loss increased to 1.21dB. This was for a PAIR of transformers connected in series to make a 1:1 transformer. This of course removes mismatch losses, so it is twice the real transformer loss. Actual loss would be .35dB @1MHz increasing to .61dB at 30MHz.

Measuring a second way, I terminated the transformer in 470 ohms. Loss measured .65dB at 1MHz when mismatch loss was included. Since receivers have wide ranges of input impedance, any mismatch error might help OR hurt actual system loss. Factoring out mismatch loss the second measurement indicated about .53dB 1MHz loss with the original 2-to-5 turn transformer and .43dB with twice the turns.

Every measurement has tolerances, and the two different methods do provide different losses because measurement errors affect results differently. Still, it is safe to say doubling turns has a negligible effect on 1MHz loss (which is around .45dB).

HF Receiving Loop Antenna

An easy-to-make receiving loop antenna for HF

20m HF Receiving Loop Antenna

Receiving HF signals at my location is a compromise situation due to the antennas I use and the high noise environment in the city. Although my transceiver has good selectivity and excellent filters, I suffer from high noise conditions that at times make receiving a chore. This is true for both weak-signal DX as well as regional chats with friends in the Southwestern US.

I have often wondered whether a loop receiving antenna would be a good solution to my need for better reception but was hesitant to get involved with the typical preamplifiers and monstrous dimensions most of the designs I have seen require. This all changed when I came across a website that described an easy-to-build receiving loop that does not need a preamp. This design does require an external antenna tuner to provide some preselection gain and uses your transceiver's preamp. You simply connect the loop through the feeder to your antenna tuner and feed the tuner into your transceiver's auxillary antenna input connector. You peak the external tuner for maximum signal strength.

Remember: this is a RECEIVE only antenna - it is not intended for transmitting! If your rig doesn't have an internal antenna switchover relay you will need to exercise caution doing it manually. I built my first loop for 40/80m in order to improve reception of signals in the Southwest and inadvertently transmitted once on 75m. I was heard weakly, 150 miles away -pumping 300 watts into the loop - it didn't damage anything but you don't want to operate this way for long!

I built this loop directly from the greertech.com website dimensions (see below) and added my own wooden

support design made from 1/2X3/4 inch stock from Home Depot. I first built the loops and supported them with a simple 1/2 inch PVC pipe mounting system to evaluate them. I liked this antenna so much that the final versions have a simple wood support built into my operating desk for hand rotation. I can remove the entire antenna system in a manner of minutes when I don't want to use the loop.

The photos here show the basic parts and how small the 20m loop really is - each wooden frame piece is 22 inches long. The feeder from the loop to the antenna tuner is 34 inches long, and the loop itself is 5.9 feet in length, per the greertech.com dimensions for RG-58/U coax. If you use a different coax type, make sure you use the appropriate dimensions in the referenced material.

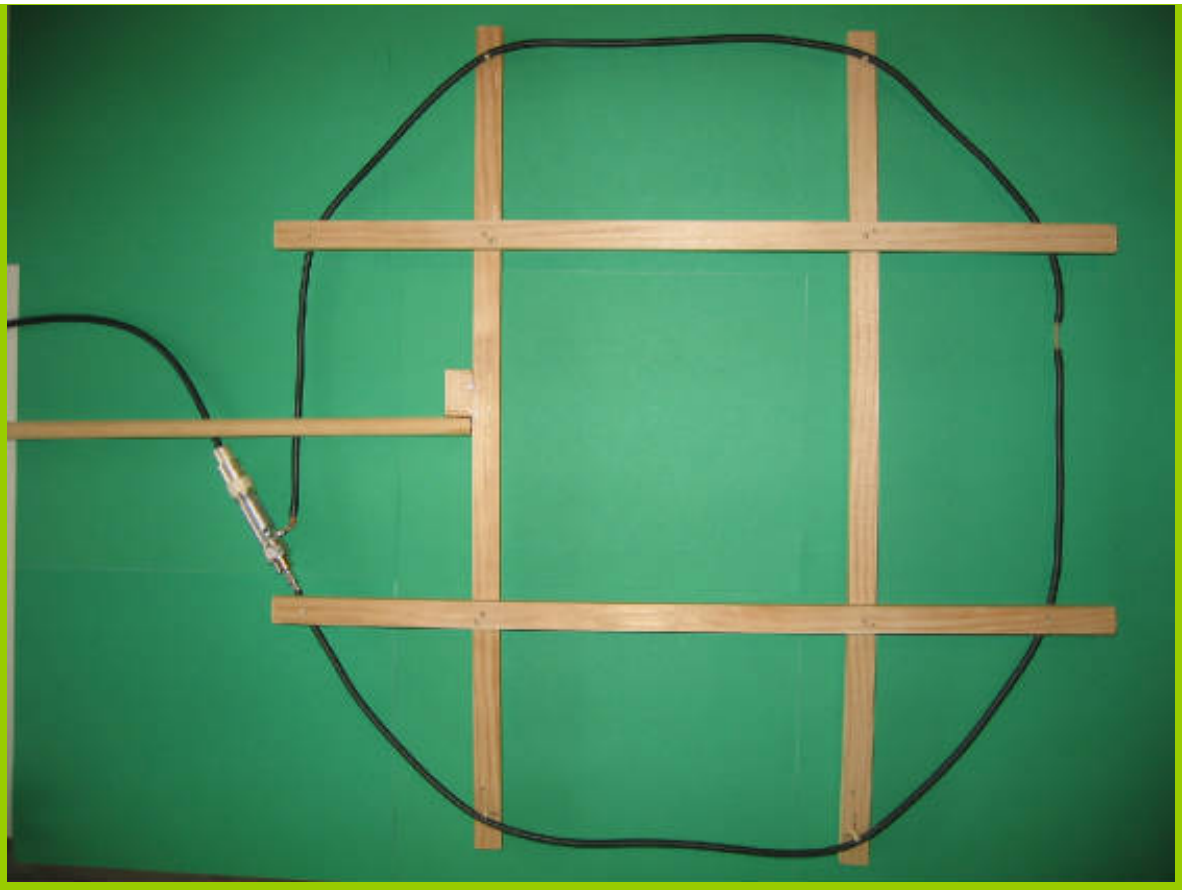
Loop components

I pegged the pieces of the loop support together using dowels so as not to have any metal inside or close to the loop. I made the shorted end of the loop out of an old "blitz bug" lightning arrestor which was in my junk box that conveniently has female '259 connectors and a screwhole in the barrel. Make sure you short only the braid to the center conductor to the braid and don't short out the center conductors! You could simplify things and skip the connector altogether - just solder the center conductor to the braid to the shield as greertech.com indicates on his website. My first 40m loop was built this way and it took about 15 minutes to construct.

Notice the very important gap in the shield braid on the side of the loop - this is one of the key features that makes this design work.

See the greertech.com website referenced below for the electrical details and principles of operation - this is an excellent source of information for these simple, constant-current magnetic loop antennas.

Completed 20m HF receiving loop



RESULTS

This simple and inexpensive loop works remarkably well for something so cheap and simple. It has given me enhanced receive performance in three areas:

1. Nulling noise sources and interference - Orienting the loop so that the plane of the loop is directly aimed at a noise source (and it works for noise sources either near or far, it doesn't matter) allows you to essentially remove the noise. The nulls are sharp, meaning a slight rotation of the loop will pass through it if you're not careful. Of course, if the noise source is in line with the bearing to the signal you want to receive this is not going to help - but in cases where the bearings are different it is a significant help. I am now able to eliminate some sources of noise that have plagued me for years.
2. Peaking desired signals - Aim the plane of the loop to maximize the desired signal and other signals are reduced in strength (unless they are on the same bearing). This loop receives a bi-directional figure-8 pattern, where the peak is in the plane of the loop and the null is broadside to the loop. This little antenna has excellent directivity - I have enjoyed orienting the loop for peak signal strength on both DX as well as US stations and for the majority of cases I can determine the Great Circle Bearing within 5 degrees of the actual bearing. If you enjoy RDF (Radio Direction Finding) pursuits on HF, this is a neat way to do it. There are instances where signals don't show much directivity - I have especially noticed this on Near Vertical Incidence Skywave signals.
3. Lower noise floor - The loop delivers a lower strength signal than a conventional antenna so you need to compensate for this with your transceiver's preamp (or use an external preamp after the antenna coupler and in to the receiver) to bring the signal back up. By doing this in combination with reducing your RF gain and using your AF gain to bring up the signal for comfortable listening you will have reduced the noise floor in your system and will enjoy quieter receive performance. Of course your S-meter won't read like it normally does, but that's a slight penalty to pay when you can hear signals without so much noise!

I am pleased with the improvement this loop has provided in my receive capability. I am able to copy some weak-signal DX I previously could not copy at all and I can now listen on the lower bands with the 40/80m loop and enjoy improved noise conditions.

Here is the greertech website on this loop design:

http://www.greertech.com/hfloop/mymagloop.html

Prototype 40m Loop - works great!

Final 40m version of the Loop...

QRN USA Lightning Storm Map

For an instant check on USA mainland QRN click on this link or this link to a weather map of thunderstorms.

Some of this site's (W8JI.com) contents are listed below:

New Page Cebik Dipole and other short dipoles. Feedline and tuner analysis!!

Amplifiers

SB-221 Tank Voltages and the parasitic oscillation myth. The real explanations behind amplifier parasitic oscillations and alleged damage by HF amplifier parasitic oscillations. Look at voltage throughout the tank at frequencies between 1 and 300MHz, and decide for yourself. Related article at Arcs, what makes an amplifier arc?

Preamplifiers for receiving. Measurements of receiving preamps. Compare your favorite pre-amp (text corrections 4/27/03)

Arcs, what makes an HF amplifier arc? This explains causes of amplifier arcing in any amplifier, including the TL-922 amp, Ameritron amps, Heathkit SB220 amplifier, and any other HF

power amplifier for amateur or commercial service. Simple failures and design or operating shortfalls are often explained as parasitic oscillations

Bandswitch failures the real causes and cures of bandswitch arcing and failures in HF power amplifiers that are often attributed to poor parasitic suppression causing oscillation

How to load or tune your HF amplifier and why an amplifier arcs when tuned incorrectly

Inductors deals with antenna loading coils but also applies to amplifiers

Related page: Inductor spice model

Relays how to speed and sequence amplifier T/R relays and how antenna transfer relays affect amplifier failures

Tank Circuits two models showing tank voltages, currents, loss, and phase shift

Vacuum Tubes how they work in RF power amplifiers and why vacuum tubes arc in amplifiers Includes details on 3-500Z and 8877 3CX1500 A7 tubes. Learn reasons tubes fail in amps

Vacuum tubes, how they convert d-c to RF how RF amplifier tubes convert dc to RF power

VHF Parasitics and general stability. Is your amplifier unstable? If you own a TL922, SB220 series, 30L1, or other amps with grid "negative-feedback" you will want to read this! (rev 5PM Feb23/03) Spice models. The resistor think might be non-inductive might not be what you think. Includes internal photos of various resistors.

ANTENNAS and antenna related topics

New Page Cebik Dipole and other short dipoles. Feedline and tuner analysis!!

EH antenna: the E-H and CFA antennas. How they work. See how my early theoretical predictions and descriptions compare to actual field measurements of this most recent antenna theory

hoax! For measurements click here.

If you think ***baluns at the inputs of tuners*** are a good idea, go to this W7EL link and read the section on current baluns. You might be surprised!

Another suggested tuner link is ***W9CF.***

Balun and Core Selection: (mostly receiving) Contains information on core selection for transformers and baluns (it isn't a balum)

Balun, sleeve baluns: How a sleeve balun works and what is important

Balun, transmitting: Testing transmitting baluns and untrue folklore about choke, voltage, and current baluns. Dispelling myth that grabbing coax adequately tests a balun

Baluns: winding methods with toroid cores and debunking myth that a split winding improves performance

Baluns: Common-mode noise. How baluns can help reduce receiving system noise

BALUN TEST: New!!! Test data on transmitting baluns.

Beverages: Construction, Endfire Beverages, Broadside Beverages, Beverage Arrays for low band DX and other low noise receiving antenna arrays for 160 meters and other low frequency bands. Also see balun and core selection for Beverage transformers.

Combiner and Splitters: Contains information on Magic-T splitters and combiners, how they work and what they do

Detuning Towers: A tutorial with an important correction of the common error that we adjust for minimum current!! (revised slightly Feb 17, 2003)

Gain. Stacking (Broadside) and end-to-end (Collinear) gain. How it works, dispelling the 3dB myth.

Loading Inductors: A brief tutorial on loading coils (inductors) and inductor Q

Magnetic Loop Antennas: receiving

Mobile and Loaded Antennas: Loading coils, ground losses, and currents in the system. Related page: Inductor spice model

***Power Stroke Diesel RF Noise*: PowerStroke Diesel noise and how I corrected the problem in my 2003 F-250**

Noise and common mode noise. How it gets into the receiving system Power line and other noise sources

Omega and Gamma Matching: Contains technical information on Omega and Gamma matches, impedance limits, component selection, component failures

Phasing, Crossfire: Contains information on cross-fire phasing and why cross fire phasing is superior for broad bandwidth low-band receiving arrays

Phasing Systems: A quick discussion of phasing methods

Polarization and diversity: Think you can have the best of the two worlds of vertical and horizontal? Think again!

Radiation and Fields: Electric field, magnetic field, Fresnel zone What the terms we use actually describe

Radiation Resistance: A revised (as of Feb 14, 03) tutorial on radiation resistance and how it is used and misused

Receiving and receiving antenna pages: Relative ranking of antennas for Topband DX plus various articles on low-band DX receiving antennas...including low band receiving antennas such as Beverage antenna and Beverage antenna construction. Elongated Loops and other loop receiving antennas such as K9AY, EWE, and flag antennas, small Topband or HF low noise receiving Verticals , my receiving antennas (with a demo), end-fire or cross-fire Beverages, common-mode noise in low noise receiving systems, and more.

Skin depth: The best explanation I have found

Transmitting: Contains information on my various transmitting antennas, including my eight

direction four-square

Traps: Measurements and models of traps, including Coaxial and Tribander Antenna traps

Receivers

Diversity reception "diversity" receiving using stereo along with some sound file examples

How I test receivers

Receiver Tests of some transceivers and receivers. Newly added 756PRO FT1000 MK V Kenwood TS870 (modified)

Receiver IM improvement **mods for FT1000** FT1000D

DX Sound files: What some signals sound like here

1000MP MK V....mods for FT1000MKV receiver IM and transmitter clicks

Key Clicks

Includes sound files of signals with excessive bandwidth, a technical description of what causes clicks, and mods for the FT1000(D) and FT1000MP.

What Causes Clicks....The technical cause and what we can do about clicks.

Keyclick-MP.... An analysis and patch for the FT1000MP 's infamous key clicks

Keyclicks 1000D.... An easy and cheap patch for the FT1000 and FT1000D

Keyclicks 1000MP MK V....mods for FT1000MKV receiver IM and transmitter clicks

Also see Radios.

Noise

Technical article about noise and receiving/ receiving antennas

Power Stroke Diesel RF Noise: PowerStroke Diesel noise and how I corrected the problem in my 2003 F-250

MFJ-1025/1026 Technical Information

Common-Mode Noise issues with feedlines, and how to avoid problems

MFJ-259B Alignment instructions and some technical information MFJ259B.

MFJ-1025 and 1026 phasing unit technical information.

Local ARES activities will be included later. We have a local repeater that covers a good bit of I-75 between Macon and Atlanta. Please give a call on 147.225(+600) if you are passing by.

Special thanks to my friend Bill Fisher, W4AN, who is now a silent key. It was Bill's encouragement and generosity that made this site available.

HISTORY
of
160 METER DX
by
W1BB

This HISTORY is presented to you, by W1BB, in the hope that it will be found useful, and interesting, in connection with your 160 meter activities.

Please advise of any corrections, errors, or omissions noted. Your help in this respect will be very much appreciated.

Best of luck, and HAPPY HAMMING to you always!!

B.C. N. U. on 160 !!!

W1BB

HISTORY
of
160 METER DX TESTS
(Dx vs W/Ve)

(The following data for the period from 1931 to 1946 is taken largely from an article by Austin Forsythe, G6FO, Editor, in SHORT WAVE MAGAZINE, for April 1946.)

1931 DECEMBER — G to European Continent contacts. Up to 10 watts power. OK3SK made it with 5 watts power. (3)

1932 JAN-MAR — G to European Continent, Almost as good as 7mc.

DECEMBER — Gs organized tests -- W1DBM with 450 watts, directional 360' antenna on tip of Cape Cod -- Heard s5 to s7 up to 0800 GMT. Peak period 0530-0730.

1933 FEBRUARY — G6FO using 9 watts and 66' antenna with counterpoise, worked W1DBM 0600-0715 for FIRST Transatlantic Crossing. GW5WU also heard in USA

1934 FEBRUARY — Several more Gs worked Across.

1935 JAN-MAR — G6FO-G2PL-G2II-G6YQ, and GW5WU worked across. VE1EA worked G2II and GW5WU first time he ever tried 160 Dx.

1936 JAN-MAR — No scheduled 160 meter Dx tests -- However, FIRST USA/AFRICA 160 meter QSO made by W1BB/FA8BG on 2/23/36. VE1EA worked G2II - G2DQ and G6UJ

1937 JAN-MAR — No scheduled 160 meter Dx tests -- However G2PL/W1BB made FIRST 5-B.T.O.C. within 24 hours, working on 160-80-40-20-10. VE1EA worked across on 160 to G2PL. W2EQS heard in Wales with 30 watts.

1938 FEBRUARY — G6FO - Short Wave Magazine, arranged series of tests. Heard W1BB but could not work across to W/VE - Conditions poor.

1939 JAN - FEB — Band cracked wide open Jan. 8-15-22 and Feb 4 & 16 between 0500-0830. Fifty stations worked across including G-GI-GW-HB-F-FA-SM-OZ-W1-W4-W8. W phones were heard and also identified, but not worked. Interest mounted high. W1BB outstanding W station. Gs across were: G2DQ-2PL-2RC-2CF-2MI-2AO-3GH-3JU-5MP-5RI-5JO-5XH-5QY-6MK-6WY-6QM-6QH-6SQ-6XL-F8ZP-GW2IP-GW8HI-FA8BG.

1940 — WAR --- Band Closed

1941 — WAR --- Band Closed

1942 — WAR --- Band Closed

1943 — WAR --- Band Closed

1944 — WAR --- Band Closed

1945 — WAR --- Band Closed

1946 — Band opened up in "G" land 1800-2000 kc. Local working. No Dx. Loran QRM. Band closed in USA

(The following data from the year 1947 on from the notes of W1BB, other interested Dx Hams , and SWLs.)

1947 — Local G working -- no Dx. Band closed in USA.

1948 — Local G working -- No Dx. Band Closed in USA.

1949 JAN-MAR — Gs heard across again. --- April 9th 1949 W band opened up again by FCC 1800-1825 Kc and 1875-1900 Kc. -- Also other bands for Western USA - See FCC notice.

DECEMBER — VE1EA heard G6BQ and G5JU 12/17/49 11.19PM EST -0415 GMT. G3PU and W4NNN made First Post War crossing 12/18/49 with QSO. GD3UB and VE1EA made second post war crossing 12/19/49

1950 JAN-MAR
-Unorganized tests by leading G and W/VE stations, indicating that band had potentialities for D.x.
-G2PL and G3PU outstanding Dx stations. Other Dx stations working across were: G3FAB-G6BQ-G6GM-G8NF-GD3UB-KV4AA-G2YS. Heard across were GM8UM and EK1AC
-Of special interest - W1BB repeatedly heard very weak signal - almost but not quite identified- called "QRZ QRZ QRZ G6?N G6G?N G6G?N G6G?N - a number of times -- this was later identified as G6ZN with only 3 watts power!!!!!
-VE1EA - W1BB - W4NNN outstanding W/VE stations. Other W/VE stations working across were 10E-3IU-3LII and W2WFZ.
-Of special importance was first G/W two way phone contact on 160 meters between G2PL and W1BB
-W1BB-W4NNN-VE1EA signals heard by FA8BG and EK1AO in Africa.
-FIRST 3 element 160 meter beam tested by W2WFZ with G3PU and with excellent results.
-Eighteen Gs worked EK1AO Jan. 22 -- KV4AA heard by G4LX -- ZB1AR worked several Gs -- HZ1KE worked GM2HIK-GD3UB-G6AB-G6BQ
-W4NNN (Now W9NWX) worked HC1PK during 1950 ARRL DX contest for FIRST USA/South America 160 CW QSO. (Per QST July 1953)
-HZ1KE QSO'd by G. First G-HZ??? First Asiatic??
-TA3FAS QSO'd by G2pl - FIRST G-TA on CW and PHONE.

1951 JAN-MAR
-Organized tests -- by G6FO Short Wave Magazine - and W1BB announcements by QST.
-This was a very successful season, summerized by the following "Outstanding events" from W1BB's report as follows:

#1-First crossing this seasonby VE1EA working G6BQ on Dec. 31, 1950. G6BQ 349 and VE1EA 449
#2-First N.A./Africa Postwar QSO VE1EA/EK1AO Jan 7 - both RST 449
#3-FIRST!!!! Contact between Asia and N.A. on record. between VE1EA and HZ1KE Jan. 14 1951 - 229 both ways.
#4-VE1EA has worked 4 continents - 8 countries Post War - total of 10 countries all time.
#5-W1BB also worked 4 Continents - 8 Countries post war total of 11 Countries all time.
#6-W1BB worked South America HC1JW Jan.21 '51 BB was 469 and HC1JW was 567
#7-W2UKS QSO'd N.A./S.A. same date 349 - W8BKH also. w/HC1JW
#8-W1BB and W9CVQ both heard in NEW ZELAND by ZL1AH Ex G6AH and ZL1MP Ex GW6AA-Ex G2II of early 160 meter DX fame. These reports confirmed. Also an unconfirmed repor of W2QHH being heard by ZL1HM. Howy using 20 watts and 12' high antenna.

#9-A number of Phone/phone and CW/PhoneQSOs were made. G2PL/W1BB p/p F8PJ/W8FNS p/p W1LYV/GW3ZV p/p W1LYV/G2PL cw/p

#10-OUTSTANDING and Most Consistent DX station EK1AO - 300 Watt

#11-Also EXCEPTIONALLY OUTSTANDING for 10 Watts!!!! GW3ZV using miles of wire for an antenna!! Signals up to 589 at times!! This performance deserves a lot of credit.

#12- More US districts worked than ever before!!! W-1-2-3-4-8-9- VE-1-3

-DX working across were: G2PL-YS-MM-ACV-FLK-DA G3PU-SU-DIY ERN G5HB-RI-UB-KM-JU-GU-VB G6GM-QB-BQ-LB G8JM-NF GD3UB EK1AO HZ1KE GW3ZV-FSP HC1JW F8PJ KV4AA.
Heard but not worked were the following stations: G2DPV,NP and G3GGN

-W/VEs working across were: W1BB,EFN,PLO,OMP,ZE,LYV,BEU,SAN, SS,KDX,DVS,RQR,BEU,NRE,AXA,MQB --- W2PTV,ESO,UKS,BQS,BFA,BLR, PEO --- W3LII,FNF,PMG,LOE,EIS --- W4KFC --- W8WKV,FES -- W9FIM,CVQ,PNE, -- VE1EA -- VE3AAZ. Heard also were the following W1AW - W2WC - W2KZX W3OKU,AAA,JAA -- W8FIR,FLH, FLV and WØTQD.

-FIRST!!!!! W9CVQ worked ZL1AH December 31, 1951 RST 229 both ways - after a series of tries and schedules, making FIRST W/ZL 160 meter QSO on record!!!!

-This was an outstanding year -- But??? The SUNSPOT cycle in on the down grade - lets see what happens next year!!

1952 JAN-FEB

_Band was very much poorer than last year -- Due to Sunspot cycle being on downgrade????

-Outstanding events were as follows:

#1-VE1EA made first crossing working G3PU Nov. 25. 1951

#2-W1BB,W9NH,W2QHH and KV4AA heard in New Zeland by ZL1AH and ZL1HM during tests. SPECIAL NOTE!! W2QHH using 6L6, 17 watts, 270'wire 12' highat one end and 3' at the other heard by ZL1HM and CONFIRMED!!!

#3-W1LYV was heard in RUSSIA - received SWL card!!

#4-VE1EA worked HZ1KE for second N.A./AFRICA 160 QSO.

#5-FIRST!! W9/G QSO on record when W9CVQ worked G5JU and GW3FSP December 23rd. 1951 -- but included in 1952 "Season" report here

#6-W2QHH made FIRST VP4 QSO w/VP4LZ on February 23. (Again using only 17 watts.)

#7-W2ESO, Gene Black put weekly reports of test results on Voice Of America broadcasts with special note of FIRST W/ZL QSO

-Dx stations working across were: G2PL,AJ. - G3PU,ERN,COJ,DIY. G5JU - G6GM,BQ- GW3ZV,FSP. - EK1CW - KV4AA - ZL1AH - VP4LZ. ALL Dx heard was worked except GM3OM who was heard and not Wkd.

-W/VEs working across were - W1BB,LYV,SS. - W2TRK,BQS,K2USA - W2RGO - W9CVQ,NH - VE1EA and VE2WW

-It will be noted that while there were several outstanding events, contacts to Europe wase way down, and it was seriously considered giving up the tests for 1953. It was W1BBs suggestio that they be continued to see what would happen.

1953 JAN-FEB

-In spite of poor conditions, there was a lot of activity and interest and good contacts were made. This was due in some measure to better antennas, beter receivers and MORE ACTIVITY.

-The OUTSTANDING EVENTS for 1953, were as follows:---

#1-W1LYV made first crossing for season Nov.9th 1952 working G6BQ, GW3FSP, G3HYG and G3GGN.
#2-FIRST!!! W5/G QSO between W5ENE and G5JU January 4th. G6GM and G3PU were also heard by W5ENE.
#3-FIRST!!! ~~NORWAY~~/USA QSO between OH3NY and W1BB JAN. 11th 0600GMT. W1BB using KYTOON (Balloon) antenna 260' vertical BB/449 NY/339
#4-NEW COUNTRY, EI9J on for the first time - Thanks to W2QHH - with outstanding signal and worked many W/VEs - Had special permit from his government for operation during the 160 meter DX tests.
#5-W1BB,W3EIS heard in South Africa by ZS3K
#6-W1BB,EFK-W2EQS-W3EIS-W9PNE-W9NWX all heard by ZL1AH varying RSTs 229/259 - and various dates during tests.
#7-W1BB experimenting with 260' vertical KYTOON - (Helium Balloon) supported antenna - slightly better than horIZONTAL ANTENNA _ BUT NOT OUTSTANDING _ WEATHER too much of a factor to make it practical. Hope to run further tests for confirmation.
#8-FIRST !!! ASIA/USA QSO on record - W1BB worked ZC4XP on March 8th.
#9-VE1EA worked ZC4XP for his third ASIAN QSO - having previously worked HZ1KE twice.
#10-Several QRP contacts of note were made:
(a) G6ZN with 3 watts worked K2ANR
(b) W2QHH and W1LMU with 17 watts each worked across
#11-A number of phone stations were heard and worked across
#12-First Post War W/EI contact - W2WWP/EI9J Jan 11th.
#13-First Post War VE/EI contact VE1YW/EI9J
#14- W9NH completed FIRST 160 meter "WAS" -(Worked all USA States) - on record. !!!

-Dx working across were: G2HDT,FGD,SU,JF-G3PU,GGN,BKF,FGT,GZK, ATU,GLW,-G5RI,JU,TN-G6GM,CJ,LB-G8KP,JR. Other countries working across were EI9J - GI2ARS-KP4DV-KP4KD-VP4LZ-GW3FSP-OH3NY-KV4AA
--Heard across were G2PL-G3GKQ-G3US-G5VB-G3HVX-G3FEW.
-W/VEs working across were:- W1BB,LYV,LMU,AHX-W2EQS,WWP,QHH,WC. W3EIS - W5ENE - W9PNE - VE1EA -VE1HJ - VE1YW.
-W/VEs heard only were - W1QJM,HSC,AYG,SS,TCR,OJM,FYS,QCA,RQR, DWO,AW,OE - W2KNZ,JPW,HCW,ESO,AMC,NC-W3HL,AVL,TBG - W4VFL,LRN W8NJC,HFG,GDQ - W9NH,MFV,FIM,CZT,BQQ - VE2AIE.
-January 11th was the outstanding dsy of the tests - Dx was gOOD _ QRN was low -- later tests were QRN'd out with terriffic QRN, coinciding with the great hurricane and floods in Britain and Holland.

APR-SEP -SPECIAL NOTICE!!!
-In April W2WWP received word from ZL1WW via ZL2ACV on 40 Cw that 160 meter faint signals were being heard, and asking for schedules.
-On May 3rd W2WWP 1899 Kc QSO'd !!! ZL1WW 1904Kc RSTs WWP/349 WW/239, for SECOND ZL/USA 160 meter QSO on Record!!(See W9CVQ Dec. 1951 for FIRST ZL QSO) -- This was FIRST W2/ZL QSO! - Times were 0900-1030 GMT -- Sunrise this end -- early evening ZL time.
Thereafter W2WWP worked ZL1WW a number of times.
-W2WWP invited W1BB and W9NH to join in on further tries.
-W9NH heard first ZL on July 1st 119rst
-W9NH next worked ZL1WW on July 29th 1022 GMT - MH/449, WW369
-On the same date W2WWP also worked ZL3RB.
-W1BB worked ZL1AH Sunday August 16th at a different time, 0605 for a short "Contact" type QSO. (Sked suggested by ZL1AH)

-W1BB worked ZL1WW, ZL3RB and ZL1AH all on the following Wednesday August 19hh 0945-1030. ZL1WW was a solid QSO. RB and AH short "Contact" report QSOs.
-W2WWP the same morning, as signals were unusually good, almost had a phone QSO with ZL1WW when signals peaked - they heard each others modulation but no phone QSO -- CW QSO again OK..
-W1BB exchanged reports with ZL1NX on August 23rd - also Wkd WW
-Tests are continuing (At the time of this typing) during the summer months and fall of 1953 to see if enough can be learned to establish regular tests in which it would be worth while for all Hams to participate - lots of lost motion this summer.
-Many Many thanks to ZL1WW, ZL2ACV and W2WWP for starting this thing off.
-FIRST !!! 160 meter "WAC" on record made when W1BB QSO'd ZL1AH, ZL1WW, ZL3RB, ZL1NX.

-W2WWP the same morning, as signals were unusually good, almost had a phone QSO with ZL1WW when signals peaked - they heard each others modulation, but no phone QSO resulted. CW qso again OK.
-W1BB exchanged reports with ZL1NX on August 23rd - also worked ZL1WW
-Many Many thanks to ZL1WW, ZL2ACV and W2WWP for starting this ZL wk
-Thus the FIRST!!! 160 meter "WAC"-(Worked all Continents on 160) on record was made when W1BB, QSO'd ZL1AH, ZL1WW, ZL3RB and ZL1NX.

1953 OCT-DEC
1954 JAN-MAR

-This "SEASON", the organized tests were held per G6FO, Short Wave Magazine, and W1BB with announcements in QST/CW and "Break-in".
-There was more activity than ever on 160 - more C ountries, and all 6 Continents heard from.
-Much DX was worked in between the "Organized" tests, and it looks now as though, through these "organized" tests, that the band is being opened up more and more to general operation, and year/mmmm round DX efforts.
-Summary of this seasons OUTSTANDING EVENTS from W1BB's log follow

#1 W3RGQ arranged special tests starting October, and the FIRST CROSSING this season was on Oct 4th when W3RGQ worked G3PU. W1LYV Contacted G3PU later the same evening/ Signals 239/449
#2. FIRST!!! ZL/G QSO!! - 12,000 Miles, October 10th 1953 0640GMT. ZL1AH worked G6GM. AH339, GM339 Half Hour QSO. On the following night, OCT 11th another QSO was made, this time 559 both ways. On Oct 21st G6GM QSO'd ZL3RB - RB439/GM449 -ZL1AH QSO'd G6GM again also.
#3. FIRST W/HB QSO on record -when W1BB worked HB9CM Dec 20 '53 W1BB 449 HB9CM459 0637 GMT.
#4. FIRST Canal Zone/W QSO on record!!! When W3RGQ worked KZ5DE, January 16th 1954
#5. LOWEST POWERED G QSO this season. G2HKU, 5 watts worked W1BB Jan 3rd. 0640GMT - Isle of Sheppy. HKG/329 BB 579
#6. FIRST Hawaiian/New Zelamd QSO. KH6MG/ZL1WW March 24th 1000 GMT
#7. Some FIRST KP4KD QSOs. - EI9J Jan 31st. G6BQ, Jan31st. VP4LZ Feb 21st -VP6EB Jan 31. - VP7NM Jan 31 - VP9BDA, Feb 28th - KZ5DE Feb 7th VE 1EA Feb 14th.

-In general, the first part of the TESTS had better conditions th than the last.
-An unusual phenomonon was observed in that the path seemed to shift from good E -W conditions early, to a more NE -SW path, as evidenced by Canal Zone QSOs with W and G stations

#8. FIRST G/C anal Zone QSO when G3PU worked KZ5DE on Jan 16th

-We had TWO FAKES this season VR2BJ and LU4DM who fooled several.
-DX WORKING W/VE, were:-G3PU, ERN - G5JU, KM, RI - G6GM, QB, BQ, GJ - G2HKU - G8JR - GC3EML - GW3ZV - EI9J-HB9CM-HB9T-KZ5DE-KV4AA-KV4BB-KP4KD-VP4LZ-VP7NM-VP9BDA.
-DX HEARD were G3HVX and G3BKF.
-W/VE WORKING DX were:- W1BB, DBE, LYV, TMA, VDB, EFN, AQE, UJP, ZL -- W2GGL, EQS, AMC, VC, K2ANR, BWR, QHH, WH, PP, UKS - W3RGQ, EIS-W4KFC-W9PNE W0NWX-VE1EA-VE2AIE0VE2WW.
-W/VEs HEARD only by DX were:-- W1AHX, LMU, QCA-W2JIL, MCU, TRK, AMC HEY, KV -, W3FWF, TBG, HL, PA.-W4BRB, POB, KMS-W5ANO-W8GDQ, HQ, IKN, EJL - W9EWC, CZT, NH.
-SWLs!!!!!! - Special Mention should be made of the splendid work done by the SWLs. To list a few of the most consistent ones, --

(next page)

-Norman Smith, BRS20601 -- ROBERT IBALL BSWL 4648 --- George Allen BSWL 4588 -- C.L. Bradbrook G3692 --- William Iball, BRS-20410 -- Mike Birch ISWL/DL2-4832 --- Jack Burgess, ISWL 2561 -- E.M. Hainsworth --- John Whitington ISWL-G3719.BRS 19771 -- Gerald Heslop RSGB A1167/ISWLG4555 --- Ian S Davies RSGB/A1182 --- John L Hall, BSWL/2333. There were others.
-These very factual and accurate reports assisted greatly and added much zest to the 160 meter TESTS. Many many thanks to these cooperative, and fine fellows - the "SWLs" !!!

#3. FIRST!!! - GC/W QSO on record, when GC3EML made contact with W1BB December 17th, 1953. GC 3EML rst 229 - W1BB rst 459.

1954 SEP-DEC
1955 JAN-APR

-This "SEASON" there was a variety of DX, with the North/South path predominating.
-LORAN became more of a problem, with a new station moving in permanently on 1900Kcs, and an intermittant station on 1850. This causes considerable QRM, and gives a high artificial noise level that many weak stations cannot get through.
-Summary, of the OUTSTANDING EVENTS from W1BB's log, follow:-

#1. Season's FIRST USA/Oceania QSO when W8ANO worked ZL3RB Sept. 5th
#2. On Sept 5th G3PU heard W3RGQ 239-349 - and then on Sept. 19th W3RGQ almost worked G3PU for a first season's QSO - when they heard each other briefly through static Crashes, but did not call it a QSO.
#3. First Transatlantic QSO of the 1954/1955 season when W2BQS and G6GM worked each other October 10th 0532GMT. Second QSO of the season - same date - when W1BB worked G6GM 0607gt
#4. G6GM and G6CJ worked ZL3RB again in Mid-October
#5. FIRST VO/W QS O!!! When W3RGQ hooked W4KVM/VO6.
#6. FIRST LU/W QSO!!! When W1BB worked LU3EL November 28th at 0707 GMT. EL/559 BB/569. This was followed by LU QSOs with W8GDQ,W9PNE,WOCVQ,WØNWX,W4ZQ and W3FBX.
#7. FIRST YV/W QSO!!! - Was between YV5DE and W9FIM November 20 1954/ -- Then followed QSOs with W8GDQ,W9PNE,W1BB in order, the next day Nov. 21st. We are greatful to "Mick" for QSOs.
#8. First HB9/KP4 QSO when "Ev" QSO'd HB9CM on 2/20/55 - this makes 17 Countries for "Ev"
#9. FIRST (So far as we know) USA/S.A. Phone QSO, when WØNWX worked YV5FH March 13th.
#10. DXPE DITION!!!! TI9MHB, provided a thrill on 160 and another First, when opening up from COCOS ISLANDS 2/20/51 0500-0800 GMT, the following were worked. A new Country, with WØNWX for a FIRST!!! - He also worked in order -- W4KFC-3EIS-1BB-8DUY-9NH-8ANO-9PNE-3KLA-2QHH-1ZL-TI2BX-9FIM-9CVQ-6KIP/6-YV5DE and 3RGQ.
#11. First YV/g - or YV/Europe QSO February 6th 1955 when YV5DE and G5JU QSO'd.
#12. FIRST!!! USA/Columbia QSO, March 20th when W1BB worked HK4DP at 0540 GMT, followed by W1ZL and W8ANO. Incidentally, this was HK4DPs First EVER QSO on 160 meters.
#13. FIRST!!! USA/HONDOURAS QSO March 27th. W1BB/HR1LW at 1015 GMT through terriffic QRN. Followed by W3RGQ at 0447. This was also "Loui's (Hr1LW) First CW Contact - and also First QSO EVER on 160.
#14. FIRST!!! USA/FAR EAST QSO, when W6KIP/6 worked VS6CQ April 3rd 1955 5.05-5.25 AM PST, at DAWN. VS6CQ using only 10 watts has been trying for USA QSOs 3 years - the only 160 meter signals heard in that time were VS6CZ, a ZL and then W6KIP/6

#15. FIRST "WAS"/PHONE made by W8GDQ - F.B.!!! This is Second 160 WAS. (See No. 14 1953)
#16. SECOND CW "WAS" - and THIRD all time WAS, Made by W2QHH

-W/VEs working DX were:-- W1BB,AHX,VDB,LYV,ZL,ORP,SFE/1,ERX,UXS, YAA,ME,BIL,WY. -W2EQS,GGL,VHH,WVP,K2EDL -W3EIS,RGQ,KLA,DGM,VAN,FBX W4VNE,KFC,ZQ,LXA,INV,LCV - W6KIP/6,VBY -W8GDQ,ANO,KIA,NSF/9,PEV, DUY,PCS,WCL - W9PNE,FIM,CVQ - W0NWX -VE2WK,WW .
-Other W/VEs HEARD only by DX were;-W1BMW,WM/2,CF,LC and VZE -W2MX,P PP,HX,SKE,K2BWR,BVN,WH,WZ,CF,DLO -W3LPN,KMS,RWH/4,HIH - W5CZ - W8 W8PCS,BMJ,SHP/1 - W9CZT,NH - VE2NI - VE3AAZ
-DX working W/VE were:- G2AJ,PL,HX,NX,NN -G3PU,[illegible],GGN,JOJ,JVI,BKF, ERN,JEA -G5JU,RI - G6GM,QB,LB -KP4KD,KP4CC - KV4AA-HB9CM-OK1HI,LM, AJB -OK3AL,VV,DG -OK2AG -ZL3RB,[illegible] -ZL1BY -ZI9J -GI3IOS - TI2BX - TI9MHB- LU3EL - YV5DE,FH-VO3X - W4KVM/VO6 - VP7NM,NG.-HK4DP -HR1LW XE 2OK-KH6IJ
-DX HEARD only by W/VE ---G3HRW, G6QB,LB -OK3VV -YU1GM -TI2WR -

1955 JUN-AUG -SUMMER 160 meter DX!!!!! -Some of the boys believed that they could dispel the myth that DX on 160 was not possible during the summer months. (ZL schedules had been successfully worked in the summer)
-G3JOJ,G3GGN and G3ERN started the ball rolling to test this out, by writing several Ws for skeds during June July August.
*The Ws responding were W1BB,K2BWR,3RGQ,9PNE,9NH.
-On July 3rd W1BB's signals were heard by G3JVI at 579 at Sunrise time G land Sunday Morning. G3JVIs signals were weakly heard.
-The following Tuesday morning K2BWR worked G3GGN 1830KCS for the FIRST!!! summer crossing on record.
-On July 12th K2BWR worked G3GGN again.
-On July 13th K2BWR and W3RGQ worked G3GGN
-On Sunday morning W1BB worked G3JVI at 0325GMT/Heard G3GGN weakly.
-[illegible] W1BB's signals were heard regularly EVERY Sunday morning for EIGHT weeks at Strengths from 349 to 589
-G signals were heard and worked only on 3 mornings. Faint signals on two other occasiona.
-The high static level kept the weak 10 watt Gs from coming thru.
-Sunrise time - G land , as in the winter, was found the ideal time for signals to peak and make QSOs

1955 SEP-DEC -This "SEASON" instead of "Tests" every other week end or so, it was
1956 JAN-APR decided in cooperation with ShortWaveMagazine and W1BB to have the "Tests" EVERY sunday morning - then, if the in-between Sunday happened to be an excellent one for DX it wouldnt be missed. This through December to March 1956.
-During SEP-November, VS6CQ,VS6CW,VS6CZ ran special tests with W8GDQ and W1BB to try and see if QSO could be made. While these schedules were kept regularly every week, no contact or signals were heard. VS6CQ "sparking" these tests has now gone back to G.

1955-1956 SEASON - SUMMARY of this seasons OUTSTANDING events, follows, and is noteworthy for the large number of FIRSTS!!!

#1 -"FIRST!!" - DL/W QSO when "Shely", W3RGQ worked DL1FF, (Who secured special permission to operate on 160 from Dec. thru Feb- December 8th at 0510 GMT!! -- Followed by W3FBV, W8GDQ, W1BB same morning -- DL1FF was on whole season, with other DLs.

#2 -"FIRST!!" - YN/W QSO, December 15th when W2QHH worked YN1AA, (1oo Watts) for FIRST Phone/CW QSO, on 1805 Kcs. YN was #59.

#3 -ZL1AH worked the long distanc e to G6CJ three times, on Oct. 13,14, &15 - [redacted] S igs weak.

#4 -"FIRST!!" - HE/W Qso on February 12th when [redacted] HB1CM/HE, Liechtenstein, (HB9CM on DxPEDITION) worked W1BB at 0505 GMT, after a previous unsuccessful attempt. HB1CM/HE's signals came thru repeatedly and unexpectedly at 0505-0600, rst 229-449. This was an unusual performanc e on HB9CM/HE's part, and he is to be congratulated. (See separate story, which has been written on this for the magazines, with photos.)

#5 -"FIRST!!" - W/VP2 160 meter QSO ever with TORTOLA, British Virgin Islands, LEEWARD Group, when Howey, W2QHH worked FP/8AK/VP2 (W2BBK) on 1801 at 4.40 AM EST March 5th 1956 to receive 449 just as he was packing up to conclude DxPEDITION.

#6 -"FIRST!!" - Barbados to USA ever QSO, April 6th 1956, when VP6RG, "Ron", a high school Boy, snagged W1BB on April 6th for a report of 429x, BB being 569x. This represented a lot of hard work, perseverance and good planning on VP6RG's part, Of special interest is the fact that the pole supporting one end of the long wire antenna was our in the sea, cuite a fe w feet from shore so that quite a part of the antenna was OVER salt sea water -- NICE !!!

#7 -"FIRST!!" - Recorded USA/CUBA Qso on 160. W1BB and CO2BL worked it May 31, 1956 at 0700 GMT through heavy QRN. BB,559 -BL,449. "Doc" very cleverly and quickly "Converted" an 40 meter antenna for use on 160 - and it worked out -- well, well enough!!!

#8 -W1BB's signals were hea rd, for FIRST SWL report - by E rnest S prock, in SURINAM, PJ2CK, South America, on July 1 1956. This is interesting news from a Country rarely heard from.

#9 -An unusual "FIRST" was made, when after a series of schedules, the team of OM/XYL, ZS2GE/ZS2KZ got across to W1BB on July 11th at 0505 GMT, also S eptember 8th 0400-0440 GMT for the very "FIRST" ZS/W Qso on 160. (A special SUMMER BULLETIN to [redacted] maga zines, covered this event in detail)

#10 -Another important, and RARE, "FIRST" !! was made by CP5EQ, Bolivia, S.A. putting that country on the 160 Dx map, by working W1BB, July 22nd at 0800 GMT to receive RST 119-349 on QSB, with bb at 449

#11 -"FIRST!!" - British Guiana/W Qso by "DAD", VP3AD 119/339 -W1BB the same, on Sept. 12th. The previous week when contact was [redacted] about to be established "Dad"s xyl announced the expected Jr. Opr. would arrive, and the schedule was QRT just in time, but fast!! - A fine little fellow did arrive!! Congratulations!!!

- These summer FIRSTS by W1BB, are the result of testing out his theory that when it is Summer up North, it is WINTER down South, and conditions would be best for the Southern Countries & it worked out that way - but meant a lot of "EAR DRUM BUSTING" by static, for W1BB to keep these schedules.

- In general it was thought that the EAST/WEST conditions were not as good this year as last - believed due to sun-spot cycle - However, as will be noted - a lot of DX WAS worked, and some have the feeling that 160 meters is the least affected band of all.

- PARTICIPATION was good --Totaling 16/1s,24/2s,16/3s,17/4s,6/5s, 3/6s,2/7s,23/8s,15/9s,8/øs - one each VE1,2,3. --- Dx as follows: Gs-26/1s,3/2s,5/5s,4/6s,1/8 --- 3/KZ,4/KP,2/TI,2/GM,2/HB,3/ZL, 3/VS,1/EI,6/VP,1/FL,3/GI,1/OA,9/DL,3/XE,2/YN,5/OK,1/GD,2/KV,1/SP, 1/HR,2/GC,1/HE,1/KH,1/CO/2/ZS,1/CP and one VP/3.

W5CGT [redacted]

- WORKING Dx were W/VEs,,, W1BB,AHX,EPE,BMW-W2EQS,QHH,K2BWR/W3RGQ, EIS,FBV,TBG,DGM,MSK-W9PNE-W8IL---HEARD only by Dx - K2JIO. -----

- WORKING W/VEs were - G3PU,GGN,KKP,IGW,JEQ,ERN,JVI,FPQ-G5RI,JU,CV,NS G6GM-G8JR-KZ5PB,DE,FA-KP1SD,KP,CC ,DH-VP7NG,4LZ,9BM,6RG,3AD-DL1FF,DA-XE1A,OK-YN1AA-GD3UB-KV4AA-HR3HH-KH6IJ-ZS2GE,KZ-CP5EC-CO2BL --- HEARD only by W/VE were G3HWI,IL0-TI2BX-EI9J

PY1-15652/Rolf:

MAR 11 1962

Here is all the latest on 160

Thanks for al your fine assistance this year

If you can help me line up a PY HAM that will QSO me

Or make private schedules - would much appreciate

Happy summer and 73 de Stew/W1BB

ROLF - I am enclosing some PUMP literature that may be of interest - apparently you are in same line of business that I am - eh??? CLENZ s/a BOMBA!!!

Also am sending you our 1962 calendar via slow mail

Stew

W1BB
STEWART S. PERRY
36 Pleasant Street
Winthrop, Mass.

Please be sure not to forget to line up some HAM who will make schedules with me on 160 - I might even send small 160 Tx if necessary if can find reliable fellow - most so far havent been reliable - did not keep schedules etc and only wan wanted me to send them somethings.

FEBRUARY 28 1962 W1BB -- 160 METER DX -- BULLETIN 1961/1962 - No. 4

de W1BB/General Remarks --- Well!!! The last regular TRANSATLANTIC DX TEST has co and gone, and the CQ-CW-WW Contest is over - so no doubt DX activity on 160 will begin to slack off - as spring approaches!! --- 1962/1961 Season hasnt been as go as some expected, or as bad as it could have been. This comparison, for example, total number of different DX stations worked by W1BB each year, might be of inter however. 54/55-19, 55/56-26, 56/57-20, 58/59-4, 59/60-5, 60/61-11, 61/62-27!!! I indicates a definite cycle, corresponding with Sun-Spot activity, and improving!! --- While 160 DX isnt completely done for this season - more DX will be worked - apparently we have had about the best of it for this season - or have we???????? --- Dont forget the new "Format" wherein underlined calls indicate QSOs, without underline, indicates "Heard" only. ---- The reports from participating stations, SWLers are just grand!! Keep 'em up and TKS!!! ----- Reference IQSY - it has not yet been determined if 160 meters data which might be collected, would add enough knowledge to Ionospheric conditions to make the venture worth-while, as the 50Mc Data was for IGY -- More on this later. --- There will probably be one more Bulle this season. ----- Occasionally an error, sometimes due to W1BB fault, and at oth times not - creeps into this bulletin --- Please excuse the "Human-Element" O.M.s However on the whole, information herein is believed to be 99 and 99/100 % Pure!!

W1BB/Summary LOG of SUNDAY MORNING 160 METER DX Activities:::

1. February 4th 1962, FIFTH Scheduled TRANSATLANTIC Dx TEST --GENER

At 0000z DHJ54/2 1800k was coming thru 549, a good omen for Dx, At 0500 449. Quit a lot of Snow Static - Wx Cloudy - Band opened up to East, Fair to good - South a W[illegible], Poor. ------- EAST -Fairly good Dx - Gs Coming thru at 0530 peaking 0730, t loudest signals lingered until 0820. Gs,5PU,6BQ,3ERN,CHN,5JU got across. Exciteme of the evening was new Country heard from when SVØWZ reported thru G3PU he was Hr W1BB 0505-0570 - unfortunately no QSO resulted. Reports as follows --G/SWL/Allen: VP8GQ,1BB,PPN,TX,2FYT,GGL,KHT,8EVL,K8EVG-VE1ZZ-ZC4BP-8HBR/8 - Thanks Geo!!! Then G/SWL/Smith: :VP5FH,1BB/1,HR3HH,2FYT,8NSF,1PPN,2EQS,VE2AYY-UB5WF--VFB Norm & Tnx!!

G3PU/ERN:: VE3BQL/SU/1803, SVØWZ, 1BB/1, PPN-2FYT, IU, KHT-K2PNF-K8EVG, HBR/8-VE1ZZ, VE2AYY, -HR3HH ----- G2PL/Peter:: 1BB/1-HR3HH ----- "DUD"/G8CJ, of "Shadow-Edge" 160 Dx fame, is back on 160:: VE1ZZ-1BB/1, PPN-2FYT, KHT. Says friend ZL1AH getting "Hot" on 160 for QSO w/HC1AGI & Others ----- G/SWL/IBALL:: 1BB/1 ----- G/SWL/Davids BB/1-VE1ZZ ----- VE2AYY/MIKE:: G5JU-VP5BP. Could have wkd VP5BP except he was to close to 1800k & BC Harmonic - suggests ALL Dxpeditions and DX stay away from ev multipliers of 10kc, 1800, 1810, 1820 etc - in future!! ------- WEST:: Conditions po A few 6s hrd weakly - no real DX. K7HDB/Dick active, but no Dx. ------- SOUTH:: HR3H was star of the evening QSOing quite a few Ws. Real excitement, when HR3HH report thru W1BB he was hearing G3PU - BB Notified PU - tried get them together - but n QSO resulted. This is first G ever hrd by Hal/HR3HH --- HC1AGI came on at 0445 CQi many times - many Ws called him-few QSOs-apparently skip conditions poor and sta bad --- A W was hrd clg VP2VL --- XE2OK also on --- BRAZILIAN/SWL/ROLF/ISWL/PY92 :: WØGBV, 559/239-K8BBI, 349 - VFB & Tnx!!! New Country hrd from on 160!!! VP8GC:: W6KIP, ØCDP, 5SOT all Hrd VP2ZA ------- NOW HEAR THIS de ZL1AH/John!!!-"Stew, I am gradually readjusting my ideas again as the sun-spot cycle takes a dive. I was t this week that you had a test this weekend so took a couple of looks at the band. At 0809 hrd W1BB/1 on 1807kc calling CQ-DX until 0810 RST 339 - would have been better except for summer static" VFB&Tnx John-sure glad you are back on 160!! We all be looking for you!! ------- HC1AGI/"Don"/W3EIS :: W8NSF, GIY, FW, WI-K8BBI -- seems like the 8's had it!!! ------- OTHER PARTICIPANTS - W6KIP, 8GDQ, HUT-9JDK-ØC VX0/9-VE1DR DX--G2IM-G3CHN, PEK, ORD, LI, OQT, NXJ, MZW, NXV, GGS, BJD, GXP, NMF, NEE-5JU- ZC4BP-OK1GT-GW3CBY, PZU-GW8PG-GI3NZZ. --- HC1AGI says - "Conditions Lousy" !!!

2. February 11th 1962, Non/Scheduled SUNDAY MORNING 160 Meter DX GENERAL --- Snow Static QRN/S7 at 0430 as snow storm passed thru Eastern USA, cu down Dx on what otherwise might have been a real good AM - all in all this was a rather poor Dx morning. ------- EAST - No Dx hrd at W1BB - Marker DHJ54/2 not hr G/SWL/Allen:: 1BB/349-2FYT/239-CN8PZ-ZC4BP-SVØWZ-EL4A-UB5WF -Tnx Geo, --- GSWL/Sm 1BB/1-2FYT-CN8PZ-Tnx Norm!! ---GSWL/Davison:: 1BB/1-CN8PZ QSOing G6BQ @ 0516/1805 TH --- HR3HH QSO'd W1BB/1 altho going was ruff w/S7 QRN!! --- HC1AGI/Don, rep "QRN so heacy all reception hopeless"!!! --- VP8G, apparently QSO'd W3FBV & W2FY No confirmation, --- W9PNE/Brice:: VP8G/1801/339-HR3HH ---HC1AGI did hear HR3HH VP3AD/"DAD" Daly was on and QSO'd VP2VL589 Tortolla Island, (Box #45 P.O.)-"Dad" and VL were both real excited for their FIRST EVER VP3-VP2 160 meter QSO!!! Con to both - "Dad" thinks 160 good for another month at least. He also hrd, W1BB/1- 2FYT-K8HBR all 569 --- PY/SWL/Rolf-NITEROI BRAZIL!!! Hrd VP2VL/449 & VP3AD/239 sure nice to be getting SWL reports from Brazil - not to get a 160 meter Tx goin there!!! Tnx Rolf!! ---WEST - W6KIP/349 QSO'd ZL3RB/139 @ 0800 - CERY FB!!!!!

3. FEBRUARY 18th 1962. - SIXTH ANNUAL TRANSATLANTIC DX TEST GENERAL - Quite disappointingly poor - of all Mornings - on the last, 6th Annual Transatlantic DX TEST - and also the ARRL Dx Contest to have the QRN "Gremlins" work spoiling things!!!!! SKIP, all directions, pretty good - however, S6 to 8 QRN covered most DX stations with a heavy blanket - nevertheless, a few lucky St did succeed in breaking thru for QSOs. ------- NORTH - VE1RAN/FP8BX DxPediti expected on - did not show. ------- EAST - The European Dx conducted a battle ro with QRN, pushing thru occasionally to QSO on "Peak" conditions. G3PU:VE1ZZ -- G6BQ:VE1ZZ - G3FPQ:1PPN -G6GM:1BB/1 - [redacted] - W3EIV:G6BQ - W1BB/1:G6GM, BQ, G3FPQ - VE1ZZ:G3OIT and others --- GSWL/Allen: W1BB/1, PPN-K1DSV-2 2EQS, KHT-3EIV-K8OR-VE1ZZ-VO1FB-HC1AGI-VE3BQL/SU-SVØWZ - Fine list Geo!!!/Tnx!! - GSWL/Smith; 1BB/1-2KHT-VP5BP & other unidentifiable signals Tnx/Norm!! --- K4KSY/Drayton hrd only DHJ54/2 weakly at 0330 - QRN S7/8 --- GM3IAA/Jim MacIntos Hrd W1BB/1 - says "It is strange why our Northern stations do not get across so on 160!!" Their strictly low QRP has something to do with it no doubt!!! Jim use to operate a TELEFUNKEN 5 KW Spark Tx at Assiut Egypt - some difference!!! GSWL ISON:1BB/1/569-1PPN/459-2FYT/449-VE1ZZ/559 - Tnx Henry!! ------- SOUTH - VE3C Noel Eaton, Vacationing Canadian Div. ARRL. Director broke thru as VP5BP, Grand Cayman Island Working W1BB/1, 3RFA, 4YHD, 8HGW, and probably others for NEW COUN QSOs. (On Saturday Night 17th QSO'd W1PPN). --- DON/HC1AGI/W3EIS, apparently was having QRN problems too. Many W/Ve frantically and frustratingly calling, 0730-0 w/no Ans. However he did QSO W1BB/1, 2IU, MSK-4KFC, YHD-6KIP-K6ZH-9PNE-KH6IJ - VFB WEST - Practically NO Western Dx heard at all except W6KIP and only for brief t

ADDITIONAL PARTICIPANTS - W/VE: 2BWR,SSC,GGL,QHH-3GQF,CJ-4OMW-K4KSY-8GDQ,TSD-K8[illegible]/8,IQC,RRH ---Dx: VP8GQ-GI6TK-GM3NHO-GM3IAA.

FEBRUARY 25th 1962 - CQ-160-WW-CW-CONTEST --- GENERAL - Hoped for A[illegible] Contest/Dx conditions did not materialize - principally due to high static levels. Mu[illegible] Dx was in there but could not be copied or worked thru QRN - although some, w[illegible] All in All, a good TEST was had however - everyone seemed to have a grand time, an[illegible] a lot of new stations were heard from!! CQ will carry the results. W/VE - W1TX/Roy FP8BX,WØVEH/VP9-HC1AGI-EI9J-HR3HH & others for score of 10,430 in 11 hrs -Not bad- had bad 60 cycle line noise!! ---W1BB/Stew: VO1FB-WØVEH/VP9-FP8BX-HR3HH-HC1AGI-G3[illegible] GD3UB.--- W2UKS/Bill - KH6IJ-EI9J-G6BQ-WØVEH/VP9-HR3HH-GD3UB-XE2OK-FP8BX - Tnx Bi[illegible] (Not QSO'd) ---VE2AYY/Mike:-"Had a ball"!! 152 QSOs including FP8BX-EI9J-HR3HH-WØVEH/VP9- now has 10 Countries on 160 - says Cdx poor to West. Hrd XE2OK,GD3UB,G3[illegible] Score 11,760 ----- Willie/W8GDQ - had some fun, but snow static terrific - missed few good ones. ------- EAST - A LOT of Europeans were on for the test, but between QRMing each other, and covering up DX, they had a lot of trouble with the QRN also Gswl/Allen:W1BB,FRR,MR,PPN,TX-2EQS,FYT,IU-K2BWR,DGT-3ECR,EIV-4KFC,YHD-8GDQ,HGW-VE[illegible] VE2AYY,3KEE-VO1FB-WØVEH/VP9-HR3HH-EL4A QSOing Gs & OKs but no Ws - Nice going Geor G3PU/ERN,says "Without doubt, best opening of season BUT ruined over here by lot Gs[illegible] in Contest calling "CQ-DX" on top of W/VEs - they were even on W1BB's Fy ev when you yourself were calling CQ or working another station - I cant understand some of these chaps!! On top of that, W stns did not seem to be tuning our Fys - I packed up after 50 Mins fruitless calling!!! Ern heard: W1BB-2FYT,HUG,IU-K2DGT-4KF 4YHD-8GDQ,HGW,NSF-K8HBR/8-WØVEH/VP9-VE1ZZ,2AYY-VO1FB-HR3HH-FP8BX!!! --- G3CHN/Roge W1BB,ME,PPN,FRR-2FYT,3GQF-4KFC,YHD-EL4A-EP2BK-OK1ZL,NR-UB5WF-VE1JX-HB9T-ZC4PB-VO1[illegible] WØVEH/VP9 589 at times!!! and many others hrd - however "T"was a bit of a carve-up at times" he says but very enjoyable, bringing in no less than 4 new ones!!! K8HBR HC1AGI-HR3HH-WØVEH/VP9-KH6IJ-XE2OK. Score 12,792 for 152 QSOs - 3,Dx and 39 Mult. Hrd no Eu in FEB - Al leaves for his job - sailing on the Great Lakes, shortly - T loaded ship antenna that he appropriates for 160 DX goes with him - best luck Al!! Gsw[illegible]MITH;W1BB/1,AWP-2FYT,UWD,IU,GGL-K2DEFT-4UK-8HGW-K8HBR/8-VE1ZZ,2AYY-9PNE-WØVEH Nor[illegible] also sent in FB list for 24th also - tnx & Congrats!! ---- CYPRUS HEARD FROM AGAIN ZC4PB/GERRY BATEMAN - With low power and poor antenna - single wire 15-20' H made 8 Eu. BOY oh BOY/W2UKS/Bill!!!!!!! Feb 21st truned in an incredible list Dx Hrd - UB5WF, [illegible]VP5AD-HC1AGI,HR3HH,G3CHN & Others ---W1BB sed to himself - there's something here worth knowing - SOOOOooooo wrote Bill, asking if by chance he had real QUIET location - and here's the answer of 160's UTOPIA!!! "I am Located on an island 2½ miles out in the Atlantic Ocean Fm mainland -plenty water all sides-plenty deep - noise level S2-S3 normal - in Loran S5 - we have NO industry in or nearby/not allo I'm using Heathkit "Q" Multiplier HD-11 w/SX28 & L.W. 200' long over large parking lot & 40' high. QTH center of city w/4&5 story hotels arnd - resort city/fairly qu in winter all directions except N - Ant runs E/W-end into shack - ant coupler-Viki II Tx/200w--sure can hear 'em/darned if can wk 'em!! Wl keep trying (And he DID!!) "Ed-Note" -W1BB also had superb reception when band was open one Sunday AM, and he was at Summer QTH 300 miles into Maine away from noises - hearing and working UB5, ZC, many others - Dx sounded like 20 meters - all of which goes to prove that the most important ingredient for 160 Dx is a quiet QTH in the clear.

PROPAGATION - We 160 Meter fellers are especially interested in this - and so for everyone's benefit we copy herewith all the latest dope - Courtesy "FLORIDA-SKIP"- "PROPAGATION CLEARED UP" -!!??- Propagation charts show an easing up of the rate a which Dx is easing off, This is proof of the slowing up of the slowdown. ---- It should be noted that the slowing up of the slowdown is not as good as an upturn of the downturn which is a good deal better than a speed-up of the slow-down. It does suggest that the propagation is about right for an adjustment of the readjustment. ---Turning to long skip, we find a definite decrease on the rate of the increase, which clearly shows a letting up of the letdown -----Of course, if the slowdown sh should speedup, the decrease in the rate of the increase of short-skip would turn into an increase in the rate of decrease of long skip. In other words, the decel/s would be accel/erated. ---The charts suggest a leveling off, followed by a gentle pi[illegible]up, rather than a faster pick-up, a slow down of the pickup, and finally a leveling off again of the pickup. --- At any rate THE PROPAGATION IS RIGHT FOR A PICK-UP this winter - that is, if you have a 10 Kw rig and a 25 Element beam!!!" forecaster Johnny Short Skip/W4SKIP. --PS - How's DX fellows??????? There you have it fellows - and this information should be VERY helpful in working 160 meter DX!!

73 de Stew/W1BB - and HAPPY HAMMING to you - Especially on 160!!!

APR 20 1962

PYswl/Rolf

Here is all the latest on 160 for you with compliments W1BB

Thanks for yourletters March 8 and 19th

The reports were very interesteing and studied carefully and entered in SUMMARY log here.

Do not know VP2VL QTH - suggest you write VP2VI W2YH T.W. WINTERNITZ, Yardley Road, Menham N.J. - He will know or DX Magazine, Don Chesser, Burlington Ky - they will surely know. Sorry I cant help more.

W1BB
STEWART S. PERRY
36 Pleasant Street
Winthrop, Mass.

I sincerely hope that you can get someone on 160 for schedules with me next fall - or send me likely suggestions to write to.

That SX71 is a real fine receiver - VFB - Know you will like it,

VERY VERY VERY FB on you and PY1NFC -- and with 40 watts if you can build it to cover 160 we can QSO - and make HISTORY - since there has never been a PY/W QSO on 160 meters - and if and when you are ready if you will make private schedules with me , you can win the W1BB CERTIFICATE for FIRST QSOs - I will give you all the needed information on Antennas - and help you in any way possible - just let me know what you need - as long as you will make the skeds with W1BB only until a FIRST QSO. And I assure you that I have a sustem that will work if you are faithful and persistent!!!

HAPPY HAMMING and 73 de Stew/W1BB

APRIL 16 1962 W1BB -- 160 METER DX -- BULLETIN 1961/1962 - No. 5

de W1BB/General Remarks --- This last 1961/1962 season BULLETIN has been delayed a bit for unavoidable reasons, but the enclosed FLASH supplement was sent to all the Ham Magazines on time. This will be the last Bulletin until the 1962/1963 season opens this fall - unless by chance there may be enugh activity to make a summer Bulletin necessary, ------- Yes - it HAS been a GOOD season, a VERY good season on 160!! with indications of possibly better next!! We say "Season" because during the winter months there is more activity and Dx worked in this latitude - the band is quieter, nights are longer, and weather males it more conducive to staying indoors at the rig. HOWEVER, we must not forget that while it is summer here, it is "Winter" elsewhere and there could be Dx minded Hams willing to work 160. In fact, W1BB wkd ZS in August, and CP in July. Most of us Northern Hemisphere people are so happy to enjoy our outdoor activities in the warm summer months, that our 160 Dx, generally speaking will be QRX until about Oct or Nov. Another advantage however, these periods of activity and rest give more ZEST to the Test when it resumes!!! SOOOOO generally speaking QSK till fall and b.c.n.u. then. ------- We cannot end this season, (or any other), without saying many many thanks and appreciation to the SWLs whose prompt and complete reports have added so much to our 160 meter tests. Outstanding, as usual, were reports from G/SWLs, Robert Iball-Norman Smith-George Allen,--Excellent reports from SWLs - Gs/John Hall, Henry Davison,Jim Sleight -VK Charles Thorpe- PY/Rolf Rasp -- not to mention a number of others who sent in spot individual reports. Next year, it is hoped to make available to any W/VE Hams who are interested and write for them, copies of these reports. "Cheers" to these bo - and fellows,keep up the good work!!! -------W1BB wishes to send thanks and 73 to all the 160 meter gang with appreciation for their QSOs, reports, cooperati and all matters which have led to greater enjoyment of DX hunting and testing on

W1BB/Summary LOG of SUNDAY MORNING 160 Meter DX activities!!!!

MARCH 4th 1962, Non/Scheduled SUNDAY MORNING 160 Meter Dx --- Genera speaking this was a dandy morning for Dx to Europe - Stations "in" for 2½ hours!!

OKINR, SWL/Allen,Smith.

MARCH 18th 1962 - Non/Scheduled SUNDAY MORNING 160 Meter Dx ---(GENER
W1BB had to go to Maine on a business trip/spent one night at old Homestead 300M
N. Boston in quiet QTH - took SX100 and Ranger/50w along. Too busy to spend muc
time on air but did QSO EI9J and Hrd G3PU,ERN-6BQ-OK1ZL - what impressed most, wa
the quietness of reception. At W1BB's home QTH Boston, the noise level reads arou
250 to 300 usually, while at this quiet place in Maine it was only 140 to 160 - o
about HALF and DX signals sounded just GRAND!!! Imagine what a difference this
makes in weak signal reception - to get away from the Electronic Clouds that
surround big cities and communities, just like the "Smog" in California - or Smok
and haze -same idea. Ph for these Island and remoht QTHs for 160 meter Dx!!!!

(EAST) - EI9J:W1BB/1ØMaine -G3ERN QSO'd UO5AA - Other QSOs were made. ---G3PU/Ern "Heard only WØ I have hrd this season WØNWX,1802kc 0610z rst229/459. Also hrd weak WØon 1999 believe WØCDP. Records!!";;;1PPN,TX,2EQS,2IU,UKS,UWD-3ECR,GQF,ØNWX - VF W2UKS/Bill::G3PU,XE2RGC,HC1AGI & QSO'd W5SOT!! ----- Gswl/Davison::1PPM/459, thru se[illegible]e QRN ----- Gswl/Allen::K2DGT/339-ØVEH/VP9/349-K2BDM/339-1PPN/449-3CQF/449-2IU/329-2UKS/339 -----Gswl/Smith::2DGTk,1PPN,TX-3MSK,ECR,GQF-2GGL-IU -----(SOUTH)- VP3AD/Dad hrd 1PPN/449 0432 and W3GQF/449 0450 other signals in there but QSB and static made copy difficult so closed up early "Guess 160 has had it for this seas Tnx Dad and b.c.n.u. Next for sure!!! -----(WEST)-----(NORTH)-----(Other PARTICIPA Gs3OIT-GI6TK,VO1FB -W/VEs: K1TKK,8HRG,8UDR,BHUk,ØNWX,TUT,LQTk ---SWL/Davison,Aller Smith. Activity and Participation dropping off as Spring/Summer approaches!!!

MARCH 24/25th 1962 Non/Scheduled SUNDAY MORNING 160 Meter DX Activitie (GENERAL) - Dx participants dropping off - QRN very high due to snow/rain static - skip generally quite good -W1BB QRT at 0555 -----(EAST)- W1BB got on early again schedule with EP2BK - hrd each other but no QSO. Also made contact March 22 and 2 0220z approx. Static very heavy. W3GQF and W2EQS tried for Bob/EP2BK also. W1BB h him 119/229 to 000. W3GQF hrd him 349 W2EQS could not copy. Skip not as good as n before when W1BB not solid QSO resulted. QRN Vy high also - at 0320 G6BQ came thru with CQ QSOing W1BB,his 449/BB559-his signals at 0400 still 449 QSBing in and out-QRN high. W2KUT also took part DXing QSO'd G6BQ/Jack getting 349/449 and giving 4 W2IU QSO'd G6BQ getting 33/49 Giving 469 -----Gswl/Norm Smith:: 1BB/1,AW-2KUT,IU, K2PNF-3FBV,GQF says "One or two weak unreadable Ws including a W5 at 0517"!! Norm going to slack off for the season - thanks for some wonderful reporting and assist Norm OM. -----W2UKS rpts no DX hrd "Appears that springtime is here" -----(SOUTH)- (WEST) -(NORTH) -Other PARTICIPANTS) -2PSQ,4WWU,8CJN,9ZQOk,ØCDP-G3ERN-SWL/Allen & Smit

---

COASTAL COMPARISON NET -(West) ----- K7HDB/Dick writes "There is a tremendous diff rence between signal levels at the Northern Vs Southern stations and I would like get some sort of NET of Coastal stations going to compare reports of signal level during these DX tests in an effort to determine the Southern ends of this zone of absorption or whatever it is that is creating the relatively poor Cdx at the more Northerly stations. Mainly interested in stations close to shore where Loran is li limiting factor in reception rather than power line noise" Those interested, write Dick - sounds like VFB idea!!!

INTERESTING !!! W1EAE/Bigelow - of EMN CW traffic NET says that on 80CW with lower Sunspot Numbers, LONG skip, and short Ground wave are setting in to such an exten on 80 that it is virtually impossible to conduct their normal NET. Will have 8 to stations on and NET Control can only hear 2 or 3 - they are eyeing 160 for possibl solution to their traffic NET Meetings 6.30-7.30 PM EST. Best of Luck Big and boys ZL STATIONS -W6KIP/Alex de ZL3RB/Mick, says more ZL activity. Look for ZLs 0720/0 z around 1975-2000Kc. ZL3BC/Joe,ZL3CO/Garth,ZL3QK/Jack & ZL3RE/Art - all active n Also ZL1AH. This one FOR THE RECORD!!!! "ZL" --FIRST !!! ZL/W QSO ever was betwee ZL1AH/John Eightman Dec 31st 1961 and W9CVQ - the Second between W1BB and ZL1AH A 16th 1952. ZL1AG has two other FIRSTS!! ZL/G and ZL/VS6. Following closely on thes ZL3RB/Mick became active and due to John's absence, and his own splendid efforts quiet QTH has been the mainstay ever since. We understand ZL1AH/John will reactiva PROPAGATION de Rod Newkirk W9BRD- "The North Atlantic propagation path to Europe highly succeptible to Magno-Ionospheric irregularities which do not significantly effect South American & Pacific Paths according to Termann" Guess this accounts fo those shut-outs while HCs & KH6s BOOM in!!! Thanks a lot Rod - Most interesting!!! SILENT KEY VP7NM/Chas - 160 Meter Hams especially, are saddened by the death of Ch "C.N." Albury. Many of us have his card confirming 160 QSO and are proud of it. He put the BAHAMAS on the 160 DX map. His presence and activity will be greatly misse IN "ZL" LAND EXCITEMENT WAXED HIGH Per ZL3TB/"Mick" and W6KIP/Alex who report that during the CQ/WW/160/cw/Contest, Mick/"There were so many 160 meters signals on bo ends of the band QRMing each other from 0700-1200GMT - I never thought I'd live t hear the 160 meter band dish out signals like it. Although I was the only one to contact W6KIP, - ZL3CO,BC,OX all heard an earful. Stations were too numerous to l Stronger signals were W6KIP,WA6CDR,HC1AGI,W6HXT,W6HRG,K6SHG,W6HG,WØGBV - all audi to 1200 when I fell asleep!! - 5 hours of Dx signals without a break or fade -Wow! ZL3CX Hrd 6KIP,K7HB,W6HG. On Sunday Band was poorer but I hrd WØNWX,2PIQ,W1BB/2 [illegible] would have gladdened your heart to hear that crowd - FUN!

160 DXPEDITION ????? --- K4KSY/Rev. Drayton writes "Wonder if any of the gnag woul
be interested in a DX-pedition to one of our Barruer Islands down off the Coast, W
lived there a couple of years and found conditions absolutely ideal!!! The place i
EDISTO Island - 1½ miles off the lower South Carolina Coast. ---Heard Low Fy Dx
th e that is considered practically impossible elsewhere - European BC stations
consistently - "Scads" of stuff on 160 and 80 -- Next winter possibly some of the
Yankee group going South might like to stop off for a weekend - have access to an
authentic ANTE-BELLUM Mansion just 20 feet from the salt water and poles already
set for antenna. Only power line nearby is the small one to the house. Nearest
neighbor is 2½ miles away. Perfect for anyone DXing in a 50 watt way!!!" ---Anyone
drooling besides W1BB??? Thanks a million Drayton and We'll see!!! (Incidentally
watch for some 160 meter dope in "73" Magazine in near future!!!!)

April 1, 1962

!!! --- 160 METER FLASH de W1BB --- !!!

THE EP2BK story!!!!

EP2BK works VE1ZZ -- W2IU -- W1BB -- WØVEH/VP9 !!!!!!!!!! FLASH!!! On 160!!!

Everyone was thrilled with the appearance of EP2BK/Bob at ABADAN, IRAN - the FIRST time that Country has ever been heard on 160 - QSOing quite a few Europeans

THEN!! during the CQ-160-WW-CW Contest, FEB24, a brief, not too good but definite contact was made with VE1ZZ/John, for the FIRST [redacted] EP/VE -- Congratulations to both Bob and John!!!! During the same morning EP2BK was also heard by W4KFC/Vic, (And others) peaking 588 and thought to be a "Phoney" because of his strength - however, EP2BK also heard W4KFC at 589 and SWL'd

Following this, on March 8th EP2BK arranged regular transmissions and schedules with W1BB (First at 0300, then 0220Z, to attempt a W contact and QSO - finally making definite, but "Touch and Go" contacts with W1BB on March 22,24 and 26th - but no "Solid" 100% QSOs.

FINALLY!!! on March 27th at 0150Z, the FIRST ever Solid 100% QSO, EP/W was made between W2IU/Sam (Ex W9NH) and EP2BK, and followed by W1BB as No.2 at 0220Z their regular schedule time. Bob's signals varied greatly from "nil" to 449 & 53 peaks. W's maximums were W2IU/339-W1BB/449.

IN ADDITION -- Bob/EP2BK also contacted WØVEH/VP9 at 0245 for a not too solid nevertheless definite QSO!!! WØVEH/VP9 peaked at 569 in IRAN!!!

CONGRATULATIONS !!!! Go to Bob/EP2BK for his splendid operating, patience, and perseverance!!!! And also to "Sam"/W2IU for this FIRST!!!

Dick

CONDOLANCES and sincere regrets go to W3GQF/who indirectly made the W2IU QSO possible, when he made this earlier than usual schedule with EP2BK, invited W2IU in on it, and then for some reason or another failed to make contact himself. Also to Charlie/W2EQS, who came in on the opening rather late, and also failed to make itto IRAN. This was all the more disappointing because of the fact that this was EP2BK's last morning on the air in IRAN before closing down and leaving the Country. Also to Shely/W3RGQ who was also heard to make a call this last AM.

BOB accomplished this VFB feat of 160 meter DX using an 813 at 100 watts - into a 15 meter Lazy H antenna 75 Feet high - with an AR88D receiver. He has also worked many Europeans, and we are anticipating a complete report from him soon giving the complete story on his 160 meter acfivities!!!

THE HC1AGI 160 Meter DXPLOIT!!!!!

Another FIRST!!! when HC1AGI and G6BQ QSO'd at 0610z March 11th for the FIRST ever HC/G QSO on 160 Meters. G6BQ was 449 in HC-land. CONGRATULATIONS to both Don/HC1AGI (W3EIS) and Jack/G6BQ VFB indeed!!!

160 sure has been "places" this season!!!!!

EL4A --Ken and Traut Bale expect to be on for a while longer this season. W1BB has sent them crystals for 1827½ and also 1803.0 Kcs Watch for them!!!!!

OCTOBER 15 1962 W1BB - 160 METER DX - Bulletin 1962/1963 No. 1

de W1BB/General Remarks ----- Hello Fellows!!!! - W1BB checking in with you on wha promises to be our BEST 160 meter Dx season in a long time!!! -"Chatter" collected since spring ended the 1961/1962 season will be found herein. The band was more op this summer than last, with VP8-ZL3-VK3-EI9-G6-W6-XE-FP-GW making real news!! FIRS TRANSATLANTIC QSO (W3RGC/G6BQ) was a month earlier than usual this year. Much new with some suprises is expected!! Many stations W/VE-Dx have used the summer to g advantage for new antenna and ground system construction. As the Sunspot Number go lower and lower, 160 Meter conditions get better and better, so we are apparently for an extremely interesting and exciting season!!! SOOOOOOOOOOOOOO join in on t FUN - get those antennas up high and strong for the winter storms - your SWR 1/1 - check your receivers and transmitters for best performance - mark your calendars & store up a bit of extra rest for those "wee small hours" when 160 is at it's best. HAPPY HAMMING - best of luck and best of Dx HUNTING on 160!!! 73 de Stew/W1BB.

ANNUAL TRANSATLANTIC AND WORLD-WIDE TOP BAND 160 METER DX TESTS ----- Will be held as usual, and this year on Sunday Mornings, December 2 & 16th --January 6th & 20th February 3rd and 17th, from 0500-0730 GMT. During these tests, special efforts will be made to contact European, Asian, African and other 160 meter DXers throughout Transatlantic World, for general DXing, and particularly to also make observations and to contribute to the study of propogation conditions on these frequencies. The ANNUAL 1.8 Mc Activity since 1932 has been planned as TESTS and not Contests - as an unusual operating activity, without competition. W/VE stations will call "CQ DX TEST" the first 5 minutes of each hour, and each alternate 5 minute thereafter, LISTENING the second 5 minute period, and each alternate 5 minute period after that unless working or hearing DX. Dx will of course, use the opposite periods for transmitting and receiving. When DX is coming thru, the idea is to work it regardless of time periods.

Most W/VEs East of the Mississippie River will operate 1800-1825kc segment, while those WEST of the River will use 1976-2000kc, clustering near 2000kc. Most DX wil usually be found bentween 1795-1850kc, while some will be found near 2000kc (ZL). DX stations should cover 1975-2000kc carefully for unusual and choice W/VE Contac W/ stations should send their reports for these TESTS to W1BB, for tabulation, Recording in the booklet " THE 160 METER DX HISTORY" in the making, and especiall for transmittal through BULLETINS to ARRL-CQ-SWM-Western Radio-DX-RADIO ZS and ot G,GM,GI,GW etc should report to L.H. Thomas, DX Editor Short Wave Magazine, 186 Winchelsea Rd., Hastings Sussex, England. Other DX may send their reports to eith of the above. Please DO report accomplishments, Happenings, Rumors and Data!!! W1 will award Certificates to all DX stations working W1BB, if requested, and to DX SWLs who send 7 verified reports of W1BB's signals - also IF requested. Certifica for past work on this band are available - contact W1BB for further details. ---- Working DX on 160 is indeed challenging, and extremely interesting. Conditions su as static, BC Harmonics, QRN, QRM, LORAN, NOISE, QSB, all require extreme patienc with perseverance, a top-notch station and A-1 operating ability. There are many FIRSTS yet to be made and many unusual conditions to cope with. One gets anew the thrill of early Amateur Pioneer days, when HAMS were relegated to "TWO HUNDRED METERS DOWN", and Paul Godley made the FURST Transatlantic Crossing via Amateur Radio, thereby inaugurating the first of what has now become Yearly TESTS, enjoye by many 160 meter enthusiasts. In addition you will make many friends, among the finest and most sincerely devoted HAMS you would ever care to meet!!! OK?? b.c.n.

160 mete

CONTESTS ----- W1BB and many other W/VE 160 meter HAMS will give special/attentio to DX stations during the ARRL and CQ DX Contests and also the special CQ 160 Met CW Contest, (Which will come earlier this year - watch CQ). W1BB invites any special schedule arrangements from any of the DX gang desiring to make a real try for an extra band multiplier. AIR/MAIL your intentions to W1BB in this respect, i advance if possible, otherwise W1BB will generally cover all 160 DX Frequenc

W1BB 160 METER DX BULLETIN -----Will be issued during the 160 Meter DX Season, as material is obtained, to the above/mentioned HAM magazines, via air-mail, so that they can publish whatever may be of general interest & the most important informa on TOP BAND activities. There is no mailing list to individuals, although W1BB wi oblige and send copies to any W/VE stations supplying s.a.s.e. - and to any DX station who reports regularly to W1BB on 160 Meter DX Activities - also SWLs. W1B also will send FLASH news items to Magazines on any special events and happenings

FIRST 1962/1963 TRANSATLANTIC QSOs ----- Congratulations to W3GQF/Dick/359 who on Sep. 16th QSOd Jack/G6QB/449 at 0524z one of the earliest openings on record!!! Second crossing was made by W1BB/1/489/0405 from farm in Maine Sept. 29th Third was K3MBF same date. Of interest FIRST SIGNALS were heard "Across th Pond" by G/SWL/Norman Smith Sep 1 0423 W2EQS and W3GQF/459 - Sep. 2 W3FBV/weak CQ answered by G3PU and G3OLI - Sep7 0353 W2IU/459 - Sep8 W3GQF-Sep9 G3PU Calls W3FB Looks like an excellent season shaping up with openings so early!!!!

SUMMER DX - VP8GQ!!! ----- 160 Meter DXers were thrilled with the lowering SunSpo numbers and the pick-up in 160 Dx to hear VP8GQ in the South Orkney Islands comin thru frequently this summer QSOing a number of W/VEs also EI9J "Paddy" to whom go special congratulations. Credit for VP8GQ's appearance and following info goes to Dick/W3GQF who when working him on 80 June 30 asked him QSY to 160 and try - the was "right" and results immediate!!! W3GQF/589 VP8GQ/579 0300z/1827k for a solid 20 minute QSO - contacts followed with W3RFA & W2FYT. W3HKE almost made it but no quite as signals faded. July 1 W3GQF again and W2KQT -July 2 0300z W2IU,KQT,TKG, VE3GP,DU-July 3 EI9J/0202,W1BB,W2KQT,VE3QU and W3GQF for his third QSO with VP8GQ W3GQF valiantly but unsuccessfully tried to hook VP8GQ and W6KIP/Alex but he was out of town. Finally July 9th VE1ZZ/VP8GQ QSO. Signal reports averaged S78 for W/ and 548 VP -- these results still further confirm W1BB's often expressed views th the band is best open to the South summers, after having had QSOs with CP5EQ and other South Americans during prevoius summers. These latest W/VE/EI QSOs confirm!

Further confirmation comes from PY/SWL/Rolf Rasp in R.J. Brazil S.A. who reported JUN 16 0620 hearing W6KIP/Alex/579 QSO W6ZH/Herb/559-589 1999k. "Their signals we so clear and loud that I did not miss a word. Never thought 160 signals could be loud"!!! To which could be added that W3GQF/Dick QSO ZL3RB/Mick MAY6 0955 - VFB!!

VK 160-Dx!!!!! ----- The VKs with their new liberties on 160 are pushing for 160 Q with W/Ve & Dx. On Sun AM SEP2 W2FYT was suprised to hear a weak stn clg on his f A sort of contact was established before QSB out. The station turned out to be a call uncertain - believed to be VK3AMZ on 1803k at 0614 - since VK3AGS has been i identified and it is believed he was the station. News spread and the 160 boys we "HOT" after this exotic DX!! On Sep9 VE3DU W1EFN-Maybe others- hrd ZL3RB 1015z on CW & A3 but no QSO. Then the band to VK Cracked open!!! On SEP20 K3MBP W1EFN W2FY broke the ice for FIRSTS QSOing VK3HG. On FRI AM SEP21 W1BB/1 on farm in Maine an W3GQF QSOd VKeAKR whose signals peaked 579 staying in from 1000-1100z Steadily!!! W3SO/459 QSOd VKeAKR/359 SEP28 as did Chas/W2EQS for his 34th Country!!More to co

ENVIABLE RECORD/W3GQF!!! ----- Dick kept the 160 band warm QSOing this summer & F VP8GQ-WØVEH/VP9-FP8CA-ZL3RB-XE1OK-G6BW-VK3AKR-G3OOT-GW8PG-G3ERN-G3PU and has had least one W6QSO every month!!! Says maybe odx will open up DX year/round. Suggest helpful "Markers" - DHF/1831k- and when WWV is off::: CMA/2500k/Prague/Czech/1000 1000cps/A2-or FFH/Paris/300w-HBN/Swiss/300w -JJY/Tokyo/2000w-LOL/Buenos Airi 2000w-MSF/Rugby/500w-ZLFS/NZ/30w - Thanks Dick - nice work!!!!

THANKS TO CHARLIE/W2EQS ----- who is banging away at his key on 20 and typewriter "Airmail", stirring up 160 DXers in foreign lands for this years hunting!! Report PY2BZD-HK1WW-HK4DP,1HV-GC2CNS-OA5G-VP3AD-YN1AA-YU1GM,AD-ZB1BJ-OE3SE-ZE8JJ-HI8XAG all may be on. Some have worked 160 before but others are new ones. Ken/EL4A is hoping to be on 160/but not for sure/expecting new Jr/op etc. - Charlie/EQS sport a new 160 doublet which netted him the VK and intends to do his share of Dx Hunti

EARLIER THIS YEAR/VP8GQ/Peter Hobbs (G3LET) ----- opened up one of the rarest 160 spots on the map appearing JAN28 QSOing in order HC1AGI/569/0600-WØIFH/469/0627- W1BB/1/469/0640-WØNWX/579/0653 - FEB17 WØNCS/569/0625-W3FBV/569/0640. Peter is to thanked a million times for these FIRST SOUTH ORKNEYS 160 QSOs. G3PAG, His very meticulous QSL Mgr is to be thanked too for FB QSLing - Peter's address is FALKLA ISLANDS DEPENDENCIES SURVEYS Base "H" Signed Island, South Orkneys - but QSL via

SAINT PIERRE/FP8BX/W1RAN/"Ned"-----Who made 160 so interesting for many of us dur contests says "Grand time on TOP-BAND . Golly could I hear Europeans!! They were S789 and standing out over Ws as early as 0130Z!! VFB NED - Nw we All like try FP

EI9J and 160 in EI Land -----"Paddy" says until recently licenses for 160 were no generally granted, but now can be had for the asking. At request of W4KFC, last season Paddy whipped up quick final/ got on with well known FB results. EI9J wks CW mostly but found 160 refreshing after the commercial and HAM QRM on 80. During CQ Contest "Paddy" was disturbed by many Gs calling him when he wanted Ws & other rarer DX & Multipliers!! "EP2BK answered 2 of my CQs/was so loud/ took him f phony & didnt ans.-ALAS!! Later wkd him however!! Am sure that his signals were t most remarkable of the test!! Now that I have the gear and permit an looking forw to being up on 160 the 1962/1963 season!!!" We'll all be happy to hear you Paddy!

COINCIDENCE ZCs QSOs w/Ws !!! ----- Stephen Gibbs/GM3MBS/ZC4AK now 5A3CJ/Libya refers to p4 W1BB DX BULL No.5 1961/1962 pointing out that ZC4XP was Sid Parks,,, making this comment "Stew-I bet if you examine your log you will find that ZC4AK/ W8GDQ QSO MAR3'62 and ZC4XK/W1BB QSO MAR3 '53, exactly 8 years apart to the day, would be at about the same time GMT" ----- And SURE ENOUGH!!! ZC4XK wkd BB 0400z ZC4AK wkd Willie/W8GDQ 0417z - Pretty close eh???? You boys who want to QSO ZC n know the right magic date and TIME!!! Thanks for interesting observation Steve!!

W1BB----- Celebrating his 50th year of HAM Radio - made his 60th 160 Country QSO working VP8GQ - The next 40 to DXCC/160 will be the hardest - although we MAY mak it before "Silent-Key" time!!! Great game this 160 - enjoyed every minute of it

PYswl/Rolf

Here is all the latest on 160 O.M.!!!

Nothing on 160 this morning - see log - sorry

Starting New Year will make Wed and Fri at 0600

And as soon as OK with you

Make it Tue and Thursday at 0600 instead Wed/Fri - OK????

CONGRATULATIONS yourfine work there on 160

K9GZK also reported to me your hearing him - VFB!!!

Am waiting to hear from you re crystals - tolerances

SOOOOOoooooo again Rolf - HAPPY NEW YEAR

And here's to a contact REAL SOON NOW!!!!

DECEMBER 31 1962 **W1BB - 160 METER DX - Bulletin** **1962/1963 No. 2**

de W1BB/General Remarks ----- Follows, if things have been a bit late, or some of your reports and letters not acknowledged or answered as promptly as usual - Pleas Excuse - Alice/W1DQF, and myself were called home from 12 days vacation in KP4/KV4 lands, when very recently, Dec7th, we had the second death in our immediate family with the passing of our Son's wife, 30, leaving two little children, which we are now helping to care for - all of this upset us and our normal activities in many ways - however, we expect to be back "on the beam" again real soon - thanks for yo patience and understanding!!! DX this fall was good up to October 1st, with the earliest Transatlantic crossing on record. Then, rather suddenly from Oct1 to Nov25 Dx was Nil - since there has been Dx but spotty - no real good openings only a couple "fair" ones - Why conditions which started out so promising, have be so much poorer than expected, no one knows - some feel the Pacific Nuclear and USS tests might have been responsible - others that it is just the "Way the ball bounc , normal unpredictableness of 1.8 - which incidentally makes it interesting and al intriguing. The First scheduled TRANSATLANTIC DX TEST Dec2 washed out - the 2nd De 16th only fair although participants were not lacking on either side!!! - At any r the frequency of openings lately has improved a wee bit, and lets hope for the bes Dont forget the CQ/WW Contest on 160 Jan26/27 and best of luck!!! This should a grand event!!! SOOOOOOoooooo Best wishes to all for a HAPPY NEW YEAR, with l of HAPPY HAMMING - especially if it is on 160!!!!!

W1BB/Summary LOG of 160 Meter DX Activities!!!!

Oct21 --- Poor morning to Europe-fair to South - medium w/ve activity - Wx- VFB/warm/clear/calm -felt like gang just "warming-up" for the real Dx ahead!! Alth VP8GQ put on a fine performance!!! W/Ve p/W1BB,ME,2EOS,UWD,IU,3GQF,CBM,FBV,40M SGRQ,K8IQQ,MRB,9FNE,ØCDP,RFI,GDH,VE2UQ,3QU ---p/ etc stands for Participants!!!)

EAST:::: All-not a sigNAL of anykind and a pox Gus/GW8PG decided it was time to degenerated into "Rag-Chewing". p/G3IGW,OUK/A,OIT,MYI,REP,RAA/A,OZF,OQT,AGG-6BQ-MF,PG/A. Tnx Gus! SOUTH:::: VP8GQ 1800.5 our "Southern (Dx) Star" 0500-0630z weak QSB zero/459, av 339 QSO'd Ws,1ME,TX-2EQS,UWD-ØCDP-9PNE(?),1BB-K8MBR in order was hrd by Py/Sw1/Rolf Rasp!! Says "Hrd VP8GQ QSOing one W after another, BUT the whole time through I did not hear one TRACE of the Ws - only VP8GQ- dont you think this propogation was rather strange??" Yes Sure Do Rolf!!! For Roy/1TX his QSO with VP8GQ was his 10th Country!! (Oct.7 VK3AKR his 9th!) (p/ means "Participant

OCT28:::: Extremely poor Dx Cdx. WWV sending "W3" Wx,clear, cold, windy,PB.-W/VE:::: Ws,1BB,ME,TX-2UWD,KHT-3GQF-8HCR-9PNE,CUY-VE3DU participated, calling and listening for Dx but nary a peep and by 0600 most had QRT!!

NOV4:::: Again Cdx Vy poor-no Dx at all except W3GQF reported hrg DL1FF 0530 559max - HI8XAG & 5B4PB expected but no show - There seems to be some barrier, that signals of any strength do not penetrate, since Oct1 - Nuclear Tests?? W/Ve:::: p/Ws,1BB,BHQ,ME,WY-K1LTM-2EQS,IU,KHT,UWD-Wa2IUQ-3GQF-4CXW-Wa6CDR-8CIM-K8RYU-9UKV,PNWX,VXO-VE3FF EAST:::: No QSOs but G8PG/a hrd W1BB 229-339 o530z. DJ1BZ, GM3PRA

NOV11:::: Condx still generally Vy poor especially to East. W/Ve Participan dropping a bit also. W/Ve:::: p/Ws,1BB,UZ,TX-K1LMO-2FYT,KHW,JGQ-3GQF,FBV-K7DEK/BIQS,GDQ-K8WGW,BBI,IQQ,HSW-9PNE-K9JDK-ØIFH,GBV-VE3DU,QU. EAST:::: Cdx vy poor w/ no European markers or Dx coming thru!! However GW8PG reported hrg W2FYT briefly a 0438z clg CQ DX -- Gsw1/QUEST hrd a N. African but no other Dx. p/G3IGW,HR3HH,GM3PA EI9J,DL1FF,VP8GQ SOUTH:::: VP8GQ came thru weakly 0440z QSOing W2FYT. Our old friend HR3HH/"Hal" put on best show of evening 0600-0700z QSOing Ws1BB-8HGW-K8IQQ-ØIFH,VXO and others. WEST:::: K7DEK/7 provided some welcome Western DX and new states for a few QSOing VE3QU,DU-W8GDQ,HGW-K8IQQ and others - Was hrd by W1BB S2/3 Wa6CDR active QSOing WØGBV/others!!

NOV18:::: Cdx still generally poor-QRN rather high-No Dx whole evening exce VP7NY "Local-Dx" W/VE:::: p/Ws 1BB,2DHQ-3FBV-K3MBF-4IQU-8TSD-k8RYU-9PNE-VE2UQ,3M 2FYT,UWD,GGL,EQS-1BHQ. EAST:::: Gw8PG/Gus says morning a "Dead-Loss"-Blizzard cu power lines-became good cook over fireplace but no Dx!!! SOUTH:::: VP7NY/Lowell put on a fine show wkg Ws 1BHQ-2FYT,UWD,GGL,EQS-3PAP,GQF,PMV-8QWI-K8RYU,MRB-9PNE-VE3QU,AGK. Cdx so poor his sigs varied 000-569 quick QSB 2 hours much of time unreadable in QRN/QSB WEST:::: A fine clean out FIRST!!!!! when the OM/XYL team WB6AFH/WB6AFI (Ex W9VER/K5VLG) QSO'd VR30 Christmas Island on 1991k Nov18. VR30/44 6s/559.-----(Under call K5VLH QSO'd ZL3RB&KH6IJ Fm N. Mexico early 1962 and as W8FQ QSO'd G-VE-VP7-KP4-KV4-YN4-YV5 in past years) CONGRATULATIONS!!!!!! Jean and Dean! Understand VR30 will be on regularly when he gets new Tx now being built by W6VHY. Note!! W6HRG also worked VR30-Details not rec'd hr.

Nov25:::: AT LAST the band showed some signs of opening up and quite a numb of Dx QSOs resulted - our best morning in some time!! Willie/W8GDQ says dont forge to cover 1876k fr ZLs and also claims "MOONBOUNCE" QSO w/W1BU on 160!!! Hi!!! W/Ve:::: Sam/W1BU says QSO w/W8GDQ was 1st 160 QSO since coming to Mass fm Ohio 1 °40s - using pp814s/rig fm 20yrs garage storage-has tilted ant 200° high NE end-ni to have Sam on again!!! Maybe sometime Sam and Willie will explain this "Moonboun stuff on 160!!!!! p/Ws1BB,ME-2FYT,EQS,UKS,IU,GGL-3GQF-6KIP-Wa6CDR-8FW,HGW,GDQ-ØVX(VE7AN. EAST:::: G3IGW hrd W2FYT,GGL,IU and briefly contacted W1BB. UO5AA on 160 G8PG/Gus Qsb/Qrm heavy sigs weak but wkd W1BB 1st time & Hrd W2IU -G3LHQ hrd W2FYT G/Sw1/QUEST h/1BB449,2GGL349,FYT339 - nw hrd 19 Countries 160-logged 15 Dls this yr ---Gsw1/Smith h/1BB,ME,2IU,FYT,GGL after some blank weeks!! ---- G3OQT/D "The Dx Blanket which covered everything OCT & NOV seems to hv lifted nw-hrd W2GG 449,2FYT/449 & 1BB/549-Qrm Hr Fantastic!!! Making himself an 80° vertical Beer Ca ant wl top load it"also wonders why there are no W Sw1s- says Gs wld like rpts!!! Gsw1/Iball h/1BB,ME "Have never known such activity/QRM over here!! p/G3OQT,PU,IG PXZ,LIQ/aMYI,REP,JFY,OZF,NEO-6BQ-DL1FF,DJ1JZ,UB5CI,UB5WF,UO5AA,OH2NB,OK1KAU,KSO,AI ZC YD,KVE,2KJU,5B4PB,OY7ML SOUTH:::: W8GDQ/Willie wkd YV5AGD as did W1BB,W3GQF and others. VP2VL/WØNWX Bob was on QSOing 1BB,3GQF,8GDQ and many others - believe Bob intends retire VP2land someday and work DX to his hearts content alongside next door neighbor KV4AA/Dick who sure sets a good example - Dick an ex/160 Dxer is washed our on 160 by "Regs" while on VP2 Island few miles away VP2 can wk 160! W2UKS/Bill rpts wkg VP2GX/1810k 2334z-VFB!! WEST:::: W6KIP/Alex had 17 eastern "Without trying" hrd HC1DC-VP2VL/S3 -Couldnt find YV5AGD" - Sri Alex!! Next time.

Dec2:::: W1BB was in KP4 land/unable observe conditions but understand were generally poor!! W2UKS/Bill rptd band vy NOISY & "Dx sure is scarce to date"!!! has HQ145x new/March '62 for sale $175.00!!! VFB Cdx. EAST:::: GW8PG/(G8PG)Gus 1MB29-has driven 300 miles this winter to try wk 160 fm GW8PG --- Gsw1/QUEST says "N Dx Hrd" p/G5IGW,OLI,OQT,MYI,GRL,OLB,LIQ/a,PQA-6BQ-GW8PG-GM3ITN,PBA

Dec9:::: W1BB returning fm KP4-KV4 lands unable ck conditions - however fm rpts apparently not too bad!!! NOTE- the night before DEC8 W3GQF worked an O.T. an famous early 160 meter DXer - and noted DXer all bands G2PL Peter - and hrd G6BQ, 30QT,IGW-G6GM and DL1FF!!! W/Ve:::: W9PNE hrd DL1FF259 15 mins-G3PU339 Briefly - EAST:::: Gsw1/Allen W1ME,TX-2EQS,UWD,FYT,GGL,KHT,IU-VFB!! W1TX wkd G6BQ-G3PU ---E G8PG/a/Gus hrd 2FYT449-2IU229,EQS559,GGL339,UWD339 sigs weak/QSB Predawn Peak0612- postdawn peak0747 ---"Harry"/G6GM 78 Yrs yound putting out VFB Sig as usual!!! --- Gsw1/QUEST; Ws1ME,TX-2EQS,FYT,GGL,KHT,UWD says PAØPN,SS-OH2YV,NB ou!! ---- Gsw1/S Smith Ws1ME-2IU,FYT,GGL says Ws 3 deep between 1806-8 & Fish- fones real bad!! ---Gsw1/Iball-1TX359-2FYT569-GGL559-EQS449-IU459-3GQF339 using HC1155 Rx. SOUTH:::: VP8GQ trying QSO Gs DLs/N.D. --- VP3AD/Dad hrd W2FYT/ 569/0410-UWD449/0425-UKS459.0436-8IRE559/0432 - Called all of them on 1801/N.D. Dx/Participants G2DCG-30QT,PQA,PU,LIQ/a,PHO,OIT,CHN,REP,IMV,PIQ,ERN,GRL,NHE,PC KFT,IGW,NJR-5JU-6GM,BQ,QB-8PG/a,JR-DL1FF,FL-PAØPN,SS-OH2NB-GW3PPF,VP3AD.

Dec16:::: This Second Annual TRANSATLANTIC Dx TEST was much better - but still spotty and with lots of snow static & Loran - Nevertheless quite a few QSOs ensued between 0500-0800 with a fwir number of participants and several outstandi QSOs. As a "Warm-up" W1TX on the 14th QSO'd G2PL,3ERN,6BQ,6TK and 15th G6BQ,3ERN, PQA W/VE:::: Roy/1TX wkdG3PU -has new VFB antanna on only 50' Lot - results are what count!! W9PNE/Brice hrd DL1FF 30 min peak 239 also G3PU 0700z 339 rapid QSB. NOTE!!! Dec 15 Brice wkd VP8GQ solid got 570 gave 459 for his 35th Country!!!!! (Coincidence - VP8GQ was also W2EQS/Chas's Nr 35 Country!!) --- CONGRATULATIONS!! to WØVXO/Herb for the 2nd Transatlantic QSO EVER from Wø when he QSO'd G3PU559 re 3 VFB!!! WØNWX has only other Wø-European 160 QSO on record. He also QSO'd G3PU 11 yrs ago!!- Wish could print all of WØVXO's letter/Space limited-however he hrd DL1FF569/0730z w/Horiz Doublet & NOT AT ALL w/Vert. Could have kicked myself for not putting up doublet sooner he sez. NOTE WØVXO & WØNWX both also hrd Novll by PY/Swl Rolf Rasp 0545z - FB!! p/1BU-2FBA,IU,FYT,GGL,TMG-K2BWR-3GQF-4VYB,KTA-Wa4FJ 8IRE,HRV,OOR,QWI,GHY-K8UNP-9PNE,CUY,HLY-K9GZK-ØVXO,IFH-VE1ZZ,2IL,UQ-3DU,AGX-1BB EAST:::: G3PU's signal was terriffic and outstanding, staying in from 0500-0800, peaking 579-averaging 559 dipping 229 with slow QSB and wkg quite few Ws includin WØVXO & W9PNE!!!!(CONGRATULATIONS to Ern also on his first QSO with VP8GQ this AM DL1FF was next-QSOing quite a few but not up to usual stbength. G6BQ,30QT,IGW,8JR also made QSOs. (The previous evening Dec15 G2PL569 wkd W3GQF and band was quite open half hr with fair signals) ---- Gsw1/QUEST hrd 1BB,ME w/30' piece wire at g level!! and nite before 1TX,ME-2FYT,KQT VFB!! ----Gsw1/Allen hrd 1BB,ME,TX,VP8GQ using series tuned "LOOPSTICK" 2/short 12" screened lead!!! Sone goings-eh??? say it helps out QRM/N -sumpin to try!!! ---- Gsw1/Iball hrd 1BB only Cdx bad Winds above storm force SOUTH:::: VP8GQ QSO'd G3PU/0507z CONGRATULATIONS Peter - W1 listened to both sides of QSO!!! Night before - 15th G6BQ also QSO'd VP8GQ for po FIRST - (On 15th QSO'd W9PNE and Brice's son W9CDP at 0400z) VP8GQ that is. ----- VP3AD/"Dad"hrd 2FYT569-K2BWR559-W9HLY459-W2FYT589-W1BB559-W1TX559-W8HRV459-W2GGL4 VE3AGX449 between 0300-0510z -----KP4AXU on 3.5Mc works 1.8 Mc Stns Cross-band -- PYswl/Rolf Rasp sends impressive list hrd 0500-0600z, VP8GQ589-W1BB589-2GGL589- 8IRE449-2FYT459-1ME459-2IU579-VE3AGX449-1TX459-K9GZK349-8WI239 Condx outstanding QRM/high-QSB/strong. Also 14th Dec hrd WØNWX569/0700,W6KIP589/0713 and 15th VP8G 338/579 QSO G6BQ-0515z WEST:::: No stations further West than W9/WØhrd and none reporting to W1BB NORTH:::: VO1BD heard clg DL1FF/0435z-believe no QSO. Dx-G3ORH,OQT,ERN,NVO,GGS,ROZ/a,RKA,RIQ,OFA,PWK,LIQ/a,OIN,KDV,MCY,PSB,PQA-6BQ,TK 8JR-ZL2BE-OH3NY-OK1MGmAEZmKSH,#CEA-GM3AEYpAWF-SVØWZ-GW3CBY NOTE !!!! During this week the band openedcup Dec 2nd and G3PQA put in a terriffic signal QSOing W3GQ W1BB,ME-2IU-UWD-8HRV. G6BQ QSO'd W1BB,TX - and W1BB QSO'd VP8GQ ((9PNE also QSO'd PQA)

Dec23:::: WWV sending "W-3", which is extremely poor Cdx - and so they were- not a trace of DX and all participants QRT early. Strange when morning before G3PQA put on such good show. Understand terriffic storm in G/land

NUCLEAR TESTING ON 160!!! Vs 160 Dx !!!

An extremely interesting letter from George Jacobs/W3ASK comments on our FLASH bulletin Nov.11 ---"I hve mentioned the possibility of A & H bomb explosions causi absorption in the ionosphere, with some friends of mine in this field. They are of the opinion that the eneggy contained in the many bombs exploded recently by both the U.S. and the USSR is still negligible to the amount of energy that would be necessary to induce a long period absorption effect. With Bomb-testing apparently halted, how have conditions on 160 been?" - (George, since testing stopped conditi seem to be coming back to normal for this time of year, but extremely slowly and v very spotty - whether there is any correlation or not is hard to tell - but some still feel that there is, others that there might be!!) Conditions hard to explain

FINLAND ON 160!!! ----- Here is another Country available - word from several sour OH3NY, GW8PG, etc - NO HAMS allowed 1820-1845k & 1915-1955k - 10 Watts. Our old frie Matti Paiavo/OH3NY, also OH2NB are on - Matti says "Cdx much poorer than 11 yrs ag sigs must go over Magnetic N Pole - will be active even though new QTH hr much poo for ant - 73 to all!!"

PROPAGATION FORECASTING ----- Fm WØTUT/Joe a most interesting comment --"Your coincidence of QSOs p3 Bull#1 62/63 reminds me paragraph June 62 RSGB as follows - ""IEE procedures 3/62 explains new method ionospheric forecasting being used by th D.S.I.R. based on identification of "Epochs" during which corresponding Cdx have prevailed past yrs, rather than plotting completely new forecasting maps as previo It has been found usually possible identify some period within the previous 10 yrs when almost identical radio condx occurred. The result of this new system, is a great increase in accuracy of predictions mdde several months in advance" - Tnx Jo Sorry abt ur S9 line noise washing you out on 160 Dx - Joe wants info on D.F. to find noise - can anyone help?? If so send Joe the references - Joe Check CST/ARRL.

ULTIMATE NAVIGATIONAL AID!!!!!"----- Fm Boston Globe 11/8/62 -"A new Navigational aid developed by John A Pierce, Harvard Scientist, (who also developed LORAN)-Named OMEGA - 8 times better than LORAN - Range 8000 Miles (Loran only effective 1000 Mi Three OMEGAs would replace 100 Lorans and give greater coverage -$10,000,000. cost per installation however. Expected operational not less 3 yrs nor more than 5 yrs- been in development 12 yrs. Funded by three Services through office of Navigations Research - apparently operates on higher Fy than LORAN (Dont know fy yet) -SOOOOoo maybe here's relief in sight from our LORAN QRM on 160 - We HOPE!! Anyone more dop on this????

HEARD ON 160 (Without mentioning any names) BY W1BB ----- "A fellow can stretch his ears -when digging for Dx on 160 & or any other band - but especia 160 -to the point where he THINKS he hears sumpin!! Did YOU hear ever so weak a si on 1827?? I thought I did!!! - Gosh, I doubt if my ears will ever go back into sha " - Now isnt it the truth???!!!! W1BB at least knows JUST what you mean, O.M.!!!

MARKER DHJ54/2 ----- Per G3PQA "Has packed in and is replaced by DHJ59/2 which is much weaker station - so if you dont hear DHJ - dont despair of Dx"- Tnx John !!

CYPRUS - Fm G2BVN/Steve comes word that 5B4PB is Famagusta, Cyprus & Now active - usually fm 0300-0450z 1801k alternate odd numbered days. Static high/but will TRY!

160 in FLORIDA ----- de W4XYT/Andy Florida Skip Ed. - "You said there is nothing keeping us fm at least listening in Fla to 160!! Oh YES there is Stew - LORAN!!!!! I'd like invite you Fla just ONE Night - ANY night and "Listen" to 160!! You proba couldnt stand the 40 to 60 DB over S9 racket fm our Hi Pwr LORAN Stns - Man it's JU AWFUL!!!! - lets hope however some day they'll turn off those QRM makers an allow us back on"!!! Tnx/Andy-real sympathies and hopes for a better future!!!

"FLORIDA SKIP" Mag/W4JO "Work For Joy Only", Frank, Advt Mgr, sends extremely FB comments --"160 been dead band Fla many yrs-missed band mucho- W4EB/W4JO organized "Miami 160 phone gang" in 1930-Frank used 201a Mod W/247-still has it -(In Attic)- in 1933 Mag "HARMONICS" born devoted 160/Phone/Hamming-Net met 8AM Sundays - so yo see 160 is vy dear to hearts of O.T.s arnd Miami - we used Long Wires/Low Pwr - Dx was'anywhere out of the state' tho I once QSO'd Europe with tt 201A - wl be list Transatlantics - If poss thru Loran -was THERE at the very FIRST & 2nd TRANSATLANT w/cans only " Frank O.O.T./Tnx Vy interesting Comments - Hope 160 back to Fla Soon

AMERICAN SHORT WAVE LISTENERS CLUB -----Jim Howard, Ed, says "Thinking of offering awards to ASWLC members who report overseas 160 meter Dx stations - might make it Club Contest" - this would help Dx stns a lot!! Tnx much Jim - Hope you do it!!!

SOUTH AFRICAN RADIO LEAGUE/Michael C Bosch/ZS2FM,East London ----- Writes " Our br[illegible]h has embarked on a project to revive interest in "Top-Band" in view of low M exp[illegible]ted during Min Sunspot Cycle. 73 de Stew/W1BB and b.c.n.u. on 160 follows HAPPY NEW YEAR!

November 11, 1962

!!! FLASH !!!

MIDDLE NOVEMBER

!!!-- 160 METER DX report de W1BB --!!!

Dx in all directions since October 1st have been extremely poor, although some spotty DX has broken through to W/VE, namely, VP8GQ (Weak) - HR3HH good signal - and DL1FF weak and briefly for 20 minutes (No QSOs) using his Vee beam and calling CQ DX --- European "MARKERS" have been conspicuously absent except for the briefest moments.

This raises a question as to what has happened to 160 meter Dx. Up until October, it was our best year - with the earliest Transatlantic crossing on record and lots of Southern Summer DX including VP8, ZL, VK etc and apparently continuing to improve while the SUNSPOT Numbers increased, as expected.

However - rather suddenly from the first of October on, it has been almost as though a DX barrier had been thrown up, which even the strongest DX signals can not penetrate.

Many are wondering if the Pacific NUCLEAR tests could be responsible for upsetting the Ionosphere and casting a "blanket" over 160???????

All 160 Meter DXers are active however, and holding on hoping for the "Break" to come soon!!!!!

Most active W/VE PARTICIPANTS are: W1BB, TX, ME, UZ, WY-K1IMO-2EQS, FYT, IU, UW1 KHT, -3GQF, FBV, -4CXV-5KG, NU, SCT-6KIP-Wa6CDR-K7DEK/7, K7HDB-8GDQ, IQS, CIJ-K8IQR-9PT UKV-K9JDK, -ANWX, IFH, GBV, VXO-VE1ZZ, 3QU, DU, FF DX PARTICIPANTS are: G6BQ, G3ERI LIQ, PU, CHN, OIT, PQA, IGW-[redacted] PU- G5RI-G6GM-G8PG - GM3IAA - GM3IOS - GD3UB - HR3HH - VP8GQ - EI9J - UB5WF and others.

Stewart S. Perry/W1BB

(During Week of December 2 W1BB will visit KV4AA "Dick" in the Virgin Islands --To discuss possibility of 160 Meter DX operations from "YASME and future DXpeditions

1960/1961

DECEMBER 23 ~~4th~~ 16 and ~~17~~ ~~18~~
JANUARY 6 7 ~~8~~ 20 and ~~21~~ ~~22~~
FEBRUARY 3 ~~4~~ ~~5~~ 17 and ~~18~~ ~~19~~

During these periods, Extra Special efforts will be made to contact European, Asian, African and other 160 Meter DX Amateurs throughout the world, for general DXing, and also yo make observations, as a contribution to the study of PROPOGATIO conditions on these frequencies.

An active group of English and DX Amateurs, in Cooperation with USA Amateurs are behind this effort in carrying on these Tests, which have been a yearly operat activity since 1932. All 160 meter stations throughout the world are invited and also urged to participate in as many of these TESTS as possible!!!

Most W/VEs will operate 1800-1825 Kc Segment EAST of the Mississippie River, while those to the WEST will use 1975-2000 Kc, Clustering near 2000 Kcs Usually. DX will be found mostly between 1795 and 1850 Kcs, the best segment being 1800-182 Some DX will be found near 2000Kcs. DX stations should cover near 2000Kcs carefull for unusual and choice USA Contacts!!!

W/VE stations will call CQ DX TEST the first 5 minutes of each hour, and each alternate 5 minute period thereafter, Listening the second 5 minute period, and each alternate 5 minute period of the hour, for DX. The DX stations of course will do just the opposite. Thus, each station alternately calls for 5 Minutes, and then listens for 5 minutes throughout the TEST - unless working or hearing DX. Care should be taken particularly by all participants to carefully set their clocks to WWV, etc. to be sure of keeping in step with these 5 minute periods, and not cause QRM by transmitting during the listening periods. These calling and listening peri of course apply only when no DX is being heard or worked. When DX is coming throug the idea naturally, is to QSO regardless of the periods - BUT, here again, adheran to the 5 minute periods, even for a QSO, would help to minimize QRM.

W/VE stations should send their reports for the TESTS,of activity and unusual accomplishments to W1BB, Stewart S. Perry, 36 Pleasant Street, Winthrop, Mass., US for recording in the booklet " THE 160 METER DX HISTORY", and for transmittal through BULLETINS to A.R.R.L.-CQ-SHORT WAVE-WESTERN RADIO and other magazines, etc for publication. G,GM,GI,GW, Etc. should send their reports to G6QB, L.H. Thomas, DX Editor, Short Wave Magazine, Turkey Road, Bexhill or Sea, Sussex, England. --- OTHER DX, may send their reports to either of the above as desired. Do REPORT!!!

Remember!!! --- These are "Tests", and not CONtests -- for pleasure in an unusual operating activity, without "Competition", for a change, and to develope some propogation information as a worthwhile contribution to the art of Radio.

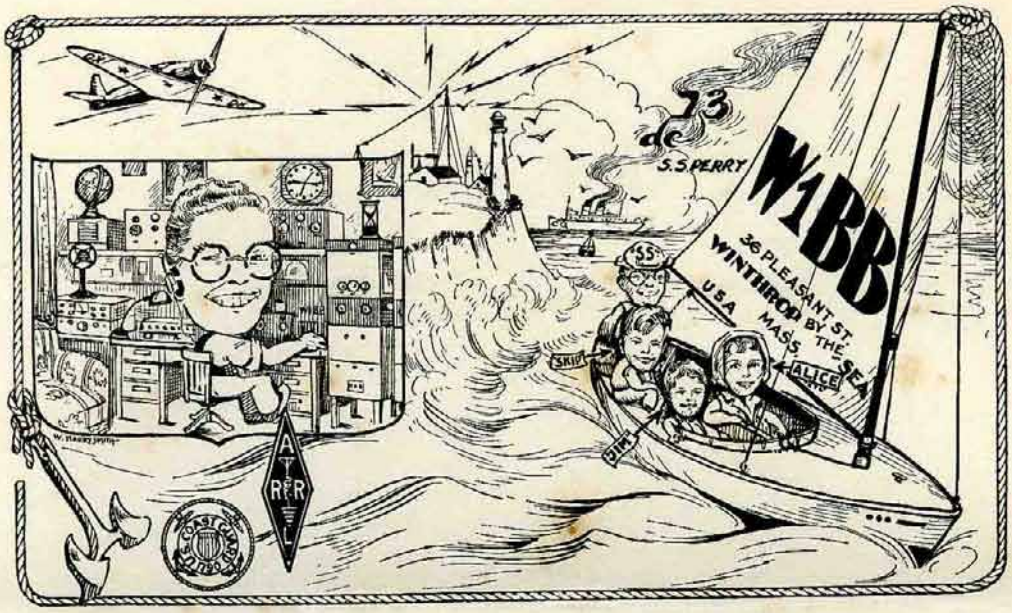
A.R.R.L. and CQ - DX CONTESTS

W1BB --- And many other W/VE, 160 Meter HAMS will carefully cover these contes on the same Operating schedule as above for the Transatlantics. W1BB invites any special schedule arrangements from any of the DX gang desiring to make a real try for an extra band multiplier!! AIR/MAIL your intentions to W1BB in this respect, in advance if possible, otherwise W1BB will cover the same frequencies as mentione in paragraph 3 on page 2 of this Special No. 1 Bulletin. CQ are proposing to run another 160 Meter CW Contest early in 1961, and it is hoped that DX stations will participate in this operating activity also. See CQ for further details.

W1BB 160 METER DX BULLETIN

W1BB --- Will issue this BULLETIN during the 160 Meter DX Season, as material is obtained, to the above/mentioned HAM magazines etc, via air-mail, so that they can publish from it, the important information on "TOP-BAND" activities. There is no mailing list to individials, although W1BB will oblige and send copies to those supplying S.A.S.E.s

Best of luck ALL - and again, 73 de W1BB/Stew.



W1BB ANNUAL 160 METER DX LETTER

Dear O.M.:-

At the start of another Season, W1BB sends GREETINGS with 73!!, and the hope t you will take an important part in the 160 meter DX activities!!!

Working DX on 160 is challengine, and extremely interesting. Conditions such a statics, BC harmonics, QRM, Loran, QSB, noise, all require extreme patience, with perseverance, a top-notch station, and A-1 operating ability. There are SPECIAL, TRANSATLANTIC and WORLDWIDE 160 Meter DX "Tests", and the ARRL and CQ, DX Contest to participate in. (See below in this bulletin). There are many "FIRSTS" yet to b Many unusual conditions to observe and cope with. One gets anew, the thrill of the early Amateur Pioneer days when HAMS were first relegated to "200 meters d down", and Paul Godley made the FIRST Atlantic crossing via Amateur Radio. In addition, you will many friends among the finest and most sincerely devoted HAMS you would ever care to meet -- these "Top-Band" boys !!!

Your participation here will also help to promote Amateur occupancy of the ban and assist in keeping this 160 meter operating priviledge. In addition, you will help to develope PROPOGATION information of real value to the art.

Through these BULLETINS issued during the season by W1BB, reports on your activities and accomplishments, and all information of 160 meter interest, will b sent to QST-CQ-SHORT WAVE-DX-WESTERN RADIO-VQM-DXing HORIZONS-FLORIDA SKIP-Radio Propogation Editor/CQ, magazines, etc., for publication. Be sure to keep W1BB wel informed of all your 160 Meter exploits and results, etc.

In case you personally are not particularly interested in 160 Meter operation, "Test" schedules, DX Contacts, or unable to work this band - PLEASE pass this BULLETIN along to someone who is. Also, W1BB would appreciate if you would send t calls of all HAMS in your Country who might be interested in 160 Meter DX, and ab to work this band. Please post this BULLETIN in your Club, and give 160 meters as much publicity as possible!! Particularly as to DX!!! THANK-YOU, very much indeed!

W1BB 160 METER DX ACTIVITY

W1BB --- Will be on regularly EVERY Sunday Morning, (Baring unexpected sickness business demands or Emergencies), from 0500-0730 GMT, calling and listening for alternate 5 Minute periods, November through March, looking for 160 Meter DX Contacts!!! Please be sure to give W1BB a call!!

W1BB --- Will transmit, Mostly on 1802½ or 1807½ Kc. However, 1817½ and 1822½ will also be used at times depending on conditions, QRM, Interferance, etc.

W1BB --- Will NOT work V/VEs during DX schedule hours - unless something of an urgent nature comes up, or band conditions are useless for DX - will Concentrate/L on

W1BB --- Will generally follow the regular 160 meter "Test" procedure. When no DX is being heard or worked, W1BB will call, CQ DX TEST, the first 5 minute period of every hour, and each alternate 5 minute period throughout the hour. W1BB will listen carefully for DX stations, the second 5 minute period of each hour, and each alternate 5 minute period throughout the hour.

W1BB --- Suggests that DX stations call W1BB on 1797½ - 1802½ or 1827½ Kcs, as these are the most QRM/free spots, usually. These SPOT frequencies will be covered with EXTREME care by W1BB at ALL times. The band 1800-1830 will be covered careful too, and frequencies up to 2000Kcs checked regularly.

W1BB --- Welcomes, and invites special schedules with any DX station that desires to make contact - at any time of year, and on any special, (Authorized), frequency designated by the DX station. Send AIR/MAIL letter to W1BB, with full details on the proposed schedules, and also any schedules on HF bands that may be necessary to make full arrangements or exchange of reports etc.

W1BB --- Appreciates REPORTS on his signals, from any station, at any time of year, with full particulars - whether you make QSO schedules or not. This includes SWLs, some of whom have submitted MOST accurate and valuable data. These reports assist in propogation studies being made. Please AIR/MAIL them weekly. Postage gladly reimbursed if desired. Special reporting FORMS supplied on request. All reports acknowledged. Please DO report!!! The more the better!!!

W1BB --- Will operate mostly from the HOME QTH, "Winthrop by the Sea", BOSTON, USA, with 200 watts, a 260' doublet antenna and 75A4 receiver. Some operation will be from W1BB/1, either at the WINTHROP YACHT CLUB, with quiet location and special antenna entirely over salt water!!, or from "Villa Mon Repos", at Harrington, Maine 300 Miles Northeast from Boston, a quiet country location, with 260° long "Vee" antenna - 260' on a leg.

W1BB --- Will mail a handsome appropriately lettered "AWARD" Certificate, to all DX stations working W1BB on this band, if they request it. In addition, for DX stations where their W1BB/QSO is a "FIRST" recorded "Top-Band" QSO between that Country, and USA, an extremely SPECIAL and attractive lettering job, in color will be done on the Certificate by a Commercial Artist, to Adequately and Especially commemorate the event. This Certificate is in effect a "KING-SIZE" QSL, measuring 10" x 14", beautifully colored, on heavy durable white paper, suitable for wall mounting or framing. DX SWLs who send in 7 or more Verified reports on W1BB's signals, or have in the past, may also have a Certificate upon request. DX stations who have worked W1BB in past years, and any previous "FIRSTS", may have one of these Certificates, back dated to cover the event, if they request it. Sixteen of these special "FIRST", Colored certificates have been awarded thus far, and in each case the recipient has written appreciatively advising that it was framed and/or posted conspicuously in the shack!!

W1BB --- Hopes that you will join in on the fun, and the challenging work of QSOing DX on 160 - and enjoy yourself and help others to make that much desired contact!! Write W1BB if you need further particulars. Keep W1BB fully informed of all 160 meter activities possible as suggested above, for the BULLETINS and reports on your doings to HAM magazines for publication, as their Editors decide.

W1BB --- Says, 73!!! HAPPY HAMMING and b.c.n.u. on 160!!!!! --- de Stew/W1BB

ANNUAL TRANSATLANTIC and WORLDWIDE "TOP-BAND" 160 Meter DX TEST !!!!

These special "TESTS" will be held this Season on the following SUNDAY Morning from 0500 to 0730 GMT, in accordance with the listings given below:---

Balun and Transformer Core Selection

[Home] [Up]

Balun Test contains model of "perfect" dipole currents.

Sleeve Balun shows how a sleeve adds impedance, useful for VHF and higher baluns

Receiving Common Mode Noise shows how lack of a balun can contribute to system noise (it applies to transmitting antennas as well)

Longwires, Verticals, and Baluns shows how unbalanced antennas can have similar problems

Transmitting baluns on testing transmitting baluns

Occasionally errors are made regarding core selection. This especially includes baluns, where on occasion some very strange ideas surface. One rather odd but somewhat popular idea is that adding a mixture of core types will allow both high power operation and high choking impedance in baluns by slowly reducing current through a balun. Other misleading claims are that extreme values of core ui, such as values in the 10,000 or higher range, are necessary on 1.8 MHz and higher. Other ideas tend support use of excessively low permeability cores for the same application.

When I recommend a core, the material selection is always based on actual measurements with proper test equipment on a bench as well as in the actual end-application.

Core Material

I mainly use 73 material for receiving applications in ***LOW POWER*** applications between .1 and 30 MHz. 73 and similar core materials generally minimize the turns count required without inducing excessive loss. One of the best indicators of correct core selection is looking at the turns required. You'll notice most of the transformers I use have only one or two turns for every 100 ohms of impedance. My 75 to 450 ohm Beverage transformers, for example, only require two-turn primary and 5-turn secondary windings. ***A low "turns count" is a good indicator the correct core size and***

core material is being used.

For high power applications at HF it is often necessary to use lower permeability cores. There are two reasons for this:

- Lower permeability cores generally are available with higher curie temperatures. They operate at high temperatures without losing their magnetic properties.
- Lower permeability cores have higher Q (lower loss tangent) at a given frequency. This means a larger part of the impedance is associated with *lossless* reactance rather *dissipative* resistance. They turn a smaller percentage of power into heat, and that is very important at high power levels.

Permeability changes with frequency. As frequency is increased from zero eventually core impedance peaks. Above the frequency where impedance peaks the impedance of the core (and the ***effective*** permeability) actually decreases.

A downward slope in permeability with increasing frequency is useful for controlling impedance in broadband transformers, but we should be careful to avoid excessive slope. Excessive initial permeability can easily move the operating area too far out on the downward slope of impedance.

A transformer or inductor operating on the downward slope of a high ui core requires extra turns to maintain critical impedance and often requires more turns than a lower ui core. The upper frequency limit will decrease, and this may reduce useful bandwidth in the desired frequency range.

Using excessive initial permeability means winding becomes more tedious (it takes more turns). The wire has to be smaller and more fragile to fit a given core window. Temperature stability is often reduced while losses increase over an optimum core material selection. In addition, stray capacitance increases needlessly, reducing bandwidth and increasing unwanted stray coupling.

Do **NOT** pick cores solely by considering initial mu, since that value is taken at dc. You should consider ***characteristics measured at the operating frequency!***

Always remember this general guideline. Les wire length (as long as winding impedance is sufficient) results in better transformer bandwidth. The best designs place maximum conductor length INSIDE the magnetic core window, and minimum conductor length OUTSIDE the core window.

Heating

At higher power levels, it is necessary to move to lower loss tangent and higher curie

temperature materials like 65, 61, or (in extreme cases) 43 materials. Even a fraction of a dB loss produces significant heating in small cores when power level is in the kilowatt range. *The loss DIFFERENCE in non-resonant applications between lower and high ui ferrite cores isn't significantly different, but* ***heating*** *can be much less!*

We often assume heat means a core is very lossy or is "saturating", but **t**his often isn't true. We must consider the power level, duty cycle, and ability of the core to dissipate heat and look at the full picture.

Very small cores, such as small thin .5 inch diameter cores used on bead-type choke baluns, can only dissipate a fraction of a watt in open air. It sometimes helps to put temperature in perspective by visualizing how hot a 60-watt light bulb runs in normal operation. When we consider the core's size, it usually has significantly less surface area than the bulb. The core also has poor thermal conductivity, and is often stuffed in a container preventing any type of air circulation.

Consider the construction of a typical bead balun, enclosed in PVC and heat shrink tubing. As little as 20 watts dissipated out of 1500 watts can produce damaging heat in tiny beads enclosed in a PVC tube. 20 watts out of 1500 is less than 0.1dB loss, yet it overheats the core!

The problem is almost always a heating problem, and not a core-loss problem. It is almost never core saturation, unless the core is subjected to very low average power and very high peak power levels. It is best that we worry about heat and the number of turns we use, not actual power loss, when selecting a core.

Core Style

Soft-iron cores (soft magnetically) increase inductance because they increase *flux density* near a conductor for a given current. With only a small amount of flux "concentration", there can not be a large increase in inductance or impedance. We need a significant increase in flux to have a significant increase in impedance.

The area outside the core window does NOT have a closed magnetic path surrounding the conductor. ***The presence of the core has a minimal effect on impedance of any conductor area outside the core window.*** Most of the flux from external wires is in air, rather the core. With only a portion of the flux surrounding the outer conductors cutting the outer layers of the core, the ***useful*** impedance contribution of wire outside the core window to system impedance is minimal. Conductor length outside the core window mostly adds unwanted stray reactance and leakage flux. If we MINIMIZE the wire length exposed outside the core, and we generally have a more effective inductor, choke, or transformer.

This effect can be easily conformed in a simple experiment using an antenna analyzer. Connect a short wire across the output of an analyzer, and measure the impedance. Lay a core against the wire,

and observe the very small impedance increase. Now pass the same wire through the core center, and observe the large impedance change. This illustrates why the winding's wire length on the outside of the core is wasted, mostly contributing to undesired effects.

Core Dimensions

The area inside the winding-window of a soft-iron (soft magnetically, not physically) core is cut by all of the flux lines, and this area has a very large effect on impedance. The core concentrates the magnetic flux surrounding a current-carrying conductor into a very small area, and the thickness of the core moving away from the area of the conductor very rapidly has less effect.

- The additional impedance caused by placing a core over a conductor or conductors is almost entirely proportional to the core's internal length (window depth) paralleling and surrounding the conductor or conductors.
- The core diameter or radial thickness only has a small effect on impedance.

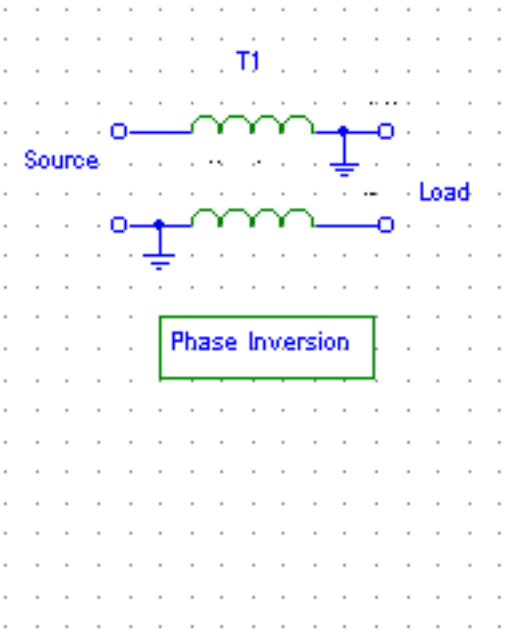
Doubling the core area **parallel** with a conductor roughly doubles winding impedance. The same is NOT true for an increase in core wall thickness, core thickness barely affects impedance.

I prefer binocular cores for most low-power applications and side-by-side stacks of cores (making a large "binocular core") for high power broad-band applications. This type of core arrangement almost always minimizes the amount of conductor hanging "outside the window". With very little conductor hanging "outside" the core window, there is less "needless" wire adding undesired stray capacitance and series resistance. For a given core material and impedance, conductor length can often be reduced to about one-third of a similar impedance choke (or transformer) using a conventional single-hole core or single stack!

Low Power Measurements

Phase Inversion and Choke Baluns

Some of my receiving system designs use phase-inversion transformers. Phase-inversion transformers are identical to (and interchangeable with) choke baluns or line-isolation transformers. For HF receiving applications, 73-material binocular cores are wound with six passes of #26 twisted-pair enameled wire. I use Fair Rite Products 2873000202 cores (about 1/2 inch square and 1/3 inch thick 73 material).

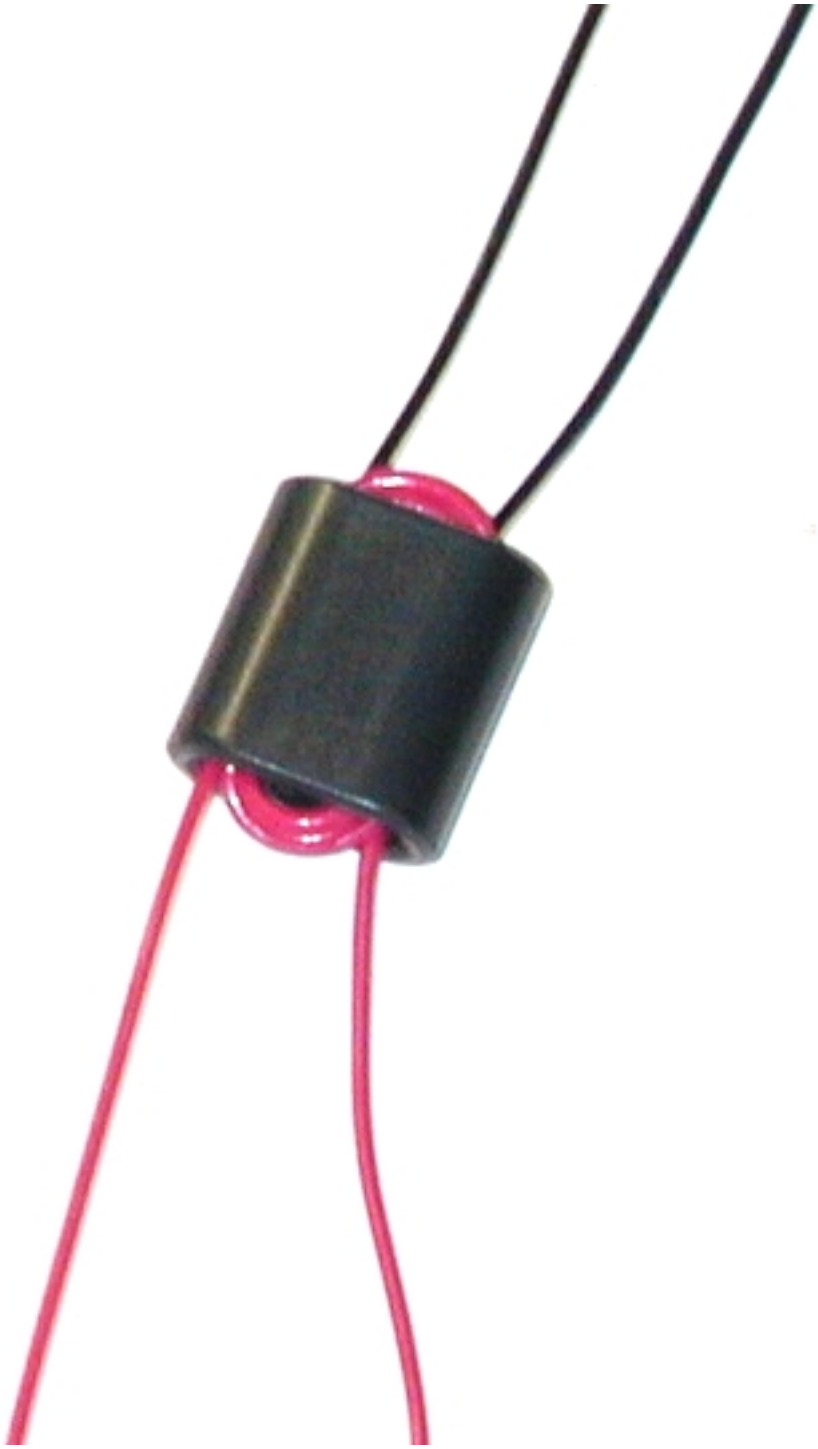


Here are measurements of a sample inversion transformer at 2.5MHz using accurate (and fairly new) commercial equipment:

Load Value (ohms)	Loss (-dB)	Phase Error (degrees deviation from 180)
100	~ 0	<1
33	~ 0	-1.2
10	0.2	-2

This shows inverting transformer construction is good, since even a 10-ohm impedance load works well!

Beverage Matching Transformer



Sometimes I use designs for a long time, and forget how I decided they were OK. I recently received an e-mail questioning the number of turns in my Beverage transformer design, so it seemed like a good time to re-confirm the design.

I retested a 2:5 turn ratio transformer using a single FairRite Products 2873000202 core (about 1/2

inch square and 1/3 inch thick 73 material) two different ways on a generator/ network analyzer/vector impedance test set.

Total loss of two back-to-back transformers was .84dB at 1 MHz increasing, not decreasing, linearly to .98dB at 30MHz. The actual transformer loss would be .42dB at 1MHz increasing to .49dB at 30MHz.

Doubling turns increased the attenuation slope. While 1MHz loss decreased to .69dB per pair, 30MHz loss increased to 1.21dB. This was for a PAIR of transformers connected in series to make a 1:1 transformer. This of course removes mismatch losses, so it is twice the real transformer loss. Actual loss would be .35dB @1MHz increasing to .61dB at 30MHz.

Measuring a second way, I terminated the transformer in 470 ohms. Loss measured .65dB at 1MHz when mismatch loss was included. Since receivers have wide ranges of input impedance, any mismatch error might help OR hurt actual system loss. Factoring out mismatch loss the second measurement indicated about .53dB 1MHz loss with the original 2-to-5 turn transformer and .43dB with twice the turns.

Every measurement has tolerances, and the two different methods do provide different losses because measurement errors affect results differently. Still, it is safe to say doubling turns has a negligible effect on 1MHz loss (which is around .45dB).

Balun Test

Sleeve baluns Balun and Transformer Core Selection

Impedance and SWR Test

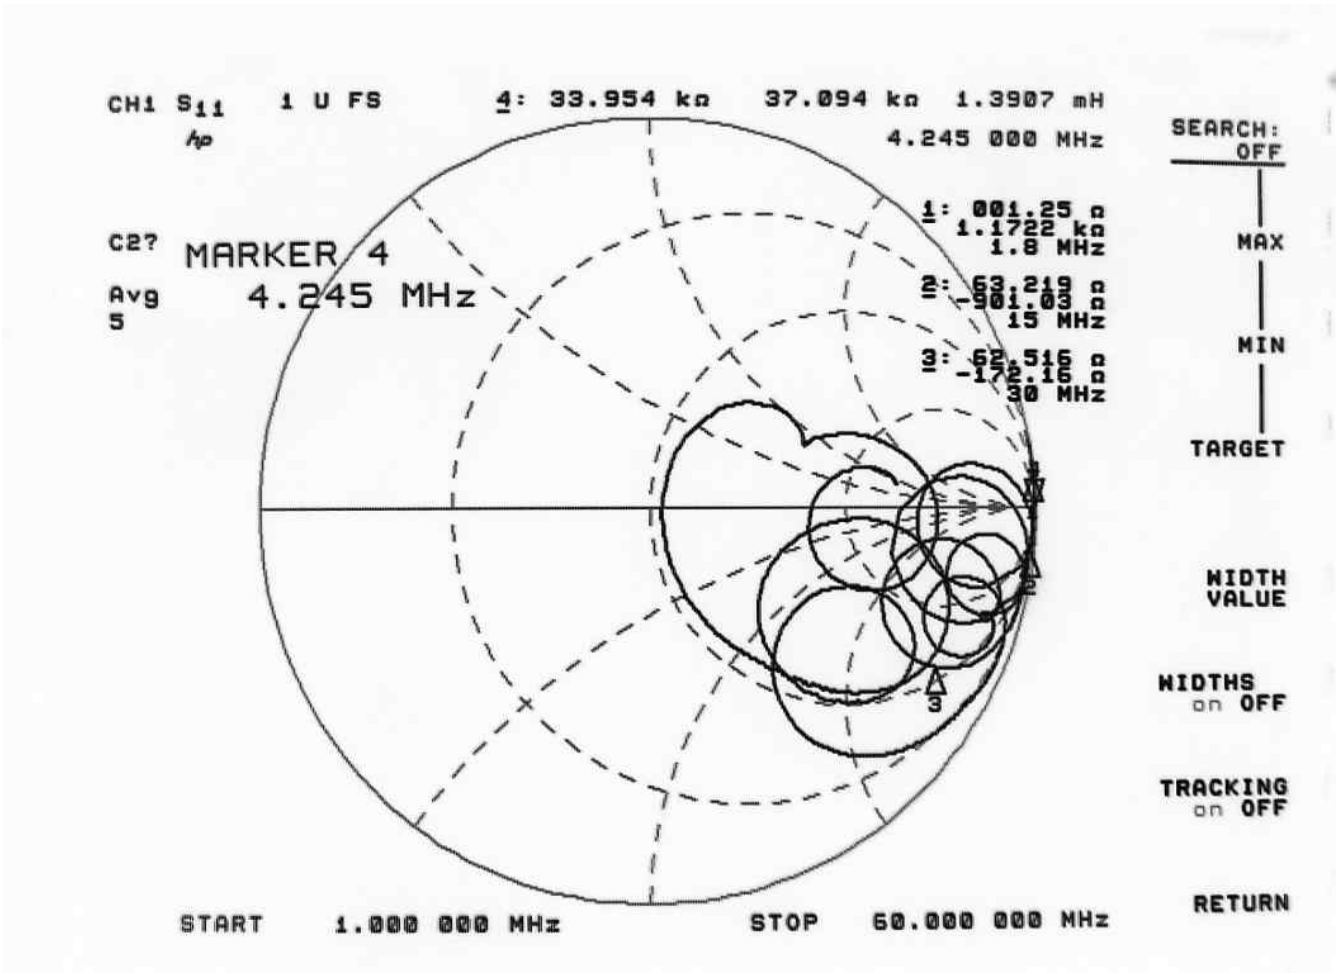
This page shows measurements of various baluns and how various baluns compare.

Choke Impedance

This data shows the common mode impedance of the balun. In general, the highest impedance at the operating frequency or over the operating frequency range is desirable. This impedance isolates the antenna from undesired signals on the feedline shield, and prevents antenna terminal voltage from exciting the feedline with unwanted currents. Common mode impedance is directly related to the care in design and construction.

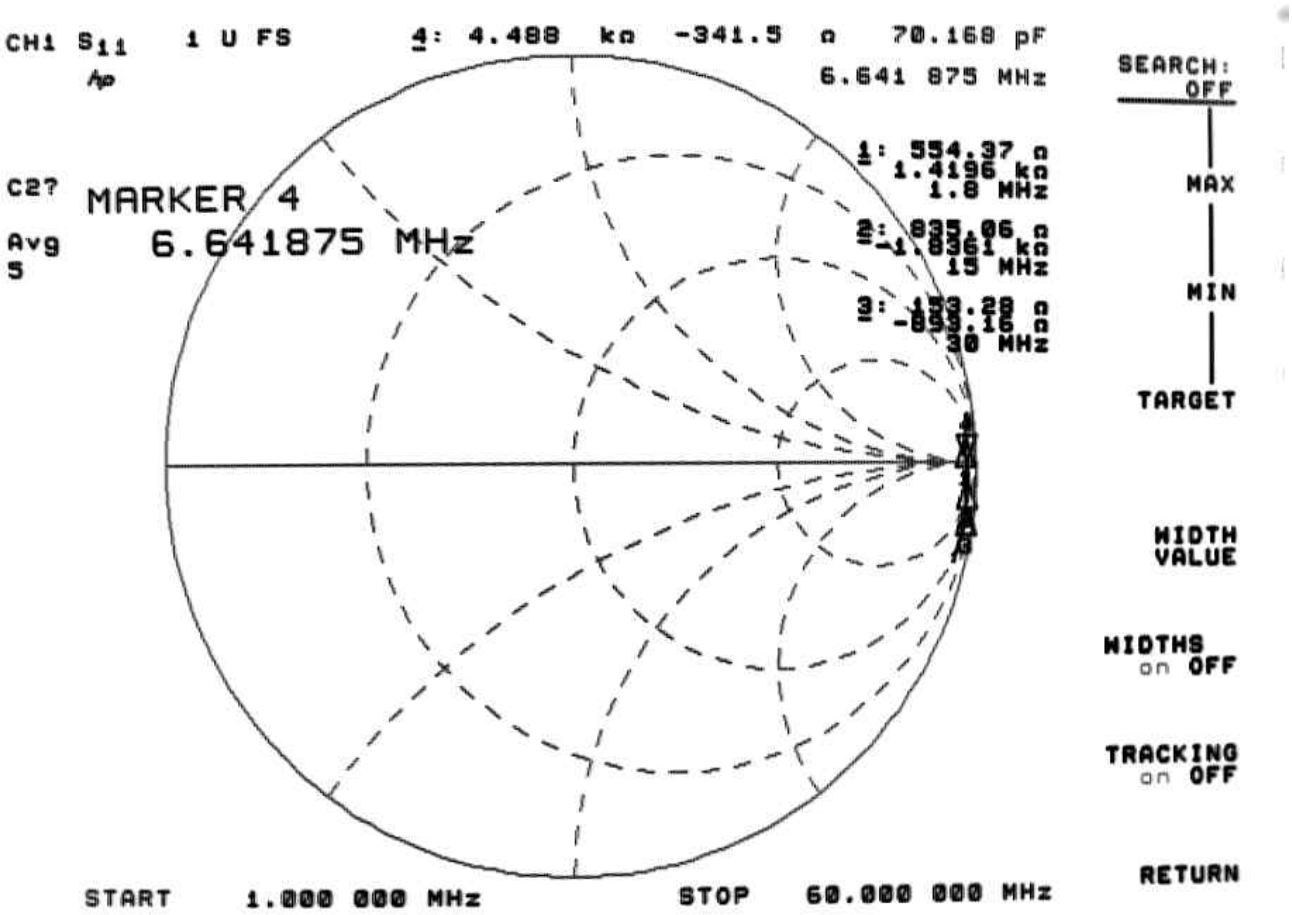
Pay particular attention to the impedance peak in air-core baluns. For narrow-band applications they make excellent baluns.

Unfortunately common-mode impedance is all over the place, as this Smith Chart plot shows:



The air-core balun is good only for a three or four-to-one frequency range, unless you pick a winding style and size that places unwanted series resonances outside desired bands.

In contrast a good core-type balun looks like this:



SWR

The lowest SWR is desirable, although any mismatch can often be compensated by adjustment of antenna dimensions. This SWR mainly comes from incorrect wire impedance inside the balun. It may be caused by excessive length of internal leads, or incorrect cable or winding impedance inside the balun. It generally is a construction related problem.

Measured SWR and Choking Impedance

The following data is measured using a currently certified network analyzer with low capacitance test fixture:

Centaur	DXE	W2DU(1)	W2DU(2)	Force 12	Scramble	Solenoid	W2AU volt

Choke Impedance								Note 2
R+X@1.8	84 129j	554 1.4k j	378 617j	230 325j	169 286j	1.67 245j	1 +1.18k j	.488 5j
R+X@15	3.76 2.7k j	835 - 1.84k j	727 -611j	761 -10j	883 - 105j	11.97 - 850j	62 -895j	1.36 42j
R+X@30	143 - 729j	153 - 893j	284 -440j	610 -296j	538 - 381j	73 162j	68 -168j	8.2 68j

Min Z@F						27.68MHz	11.7Mhz	
R+X at min Z						10 -2j	198 -252j	
SWR								
F SWR=1.25	6.8 MHz	65 MHz	21.15 MHz		20.2 MHz	note 1	note 1	20.9 MHz
1.8MHz	1.07	1.02	1.03		1.03			1.43
15MHz	1.58	1.04	1.17		1.18			1.2
30MHz	2.16	1.08	1.37		1.39			1.35

note 1: SWR not measured because construction and cable type affects SWR

note 2: This is a W2AU voltage balun. It is only shown as a example of poor shield isolation offered by voltage baluns if the antenna is not perfectly matched to the balun with the feedline exiting the balun at right angles. This type of balun is unsuitable for non-symmetrical systems such as off-center-fed antennas, verticals, or antennas with the feedline paralleling the antenna (even at a fairly large distance).

The W2DU baluns were manufactured by Unidilla. (1) is a Maxi balun and 2 is a 10-40 meter model.

The DX Engineering balun is the dipole balun type DXE-BAL050-H05-P

The scramble-wound choke was about 20 feet of RG8X in a six-inch diameter "bundle".

The solenoid balun was about 60 feet of RG-8X on a 4" PVC thin wall drain pipe coated with rubberized roofing tar.

Power Dissipation and Feedline Common-mode Current Estimates

Note: This section revised 1/2/2003 to correct model error. Please report any other errors to me!

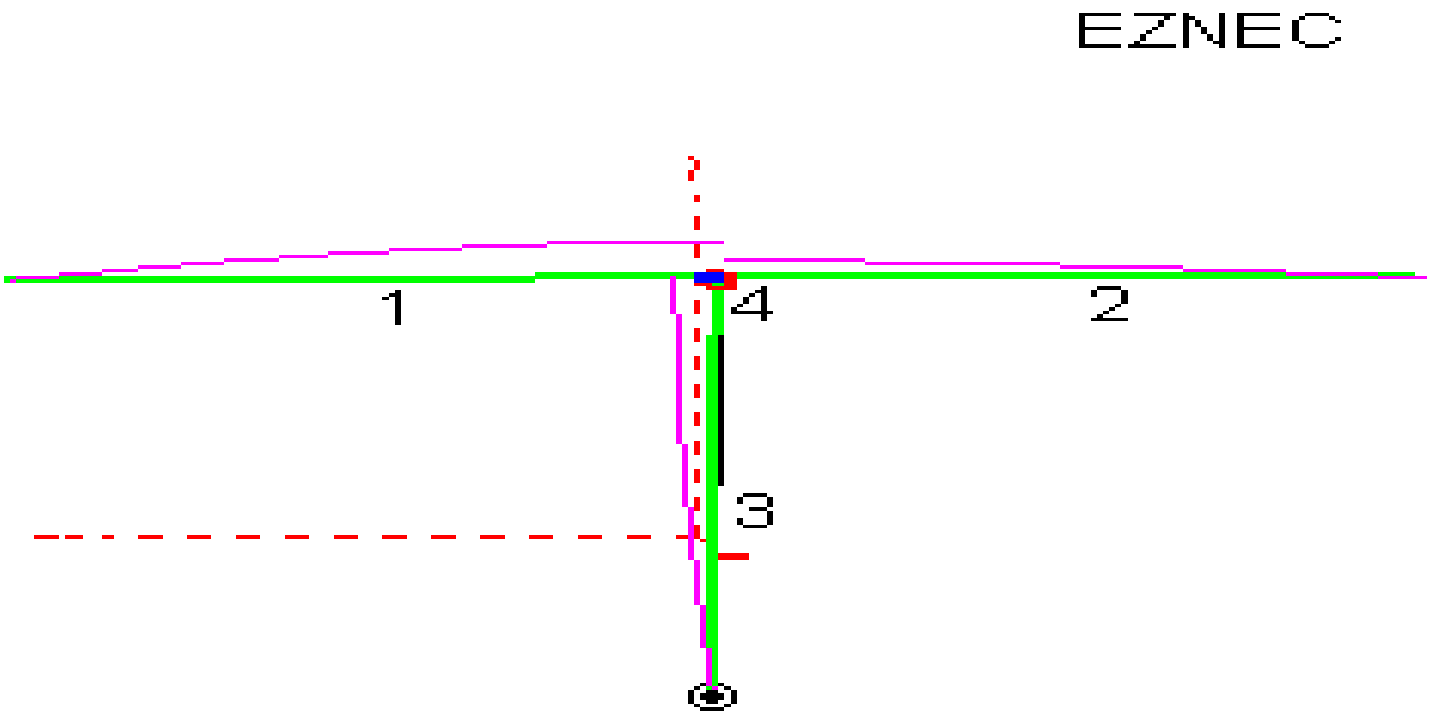
Balun power dissipation is estimated using Eznec to simulate a perfectly balanced dipole.

Here is a copy of the model used:

160m balun EZ

Please be aware I made no special effort to create a "bad antenna" other than I intuitively understand what the worse case condition of feedline length would normally be and I selected that length. I dropped the wire representing the feedline vertically from the center of a perfectly balanced dipole, and made that wire 1/4 wl long.

Here is a view of the model with no balun:



SWR is 1.46:1 power is 1500 watts

Currents at 1500 watts are approximately:

5.65 amperes into wire 1

2.63 amperes into wire 2

3.73 amperes into wire 3 (coaxial cable shield)

Using this model (a 135 foot high 160-meter dipole) we can add each of the balun impedances in the coaxial cable shield and estimate feedline current and power dissipated in the balun:

Centaur	DXE	W2DU(1)	W2DU(2)	Force 12	Scramble	Solenoid	W2AU
0.90 amp	0.12 amp	.25 amp	.47 amps	.57 amps	.87 amps	.16 amp	.4 amps

69 watts	8.5 watts	25 watts	51 watts	55 watts	1.3 watts (26w TL loss)	.03 watt (74w TL loss)	34 watts

From this we can see the following:

- Adding more beads is very inefficient. **W2DU(1)** has about twice the beads as **W2DU(2)**, yet it has 53% of the current and 49% of the power dissipation! This does increase power rating by a factor of four, but it is still too low to prevent balun heating.
- The **solenoid** has (by far) the lowest choking or balancing power loss, but it is 60-feet of RG-8X wound on a 4" diameter form in a single layer. It adds transmission line loss of 74 watts, but since the area is so large it will not overheat.
- The **scramble wound** balun has inadequate impedance since wire length is only 20 feet. It has low loss, but it really isn't acting like a balun (at 6.5 MHz it would be super, having 42K ohms of impedance).
- Of the baluns above, only the DXE, scramble wound, and solenoid would not be overheated in normal operation for continuous Morse CW transmissions.

Perspective of Heat

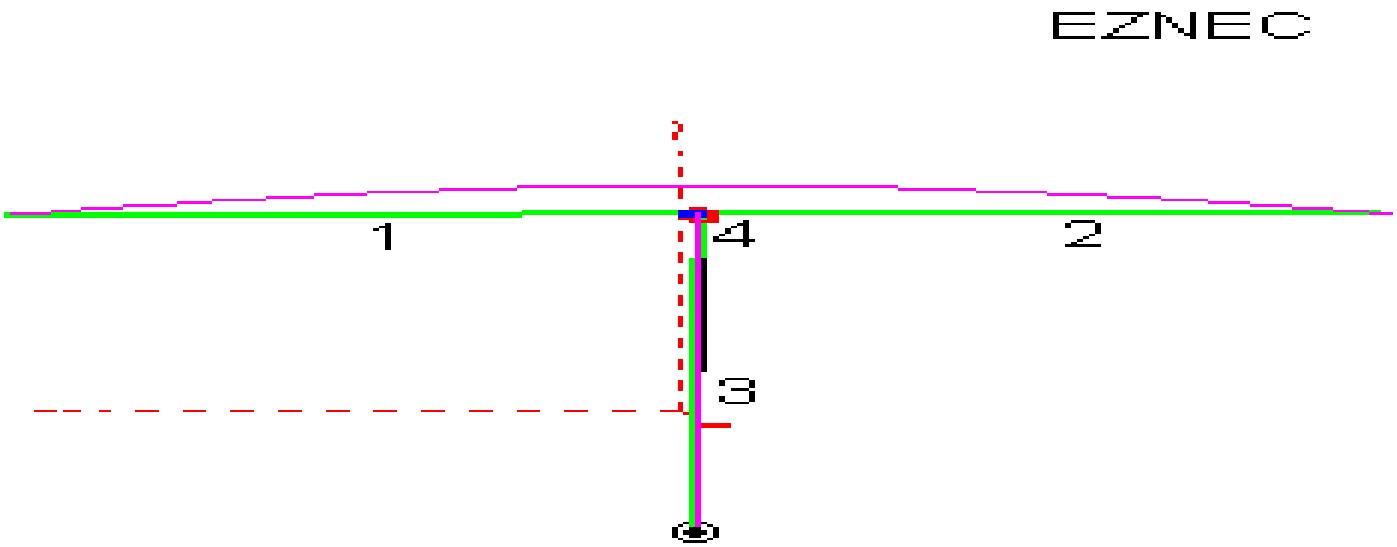
Think about the heating this way. Imagine you had a 60-watt light bulb. Nearly all of the applied power is turned to heat, and the surface area of the bulb and conduction through the base radiates that heat. Would you hold a 60 watt light bulb?

Now picture a balun core with a surface area a fraction of the size of the light bulb. This core area is enclosed in a case that often has poor thermal conductivity.

- The large air-core baluns mainly produce heat from transmission line losses.
- W2DU and other style baluns mainly have CORE losses. Transmission line losses are negligible since the transmission lines are very short.

Currents

Every ampere of current not going onto the cable shield goes to the dipole's shield-fed leg! The total is not the exact sum, because of phase differences. Here is a view of currents in the dipole with the DXE balun:



Currents are:

Wire 1 4.52 amperes

Wire 2 4.52 amperes

Wire 3 .12 ampere

Remember power radiated increases by the square of current. The feedline shield current is now .12A compared to 3.73A without a balun! The feedline radiates about .1% of the power it radiated without a balun. While pattern distortion on transmit may not hurt, the feedline radiation probably aggravates RFI and allows noise to couple into the antenna when receiving.

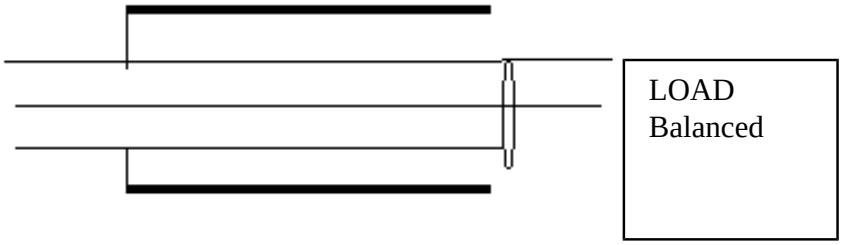
Remember the model is worse case in the NO BALUN condition. This does not mean every system or most systems will be this bad. This example was only intended to show how bad balance can be and how much power baluns (even with a matched load) can dissipate!

I'll add more data as time permits.

Sleeve Baluns

Sleeve baluns are normally used at VHF and higher. As a general rule, they are not practical at HF.

The sleeve is connected like this:



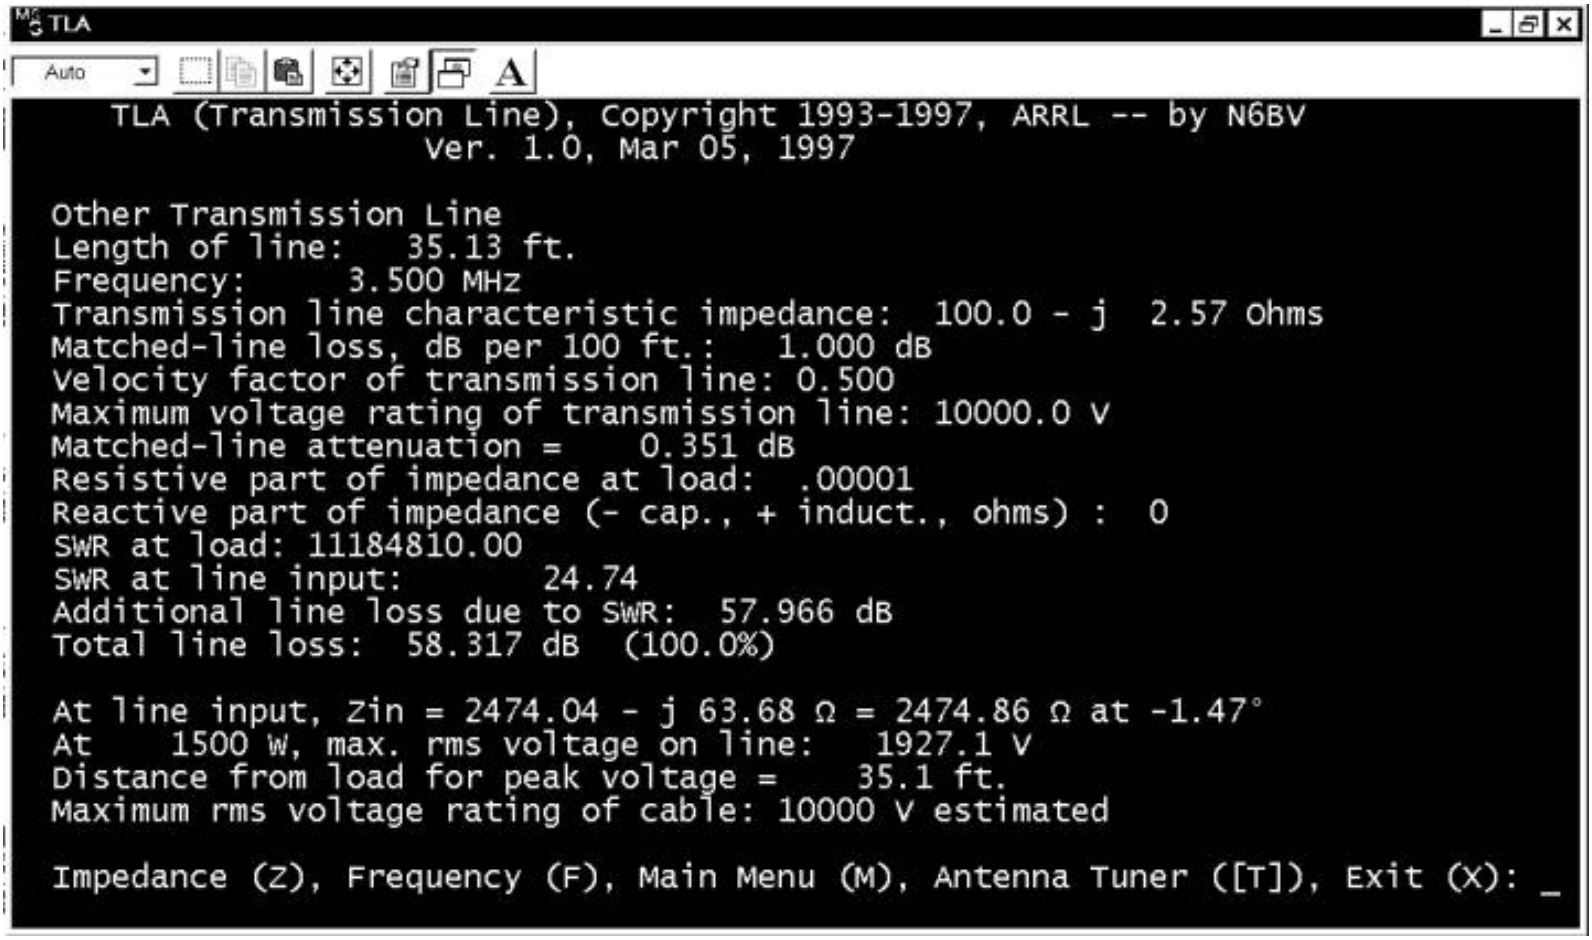
The left hand side of the drawing, once past the sleeve connection point, is UNBALANCED. The right hand side is balanced. The ***choking impedance*** of the balun is the impedance between the outer sleeve and the outside of the shield of the coaxial cable inside.

The choking impedance represents the same type of impedance we would have from any common-mode choke, such as a coil of cable or a string of ferrite beads would produce. A sleeve balun only works where it is ¼ wl electrical length, or odd multiple thereof.

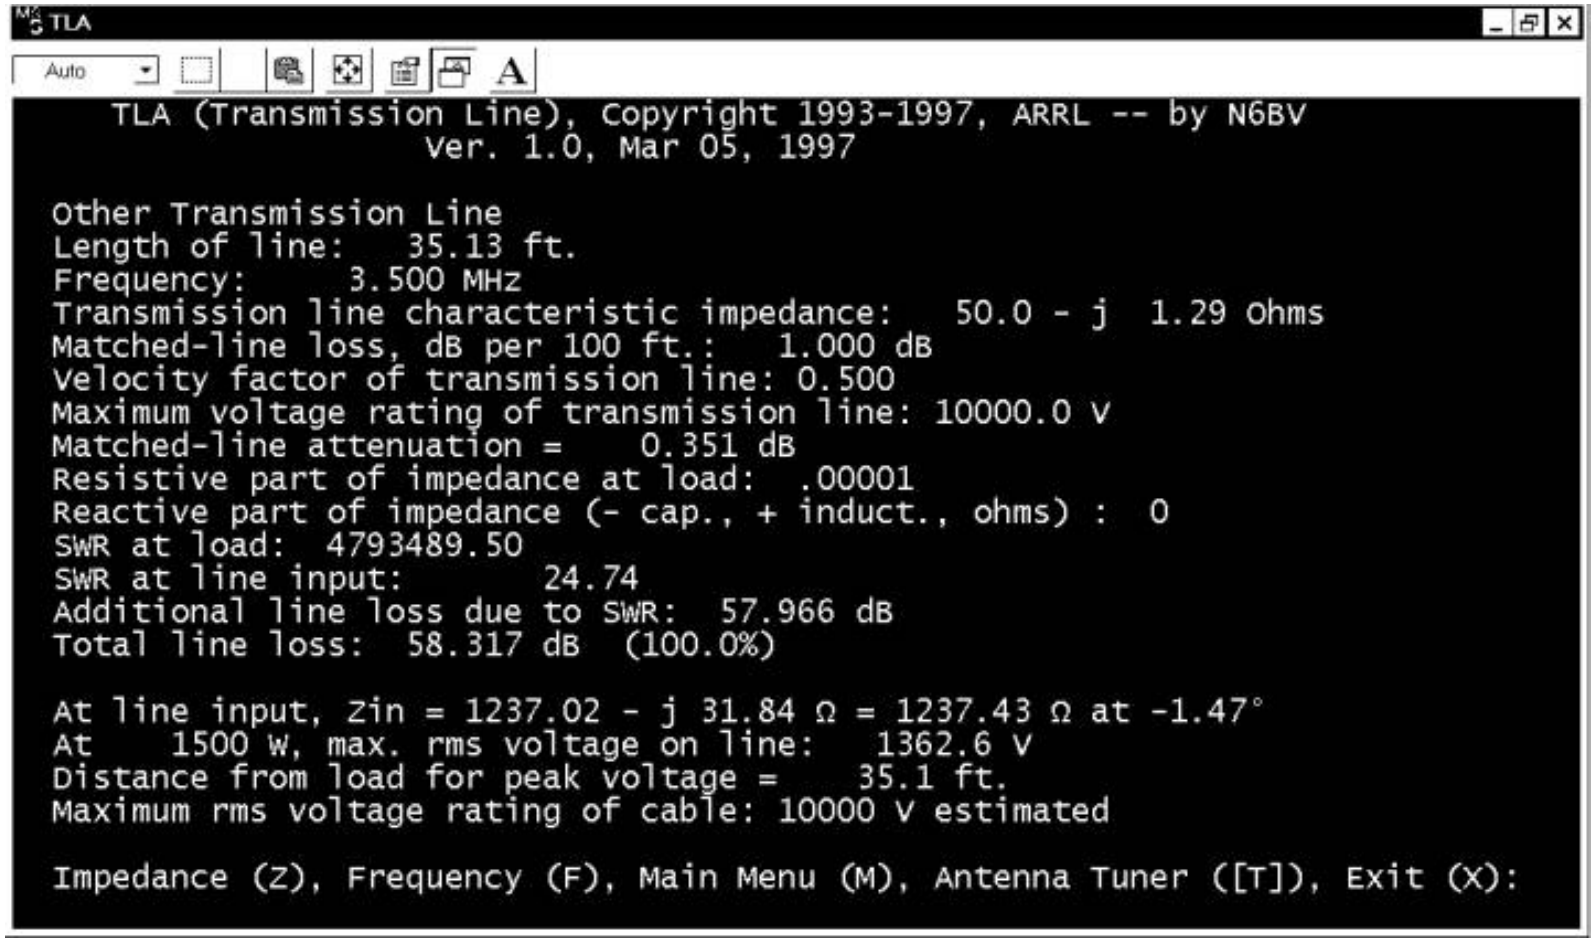
Obviously we want the highest possible choking impedance, because the balanced load terminal voltage on the shield side to unbalanced (shorted end side) voltage and impedance sets the current though this balun (as it does with any choke balun).

We can use TLA (free with the purchase of ARRL Antenna Books) to calculate balun's choking impedance.

Below is a calculation of sleeve balun choking impedance with 100-ohm Zo 1dB loss sleeve. I used a .5vF inside the sleeve.

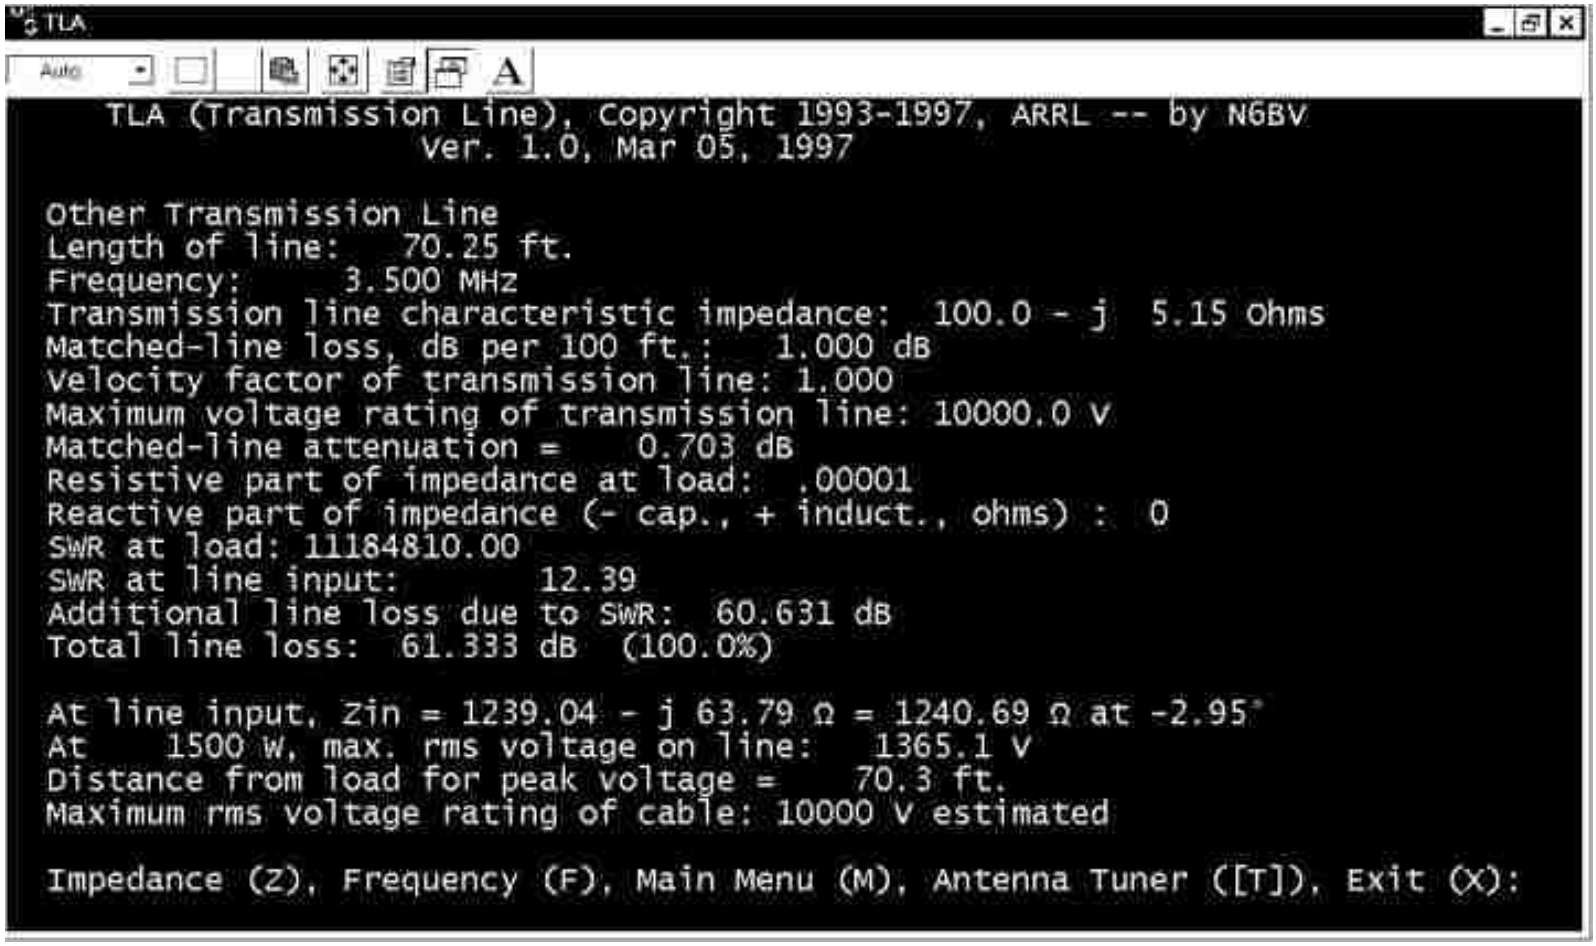


Balun choking impedance 50-ohm Zo sleeve and .351dB internal sleeve loss (sleeve 35 feet long and matched loss 1dB per hundred feet).



Impedance is now 1237 ohms compared to 2474 ohms for 100-ohm sleeve Zo.

As you double sleeve Zo, all other things equal, choking impedance doubles. What happens if we only change loss in the 100-ohm line? We can do this either by doubling the loss per hundred feet or doubling Vf at the same loss, making the sleeve twice as long (and twice the loss).



Now we have 1240 ohms with a 100-ohm Zo sleeve. The reason we have less Zo is the attenuation or loss is twice as high. If you look at Matched Line Attenuation above, it is now .703dB versus .351dB in the 0.5 Vf case.

From the above, we observe the following characteristics in a sleeve balun:

1.) The highest possible choke sleeve impedance (largest ratio of balun sleeve diameter to outside of transmission line) is desired. We won't have a good balun if the choking Zo (ratio of sleeve inner diameter to coaxial shield outer diameter) is small.

2.) The balun requires the lowest possible loss over the length of the sleeve. It forms a transmission line from the inside of the sleeve to the outside of the coax. The coax jacket is a dielectric, so we need to keep a lot of air inside of the choking sleeve or the coax jacket will increase loss and reduce impedance, both being very undesirable.

3.) The velocity factor of the sleeve, based on the dielectric between the sleeve and the shield of the coaxial cable we are

trying to balance or choke, is very important to length of the sleeve.

The following construction guidelines apply:

The cable should have a good low-loss jacket or a very large air or low loss dielectric gap between the shield and the sleeve. Since energy is normally confined to the inside of a coaxial cable manufacturers are not concerned about jacket losses. They use outer materials with long life, not low RF loss. It is advisable to use a filler material with a high volume of air to maximize sleeve impedance and minimize sleeve losses.

It is also advisable to use the largest practical diameter sleeve with the smallest diameter coaxial cable inside to maximize choking impedance.

The sleeve length has to account for velocity factor of the sleeve, since the sleeve forms a coaxial transmission line with the outer conductor of the coaxial cable it is intended to choke or decouple.

Common-Mode Noise

Common Mode Noise Isolation

Common-mode currents can be detrimental to antenna system noise or directional performance. A quick look at systems using common-mode currents demonstrates how effective they are at causing radiation. If common mode currents can radiate effectively; they can also transfer unwanted signals and noise ***into*** our antennas when receiving.

Many antennas actually function because of common mode currents. Two popular examples are the CFA and EH antennas. Both become significantly poorer radiators if common-mode currents on feedlines are eliminated. Another recent example appearing in Antennex's compact antenna articles was a thick stub "vertical" with no counterpoise. You find an example on the baluns and verticals page of how poor some large grounds can be.

A receiving example of an antenna that works because of common-mode excitation is the "Snake"

antenna. This system accidentally (or intentionally) induces common-mode on a cable shield in order to receive signals. The entire shield picks up signal, the Snake is simply a reverse-fed random wire lying on the ground.

There are many examples where designers intentionally use common-mode currents. Examples are found in textbooks, such as the "Antenna Engineering Handbook" by Jasik on and around page 22-6.

The antennas below, copied from Jasik's textbook, outline the derivation of a skirt collinear antenna from a simple feedline with the open end terminated by a "stinger".

22–6 VHF AND UHF COMMUNICATION ANTENNAS

Two or even three skirts may be added to the mast as shown in Fig. 22-5*c*, but reduced excitation of the lower sections diminishes the effectiveness of each additio skirt.[6] Thus, while the multiple-skirt coaxial antenna resembles a collinear arra in-phase half-wave elements, its gain is not as great. Typical gain values are ta lated in Table 22-2, but since no test data are available for this type of antenna, values given are merely engineering estimates.

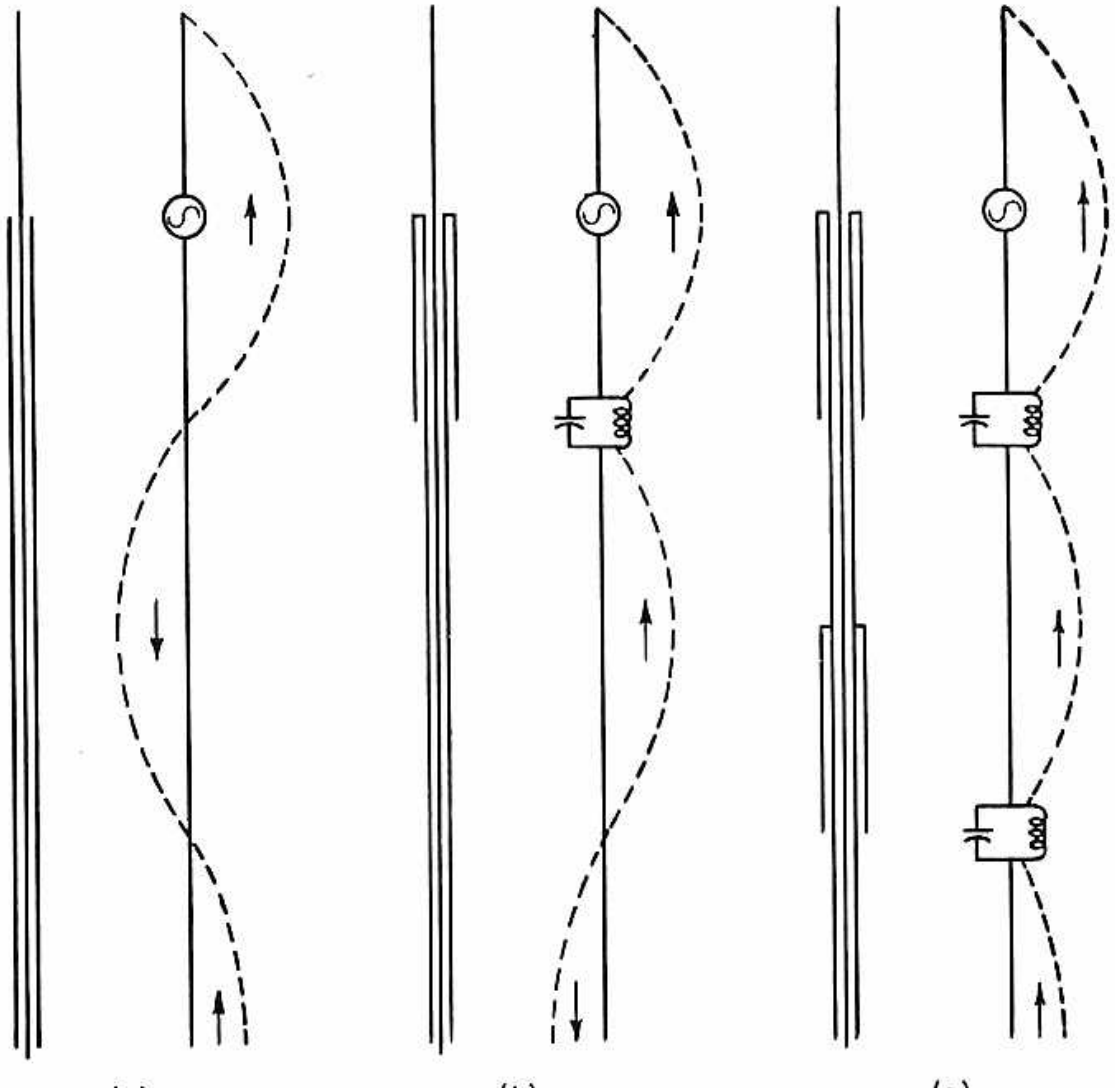

FIG. 22-5 Evolution of multiple-skirt coaxial antenna.

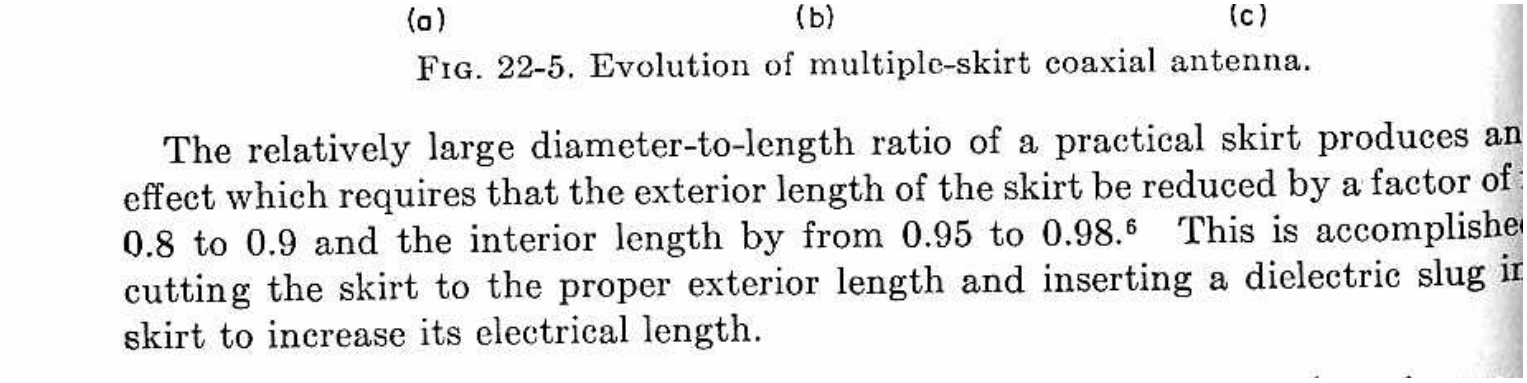

FIG. 22-5. Evolution of multiple-skirt coaxial antenna.

The relatively large diameter-to-length ratio of a practical skirt produces an effect which requires that the exterior length of the skirt be reduced by a factor of 0.8 to 0.9 and the interior length by from 0.95 to 0.98.[6] This is accomplished cutting the skirt to the proper exterior length and inserting a dielectric slug in skirt to increase its electrical length.

The center conductor termination in these drawings could easily be a ground rod (in the case of a Snake) or an antenna like a Beverage or loop. The termination does not have to be an "open circuit" 1/4 wl stinger that intentionally radiates!

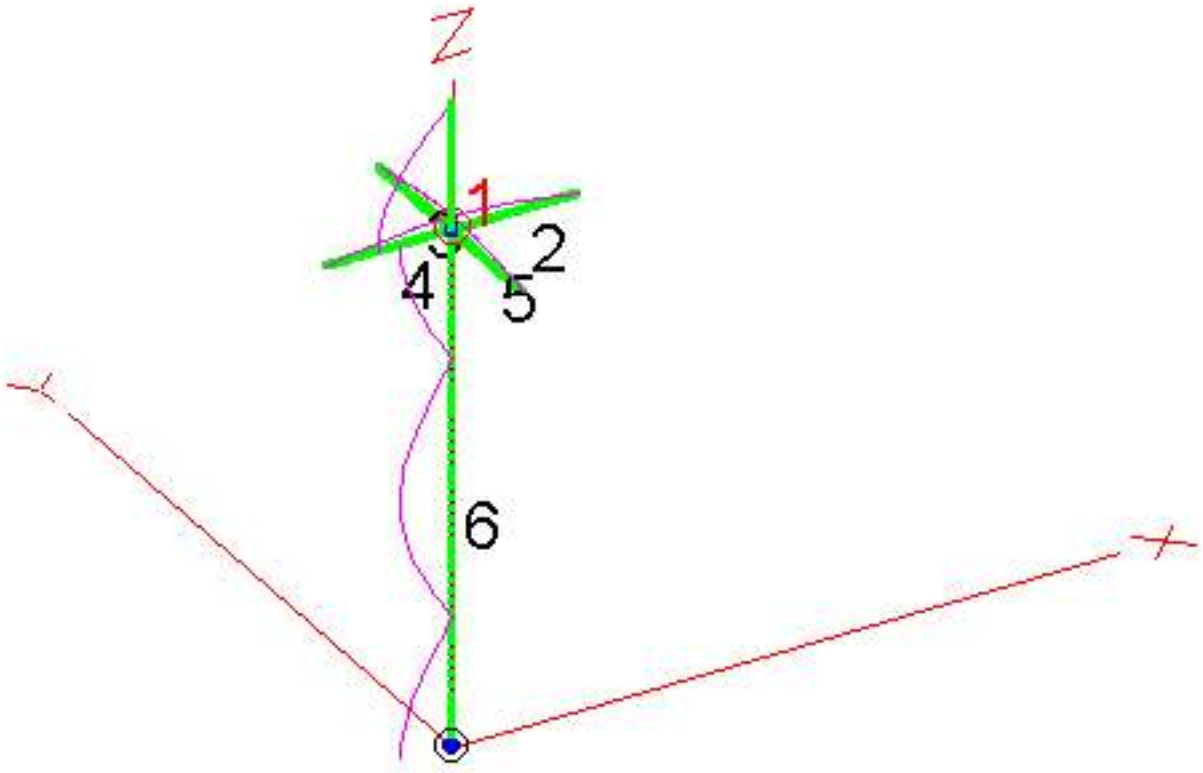
Looking at (a), we find by hanging any low impedance on the end of a coaxial cable the shield is excited by common-mode current.

The electrical equivalent is just as if the transmitter or receiver (generator symbol in the drawings) is located at the end of the shield. This causes the outside of the shield to act like a longwire antenna.

Unless the coaxial shield connects to a zero resistance ground, current with flow on the shield. Looking at (c), we find even multiple sleeves appearing as parallel tuned high-impedance circuits do not fully decouple a shield! It takes grounding and series impedance to do a good job.

Common Mode Currents and Receiving Antennas

Analyzing our antennas, we often forget grounds are not perfect. We make assumptions that four radials, or worse yet two radials, form a perfect groundplane. Even a groundplane antenna many wavelengths from earth with four radials has considerable common-mode currents on the feedline. Consider the following model of a "perfect" Ten Meter groundplane using four perfectly horizontal 1/4 wl radials spaced every 90-degrees with a 1/4 wl feedline hanging vertically and attached to the radials. The main element current was set at 100.



EZNEC ver. 3.0
Groundplane 12/14/02 6:20:40 PM
---------- CURRENT DATA ----------
Frequency = 29.95 MHz.

Wire No. 1 Main Element	100
Radial wires	19.71
Feedline shield at GP	69.96
1/4 wl from GP	2.12
1/2 wl from GP	71.3
3/4 wl from GP	.70557
At ground end of feedline	71

A glance at radial current shows the bulk of ampere-feet (ampere-feet, or current over spatial distance, determines E-M radiation levels) is on the feedline shield, not the antenna! Radiation from the feedline would be severe, yet most amateur antenna designers claim with only four radials, or worse yet two radials, no balun is needed! The claim that four radials makes a "perfect ground" is false.

Why do we depend on a simple ground rod with 50 or more ohms RF resistance to clamp a coaxial cable shield to ground?

Receiving Systems

Admittedly the above antenna is a worse-case example of feedline length and grounding, but even the best cases could cause problems. A best-case system might be "nearly perfect" when transmitting, but it could be a disaster receiving when even minor amounts of conducted noise are present on the station ground. Noise paths exist through station wiring. Only the shunting impedance of ground connections and series impedance of the feedline shield prevent excessive unwanted noise ingress at the antenna feedpoint.

Very small levels of conducted unwanted noise often go unnoticed in large high-level transmitting antennas. Noise ingress would not be an issue if local noise levels on power lines are very low, especially if the antenna has substantial common-mode feedline noise rejection.

If a feedline is very long and lies directly on or is buried in the earth, ground losses can attenuate conducted noise or unwanted common-mode signals. Unfortunately, we almost never know if the feedline shield is contributing noise, because it is nearly impossible to measure the common-mode noise contribution of the feedline!

Measuring Common-Mode Noise

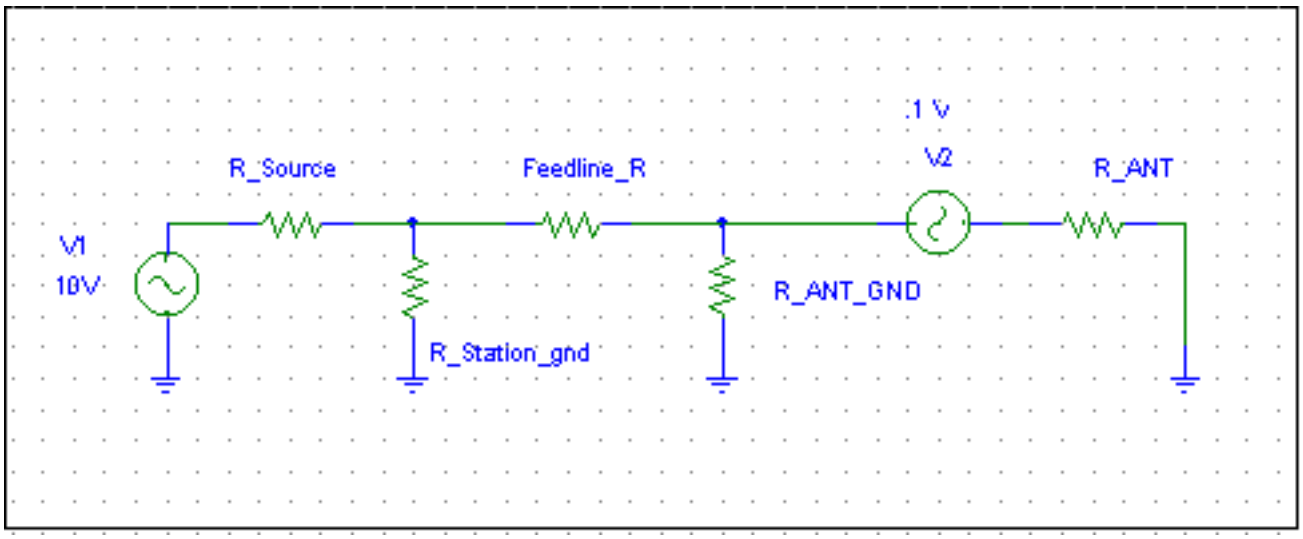
We sometime hear suggestion that we test a system for noise ingress by disconnecting and replacing the antenna with a dummy load. This idea actually has no theoretical foundation at all. The dummy load would change system common mode greatly.

The only real test would come from a dummy load with the same connections and impedances (both differential and common mode) as the actual antenna. In other words the test load has to be the actual antenna to keep feedline common mode ingress the same! Obviously this is a useless test!

The best approach is to use preventative measures in initial system design and installation. Quite often the cost of being safe is less than a few percent of the initial system expense.

Analyzing Systems

This circuit is simplification of typical common-mode paths in Beverage, EWE, and other similar antenna systems:



R_Source and V1 represent the source creating voltage across R_Station_Gnd, the station's ground impedance.

Feedline_R is the equivalent series-impedance of the feedline shield.

Current through the feedline shield path develops a voltage across R_Ant_gnd, which represents the earth connection ground impedance at the antenna.

V2 is a voltage source representing desired signals, while R_ant is an impedance representing the sum of the coaxial differential input impedance presented to the antenna (from the desired signal path into the coax) and the actual antenna impedance.

Using the circuit below, we can find the attenuation. Assume:

R_source is 90-ohms

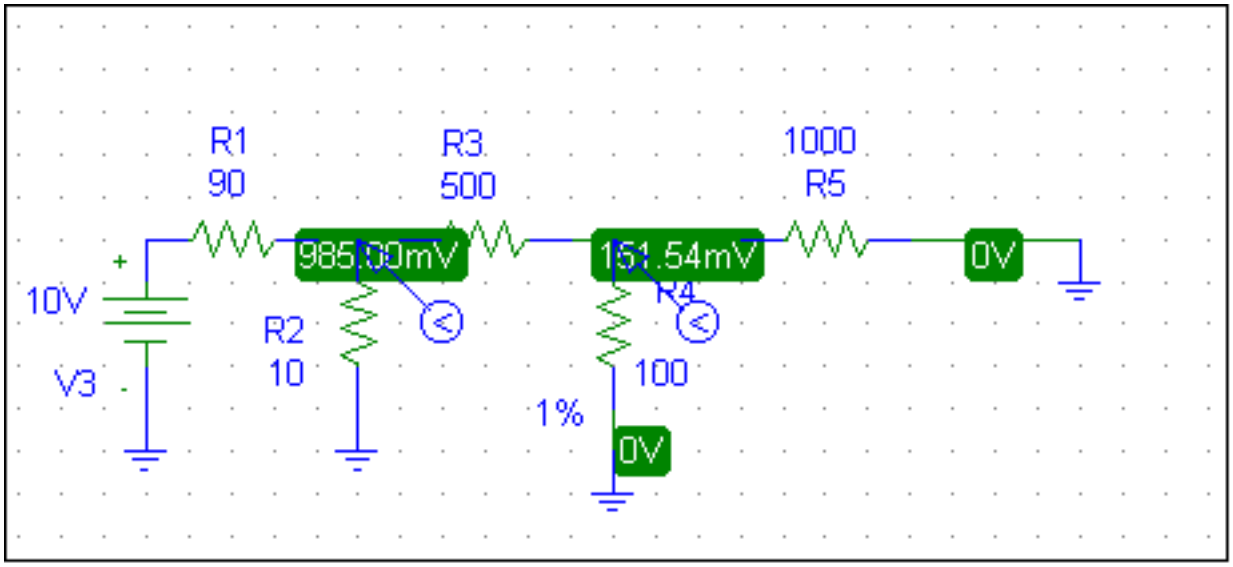
R_station_ gnd is 10 ohms

R3 (the coax shield) is 500 ohms

R5 is the combined series resistance of antenna impedance and impedance presented by the feedline matching system, is 1000 ohms

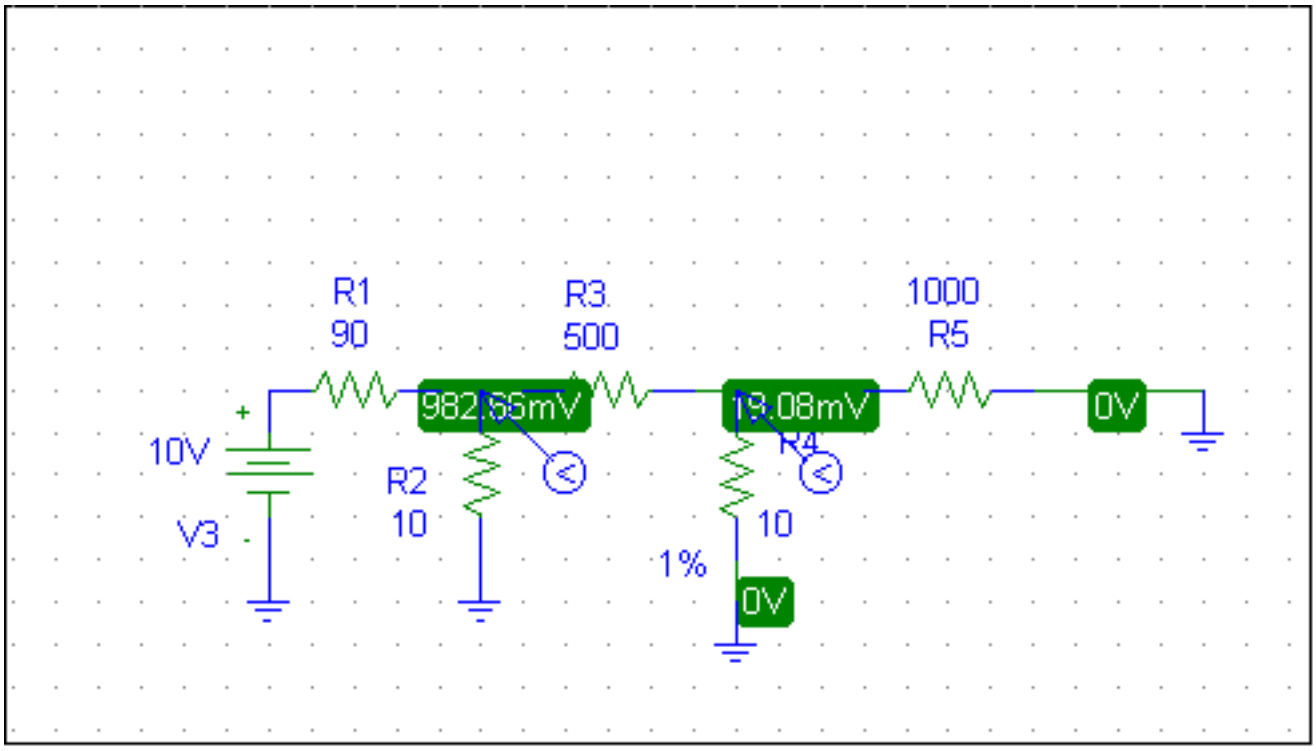
In a typical system where a single six-foot or deeper rod (the earth's skin depth prevents deeper ground rods from decreasing resistance substantially) is driven into typical soil, R_ANT_GND will typically be between 40 and 120 ohms, assume 100 ohms.

We have the following results:



Using the model above, only ~1 volt of common-mode voltage across the station ground results in .152 volts driving the feedline ***exactly as a signal from the antenna would***. Path attenuation from station ground to the feedline's differential input at the antenna is 20log 151.5/985 or **16.26dB.**

Changing the ground resistance to 10-ohms results in:



19.1/982.7 or ***~34dB attenuation*** of common-mode noise. Increasing R3 by adding beads has a similar effect. If R3 is effectively made ten-times larger, attenuation is in the 30dB range.

Obviously it takes a combination of reducing ground resistance and/or adding series impedance on the cable shield to significantly isolate any low-noise receiving antenna from conducted ground noise over

the feedline's shield.

We sometimes observe much less noise on transmitting verticals after installing a large effective ground system. Decreasing ground impedance at the antenna reduces common-mode excitation of the antenna feedpoint and reduces noise ingress, although adding a feedline choke would sometimes help.

Solutions

A typical isolation scheme would be to use an isolated primary and secondary in the matching transformer, and ground the feedline shield some distance away from the antenna's signal ground. This will introduce several thousand ohms of reactance in the common-mode signal path, as well as provide another path to earth for common-mode noise.

Another method, in cases where the feedline can not be isolated through a floating primary in a matching transformer, is the use of multiple independent ground rods with a series of choke baluns between each. This forms a multi-section pi attenuator, making even modest choke impedances effective. As an additional benefit, lightning paths are disrupted by this method.

Summary

Noise contribution can vary with time. A receiving antenna's ground connection resistance varies with soil moisture, and sources of noise come and go. As noise levels and grounding changes noise contribution as a ratio to antenna noise will change. The fact we can not readily measure noise contribution by substituting dummy loads further complicates the issue. Real systems are vastly more complex than the simple analysis above.

Since we can't easily measure noise contribution, we shouldn't take chances. It makes no sense to gamble that unwanted signals (from wrong directions) or noise are so low that they will never contribute to noise in a special antenna installed to reduce noise and interference.

While isolating feedline common mode effects from the antenna and antenna's ground may not reduce noise, isolation can generally be achieved at virtually zero time and material cost. With the low cost of prevention in mind, it is shortsighted at best and foolish at worse to not isolate a feedline shield from any low-noise antenna's signal ground path.

Follow these rules:

1. **With small magnetic loop antennas, make sure the antenna is properly balanced**
2. **Lay feedlines on or bury them in the ground so earth losses reduce shield current**
3. **Be sure shield connections are good**

4. **If noise levels are high or antenna sensitivity is very low, isolate the feedline from the antenna as it approaches the antenna by using choke baluns**
5. **Ground the feedline a few dozen feet away from the antenna**
6. **Avoid autotransformers. Instead use isolated primary and secondary winding transformers**
7. **Use an independent ground on the antenna. Do NOT connect it to the coaxial cable shield**

Noise

Also see: Receiving Antenna Design

To see world QRN (delayed): Lightning world map

To see my local QRN (nearly real time): Lightning USA Map

My local noise level quiet night from NE is -127dBm, 350Hz BW, from pair of ~800ft broadside Beverages ~375ft spaced.

The noise that limits our ability to hear a weak signal on the lower bands is almost always an accumulation of many signal sources. Below 18 MHz, the noise we hear on our receivers (even at the quietest sites) comes from terrestrial sources. Receiver noise is generally a mixture of local groundwave and ionosphere propagated noise sources, although some of us suffer with dominant noise sources located very close to our antennas.

Our locations fall into three basic "radio" categories that may or may not be related to our actual communities:

Note: noise levels quoted in this text are the average of three independent studies by Bell Labs, FCC Land Mobile Advisory committee, and the Institute for Telecommunication Sciences. Rural data are actual measurements of summer noontime and winter midnight noise at my location, several miles from high voltage transmission lines and far from any industrial or suburban populations.

Urban

In urban-type noise situations, noise arrives from multiple random sources through direct and groundwave propagation from local sources. One or more sources can actually be the induction-field zone of our antennas (in most cases the induction field dominates at distances less than 1/2λ). Urban locations are the least desirable locations because typical noise floors average 16dB higher

than suburban locations. There is often no evidence of winter night noise increase on 160 meters, since ionosphere-propagated noises are swamped out by the combined noise power of multiple local noise sources. Much of the noise sources are utility distribution lines, because of the large amount of hardware required to serve multiple users. Other noise sources are switching power supplies, arcing signs, and other unintentional man-made noise transmitters.

Suburban

Suburban locations average about 16 dB quieter than urban locations, and are about 20 dB noisier than rural locations. Noise generally is directional, arriving mostly from areas of densest population or the most noise-offensive power lines. Utility high-voltage transmission lines are often problematic at distances greater than a mile, and occasionally distribution lines can be problems. The recent influx of computers and switching power supplies has added a new dimension to suburban noise.

There is often a small increase in nighttime winter noise at exceptionally quiet suburban locations. This increase occurs when propagated terrestrial noise equals or exceeds local noise sources.

Rural

Rural locations, especially those miles from any population center, offer the quietest environment for low-band receiving. Daytime 160 meter noise levels are typically around 35-50 dB quieter than urban, more than 20 dB quieter than suburban locations. Nighttime brings a dramatic increase in low-band noise, as noise propagates in via the ionosphere from multiple distant sources.

Primary local noise sources are electric fences, switching power supplies, and utility lines. I can measure a 3 to 5dB daytime noise increase in the direction of two population centers, Barnesville (population 7500, distance 6 miles) and Forsyth (population 10,000, distance 6 miles) Georgia.

Typical daytime noise levels, measured on a 200 foot omni-directional vertical, are around -130 dBm with a 350 Hz bandwidth (noise power is directly proportional to receiver bandwidth) . Noise power increases about 5 to15 dB at night, when the band "opens". As in the case of suburban systems, directional antennas reduce noise power.

Nighttime is the "big equalizer", reducing the advantage of location as distant noises increase with improved propagation.

Polarization

Noise is generated by randomly polarized sources. Noise polarization is ***filtered*** by the method of propagation.

Noise arriving ***from the ionosphere*** is randomly polarized. It arrives at whatever polarization the ionosphere happens to favor at the moment. It has the same ratio of electric to magnetic fields as a "good" signal.

Noise arriving ***from sources within a few wavelengths*** of the antenna is also randomly polarized. It has NO dominant field, it can either be electric or magnetic field dominant.

Noise arriving ***from ground wave sources*** some distance from the antenna is vertically polarized. This is because the earth "filters out" any horizontal components. Horizontal electric field components are "short circuited" by the conductive earth as they propagate, and are eliminated.

To hear a demo of noise and directivity, go to the DX Sound page.

MFJ-1025/1026

[Home] [Up]

Noise Phasing and MFJ-1025/1026 Data

The original concept of the 1025 is based on a bridge phasing system. Many phasing boxes, such as the QRN Squasher, do not rotate phase. They are based on the concept that a 180-degree inversion allows rotation of phase when mixed through a potentiometer, but that does not occur. The only thing mixing a 180-degree shifted phase signal with another base phase signal does is vary the amplitude, and produce an abrupt 180-degree flip at the zero-crossing point. Some people have copied the flawed QRN-Squasher concept, and offer similar products.

I recently reviewed another phasing system design (on paper) which is implied to be the "ultimate". It uses a simple R/C phase advance circuit, not a bridge. The maximum phase rotation of such a system is limited to less than 90 degrees. With 180-degree or zero-degree inversion in a later stage, that allows only a 150-160 degree slice of phase choice. Even transposing inputs would only bring that to 320 degrees. Not only that, dynamic range is limited by a very poor choice of operating parameters for the FET driving the phasing system.

To have a perfect product you need 360-degree rotation with no level change. Even with perfect design, phasing systems are tedious to adjust. Other systems rotate phase over a wide range, but have severe level change as phase is rotated. The effect of a level change is you have to "walk" back and forth with phase an level every time you adjust phase! When level changes with phase adjustment, phasing units are even more unpleasant to adjust than a proper system is.

With a ****well designed**** bridge system, amplitude shift is minimal. The MFJ1025 series, despite being manufactured as cheaply as possible, outperforms any other unit I have tested (by a large margin) over its intended frequency range of 1.8-20 MHz.

The phasing system at W8JI, used to pinpoint signal directions of transmitters or jammers more than to actually cancel noise, is a more sophisticated version of the 1025 with higher dynamic range. It uses tandem bridges, and is calibrated in degrees shift. Phasing is spread over a wide, linear, control range. Phase rotates a full 360-degrees with less than 1dB amplitude shift. It is possible to resolve as little as 1- degree directional difference in arriving signals.

A Word About Dynamic Range and Noise Floor

160-meter DX'ers have the most demanding noise floor and dynamic range requirements of anyone

using a phasing unit. 160 ops not only must hear exceptionally weak DX stations using small inefficient antennas and low power, they must contend with multiple 1500-watt signals (often with excellent antennas) parked just hundreds of Hz away! CW operators often listen to CW signals with 250Hz BW systems, pushing noise floors up to 50 times lower than 10kHz filters would produce at any location. Amplifiers and other components must also handle the large powerful window of AM BC stations just below 160, as well as the SW BC stations above. At my house the accumulation of signals from stations *outside* Amateur bands is enough to light a small 12v light bulb when using a 15dB amplifier!

Obviously what works well at MW for sorting 10kHz spaced wide bandwidth signals apart is entirely different. Here we have the strong window of stations, but we are looking in that strong window for other stations that often are strong (compared to 100-watt transmitters with poor antennas). Noise floor is also much higher, and so dynamic range and noise floor are of almost no concern. The critical performance parameter is mostly adjustment range, and not dynamics.

SW BC listeners need something a bit different yet.

Everyone should be cautious assuming a device optimized for one application somehow makes it fit the other.

The only drawback of the higher noise floor of the MFJ-1025/1026 is you ***must place it after any amplifiers used with low-level low-noise antennas.*** The MFJ-1025/1026 noise floor is typically around 14dB.

The dynamic range and noise figure of my personal unit is excellent. Unfortunately such a system is impractical for amateurs and SWL's because of cost. Each unit has about $300 in raw material cost, plus the assembly time. The FET's alone are 28-volt devices capable of several watts RF power while providing a 1.5dB noise figure. But for typical operation the 1025 is almost as good. If you want to spend several hundred dollars, I can sell you a system that works almost perfect in almost any application!

Even with MFJ's well-known QC issues and affinity for building things cheap (not good) I still recommend the MFJ-1025 over all other mainstream units. It has the potential to be better than anything else with only minor changes, and is certainly betetr than all other mainstream units like the ANC-4 or QRN Squasher just as it is shipped. If you want a custom modified unit, and can not make the changes yourself, I would be happy to help.

GAIN MEASUREMENTS

The following table are gain measurements for the MFJ-1025/1026. Wiltron Network Analyzer (50 ohm detectors), transmission loss mode.

Stock Unit and Filters 50-ohm input and output

Aux Port Gain

Frequency	Gain (dB)
0.5MHz	-35
1.2 MHz	-16
1.5 MHz	-9.3
1.7MHz	-6.7
1.8MHz	-5.4
1.9MHz	-5.2
2.0MHz	-4.8
2.5MHz and higher	-4.4

From the above losses, deduct -2dB *(or add 2dB!)* ***if the input protection light bulb is bypassed or replaced with a jumper wire. I.e. 1.8 MHz gain becomes -3.4dB with the lamp removed.***

Main Port Gain

Frequency	Gain (dB)
0.5MHz	-34
1.2 MHz	-14.1
1.5 MHz	-8.0
1.7MHz	-5.8
1.8MHz	-5.0
1.9MHz	-4.2
2.0MHz	-3.7
2.5MHz and higher	-2.3

Bypass is essentially lossless.

Gain Compression and IM Dynamic Range

With gain controls wide open and pre-amp disabled, blocking begins at about -3dBm. Third order intercept is about -21dBm. This is generally well beyond what most receivers are capable of obtaining. (Click here to see the **receivers** page on this site.) The drawback of the 1025/1026 is the lack of any form of filtering, other than the high pass filter. This means the MFJ-1015/1026 sees a very wide window of signals.

With that in mind, it is questionable if removing diodes actually is worth the risk of RF or ESD damage. It would be much better to add a simple bandpass filter system for the band you are operating. However, there is some improvement offered by removing diodes. IM and blocking also can be improved by increasing quiescent current in Q5 and 6, as well as Q4. The bias modification is generally too complex for most people to do, and adding a bandpass filter in from of the unit would be much more effective anyway.

Removing Diodes and Lamps

IM dynamic range will improve about 6dB with this modification. The lamp will improve gain and noise figure of the AUX port (reduce loss) by about 2dB.

If you *never* transmit through the unit:

1.) Remove C5

2.) Remove D1,D5 at the output, remove D12 and 13 (or D10 and 11 in 1025) and D6 and 9 at the inputs.

3.) Replace Lamp1 with a jumper wire.

NOTE: If you transmit through the unit do NOT remove C5 and D1 and D5.

Sensitivity to Load Impedance

Like any typical amplifier system, this unit is sensitive to load impedance. Since it has an emitter follower at the output, it likes to see a low load impedance. Gain will increase about 5dB if you add a 1:4 step up transformer at the emitter of Q4.

The following are modifications or changes to the MFJ-1025/1026:

Gain Improvement Mod.

Increases gain and dynamic range by approximately 5dB (assumes your receiver has a 25-ohm or higher input Z):

1.) Cut the trace from C6 to D1/D5 near the small dip relay.

2.) Add 1:4 step-up transformer, low impedance side towards C6 and high impedance side to load.

Transformers are available, including US shipping, for $6.

Filter Modifications

The MFJ-1025/1026 contains BCB filters that roll off at about 1.9MHz. To extend operation lower in frequency:

Remove L3, L4, L5, L6.

Short C8 and 16

Increase the value of C12 and 13 by the same factor as the decrease in frequency. For half the frequency, double C12 and 13.

Caution: DO NOT remove filters if you intend to use this unit for weak-signal reception on Amateur bands above 1.8 MHz, unless you are sure you do not have strong BC signals.

C12 and C13 mods will reduce upper frequency limit proportionally to the change.

Extending Phase Range

Phase range of the MFJ-1025/1026 is limited by the ratio of R16 to reactance of C12 or C13. Normally phase will rotate through at least 130-degrees. SW3B inverts phase 180-degrees, and this moves the phase shift to the other side of the circle. Typically the MFJ-1025/1026 has about 280-degrees of phase rotation.

The remaining 80-degrees can be covered a number of ways. You can swap inputs (only when using it entirely passive), or modify the phasing network. I also have successfully added a relay that swaps the outputs of the low-pass input filters. A second method is to add an additional capacitor in series with the ground lead of the bottom of R16 (the wiper remains grounded) back to the junction of C14 and R17.

I'd recommend swapping the inputs, it is easier and does not degrade amplitude response or bandwidth.

Receiver_Tests

[Home] [Up] [Sorted by IM3]

Here a few measurements of receivers, using 500Hz filters.

MDS is a measure of sensitivity. -135dBm is 10dB more sensitive than -125dBm. This number doesn't matter very much in what you actually hear. **The real test is if you hear a very noticeable noise increase when you connect an antenna to the receiver. If you hear an obvious noise increase when you connect an antenna instead of a dummy load, your receiver is sensitive enough! You should check sensitivity at the quietest time with the narrowest selectivity you use on every antenna you use.**

Contrary to folklore and hyperbole, there isn't a receiver sold today that can dig into noise more than others on CW based on sensitivity or the use of a DSP or multiple DSP systems. The exceptions are:

- Increased selectivity will reduce noise
- Poor AGC design or detector problems can cause mixing of signals and noise

If you read a review that claims a receiver made weak signals appear from nowhere, you better keep a wary eye on the rest of the review. It is possible for a receiver to be abnormally bad, but it is not possible for a receiver to work better than other properly working receivers based on sensitivity.

BDR is blocking dynamic range. This is the point where a strong signal either 2 or 10kHz just starts to make your receiver lose sensitivity. The bigger the number the better, ESPECIALLY at 2kHz spacing. **The number you want here is probably around 80dB or more if you live in a reasonably quiet location and work weak signals on crowded bands. If you run two transmitters on the same band or have a neighbor who operates near your frequency, you almost certainly need more dynamic range. I'm in a very quiet rural location and have very directive antennas, and 80dB blocking DR suits my requirements just fine most of the time.**

IMDR is intermodulation dynamic range. This is the single most important number when comparing receivers. This is where two or more strong close-frequency signals mix and generate a new phantom signal or multiple tones in a adjacent frequency SSB signal mix with themselves and make what sounds

like splatter. The measurement is made just at the point where the phantom signal level is high enough to interfere with the weakest signal your receiver can detect. IMDR is a measure of how badly your own receiver causes problems you might blame on other people. Bigger numbers mean better receivers. It is most important the **2kHz** number be good. The 10kHz test number doesn't mean nearly as much, because almost any radio is good enough at 10kHz or wider. **Some number above 80dB is enough to stay out of trouble 99% of the time. If you are in a noisy location, you obviously need less performance. 85dB keeps my receivers at the point where poor quality external signals cause nearly all off-frequency problems. With 85dB IM3DR only a few of the strongest stations cause my receiver to make its own internal problems.**

Be aware the very good Drake receivers in the test below are essentially gutted and rebuilt receivers. They DO NOT use Drake mixers or amplifiers! Stock R4C's suffer from severe problems. See the notes!

TenTec Orion	-129	98	100	92	92

Note 1: The FT1000MP has the same inherent problem as the FT1000 and FT1000D. A noise-blanker FET is left on *even when the noise blanker is turned off with front panel NB and NB-W switches*. This FET connects directly to the IF, and overloads when strong signals are present. Unlike the FT1000 and FT1000D, the front panel noise blanker level control affects the FT1000MP IMD performance. * is with the NB gain control fully advanced, ** is with the NB gain control fully off. ***In ALL cases the NB off-on switch is OFF!!***

Note 1A: Yaesu copied the same basic NB from the FT1000D, and so this radio also has a NB problem even when the NB is switched off. This test was with NB gain menu set for minimum gain. The radio is worse when NB gain is increased in the NB gain menu.

Note 2: This is a MOSFET 2nd mixer R4C, aligned and in good shape but with no changes. This receiver is almost useless for weak signal CW work of any kind because of poor IM performance and filter blow-by.

Note 3: This is a tube 2nd mixer R4C, aligned and in good shape but with no changes. This receiver is almost useless for contesting or crowded bands because of poor IM performance and bad filter blow-by.

Note 4: This is the same receiver in note 2, but with the following changes:

1. Increased screen voltage on RF amplifier to 130 volts.
2. 6J6 first mixer with oscillator injection increased to 5 volts.
3. Diode double-balanced 2nd mixer with +10dBm injection.
4. 10dB of gain removed from first mixer and first IF and redistributed behind the narrow filter.
5. Sherwood Engineering 600Hz roofing filter.
6. New AGC system. After narrow filter only, no AGC on front end.

Note 5: Gutted and rebuilt with solid-state double balanced high-level mixers. No vacuum tubes in signal path. Sherwood 600Hz roofing filter.

My receiver Tests

Sherwood's Tests

We hear many things about R4C's (and other receivers), we love to talk about radios. Unfortunately most information comes from hearsay, useless subjective opinions, or from subjective reviews.

The only commonly published sources of measurements are ARRL or RSGB reviews. While the ARRL and RSGB do a good job of reviewing equipment, they publish somewhat useless wide-spaced data for receivers. Even with excellent wide-spaced performance, close spaced performance can be horrible!

Why Test at Wide Spacing?

Most manufacturers and many magazines test at wide spacing. When we have on-the-air interference problems, it is almost always with a station a few kHz or less away. Why would most of us care about a test or data at 20kHz or wider, when the bothersome signals are a few kHz up or down from us? Wide-spaced tests inflate performance, and gives us meaningless numbers for real-world performance.

Wide-spaced testing only evaluates RF amplifier and first mixer performance. Common design problems are easily and often missed when wide spacing is used. The weakest link is almost always downstream of the first mixer. There are several specific examples I can give:

1.) Receivers using DSP-based filtering systems for primary narrow selectivity.

2.) Receivers with poor 2nd mixer design (the R4C)

3.) Design errors in noise blankers, such as the **Yaesu's noise amplifier** design error

It's no wonder receivers have shown very little performance improvement over the years. Manufacturers evaluate performance on nearly useless wide-spaced measurements. They obviously only want to pass the wider test signal frequency spacing tests, because that is what we look at. Looking at 10kHz or wider tests, we all assume things are getting better. In actual use, most of our problems come from signals nearly on the same frequency, not 10kHz and especially not 50kHz away!

The only truly valid performance test is one where BOTH test signals are within the roofing-filter bandwidth. When close-spaced performance is good, wide-spaced performance is just as good or better. This is true for older radios and modern radios.

We also need to be factual in performance assessments. Too many feelings get in the way of being objective.

Receiver Myths

PIN Diode Mods

Save your money. PIN diode replacement never has changed performance in any receiver I've listened to or measured. PIN diode mods don't change distortion, blocking, noise, or any other parameter. A normal signal diode with proper bias is just as good.

PIN diodes function as "RF switches" or "linear RF resistors" only when the carrier lifetime exceeds the period of an RF cycle by a large margin. Most of the diodes used in PIN mods do not have long enough carrier lifetime to even behave like a low-distortion linear resistance, let along a pure switch. They really aren't any better than manufacturers stock diodes, with the PIN diodes barely being linear at 30MHz let alone at 455kHz. The whole "PIN diode thing" would be laughable if it wasn't costing people money!

If you have even measured a real difference, please e-mail and tell me what radio it was and what the test conditions were. If you are only going by emotion or feeling, don't bother reporting that. If I spent several hours and/or a few hundred dollars changing diodes and could not A-B the change, I'd probably think things got better also.

Drake R4C

The R4C is elevated to a status far above the realities of its actual performance. The R4C, like many DSP radios, has a wide performance variation between close and wide spaced tests. This is

especially true with the early S/N MOSFET mixer R4C's. With a wide-test, all R4C's look "good". That's because a wide test only checks the tube-type RF-amplifier and vacuum tube 1st mixer. Even though the R4C RF amp does better with higher screen voltage and the first mixer suffers from very low injection, the first two stages are still reasonable.

The problem is in the Drake 2nd mixer. The second mixer in the Drake ranges from poor to useless. The MOSFET mixer versions of the R4C are identifiable by looking at the MODE switch. If the MODE switch has CW 1.5, .5, and .25 positions the receiver has a tube (6BE6) 2nd mixer. If it is labeled CW1 and CW2, it has the horrible MOSFET mixer.

A few Drake website claims there is little or no difference between early serial number R4C's using MOSFET 2nd mixers and later R4C's using vacuum tube 2nd mixers. Nothing could be further from the truth. Worse yet, these pages steer people into a wide 6- or 8-kHz roofing filter for weak signal CW work, a very foolish choice as we will see by actual measurements. For serious CW work, the Sherwood Engineering 600-Hz roofing filter is an absolute must! R4C's have far too much filter leakage to be useful on crowded bands using CW with a wide roofing filter.

Roofing Filters

In order to significantly improve close-spaced performance a roofing filter has to attenuate signals on ***adjacent*** channels. We could have strong and weak signals CW alternating every 500Hz across the dial, assuming our transmitters were cleaned up. In the case of CW a roofing filter, to be useful, needs to be about 500Hz wide or less.

For SSB, we could consider channel width 3kHz. A roofing filer really needs to eliminate the adjacent channel up and/or down, and that means a roofing filter that passes only 3kHz or less.

While the typical wider roofing filters do a good job knocking down problems caused by signals up or down the band several kHz, they don't do anything for signals within the bandwidth of the roofing filter.

Testing Radios

TEST SETUP

My test setup uses two low-noise crystal oscillators. One oscillator is fixed on 1840-kHz, the other oscillator is selectable at 1840.5, 1842, or 1850-kHz (***note***: I now use variable frequency generators). Both oscillators use low-noise CATV transistors, and provide 20dBm output. These oscillators each feed a 1dB per step attenuator, with a total attenuation of 160dB available.

The attenuated outputs are fed to a "Magic T" combiner. "Magic T's", like every low-loss passive combiner system, are load impedance sensitive. Any mismatch reduces generator port-to-port isolation. In many cases, marginal generator-to-generator isolation can cause IMD in the signal sources. This generator-sourced IMD corrupts readings, changing IMD performance. To reduce combiner mismatch, the output of the magic "T" feeds a small ~3dB attenuator.

Signal level from each individual source can be varied in 1dB steps from +20dBm to -140dBm. +13.5dBm is the maximum level available, after combiner system losses of 6dB are added, for a final receiver signal range of +13.5 to -146.5 dBm. This range is ideal because my own transmitter is typically +15dBm on my closest receive antennas, while my daytime 250Hz bandwidth noise floor is near -140dB. Most of my receivers have sensitivities in the -140dBm range, allowing them to marginally get down to noise floor in the daytime. (Noise increases 10-20dB at night, on quiet nights, because of distant noise sources that propagate via sky-wave.)

Note: *Most setups use a single attenuator after the combiner, I chose not to do that. To reduce generator IMD, I decided to attenuate each signal source with carefully matched attenuators. If a test requires 30dB of attenuation, generator-to-generator isolation will be the sum "magic T" isolation and each attenuator pad isolation. In this case, generator-to-generator isolation would be well over 90dB, far more than I could obtain with the "Magic T" alone.*

The Magic-T combiner also has a 3dB 50-ohm output attenuator. This pad helps stabilize load impedances seen by the "Magic T", insuring return loss is at least 6dB. Total attenuation through the "Magic T", including the internal attenuator pad, is 6.5dB. The port-to-port cross talk of the magic "T" can be nulled with a small trim pot. This adjustment is only necessary when doing tests with near-zero attenuation and a mismatched receiver.

MEASUREMENTS

Since virtually every receiver overloads in stages after the attenuator or pre-amplifier, there probably is no compelling reason to measure receivers with the attenuator on. Adding an attenuator will not increase the dynamic range, it will simply move the raw measurement numbers higher. In other words, we don't care what the absolute numbers are...we can always add or remove gain external to the receiver. What we do care about is *dynamic range* of the system, both for blocking (a strong signal makes the weak signal disappear or get noisy) and intermodulation products. The lower the dynamic range numbers, the worse the receiver will be.

Measurements involve three basic procedures, all measured in dBm (dB milliwatts).

MEASURING MDS

A conventional signal generator is used to measure minimum discernable signal (MDS). This point is where the signal is just clearly audible, about 3dB out of the noise floor.

MEASURING BDR

Blocking Dynamic Range is measured by setting one oscillator (or the signal generator) to a test frequency either 2 or 10 kHz above the interfering signal. This test is equivalent to having a single strong station come on a certain amount away from a very weak station you are trying to copy, and making your receiver lose volume or have a hiss that increases compared to the weak signal's level.

To minimize generator noise, the low-noise crystal oscillators are used for the strong signal. This creates a "perfect" zero bandwidth strong signal with virtually no broadband noise.

The level of the strong signal is adjusted until the slightest detectable change in S/N ratio occurs. The difference between the MDS and the level causing the blocking is the blocking dynamic range. This will be the ratio of the weakest to strongest signal the receiver can handle without losing a noticeable amount of weak-signal sensitivity, if the strong signal is a perfect signal and the weak signal is right at noise-floor.

MEASURING IMDR

Intermodulation dynamic range, or two-tone dynamic range, is measured by running two equal strength signals (from the low-noise oscillators) into the receiver with a certain test spacing. This test is equivalent to having two strong signals very near each other, with just the right spacing to cause a mixing product to fall on top of a noise-floor signal you are trying to copy. When the signal level of the mixing product is just audible above the noise floor, the ratio of the strong signals to the MDS (minimum discernable signal) becomes the IM dynamic range.

Poor IMDR performance shows up as splatter on SSB and as bloops, bleeps, and random musical thumps or phantom signals on CW.

Look at some receiver measurements!

FT-1000 Noise Blanker Mod

[Home] [Up]

This mod is part of a plug-in package available from me. See the Keyclick mod page.

I've tested over 15 FT-1000 and 1000D's with this mod. This modification will reduce close-signal IM in every FT1000 or 1000D by a substantial amount!

The IM problem is created because the FT1000 heavily forward-biases the noise-blanker's first FET whenever the blanker is turned ***OFF.*** This causes the FET hanging on the IF system to have high gain. Strong signals within roofing filter BW saturate the FET's drain, causing mixing products (IM).

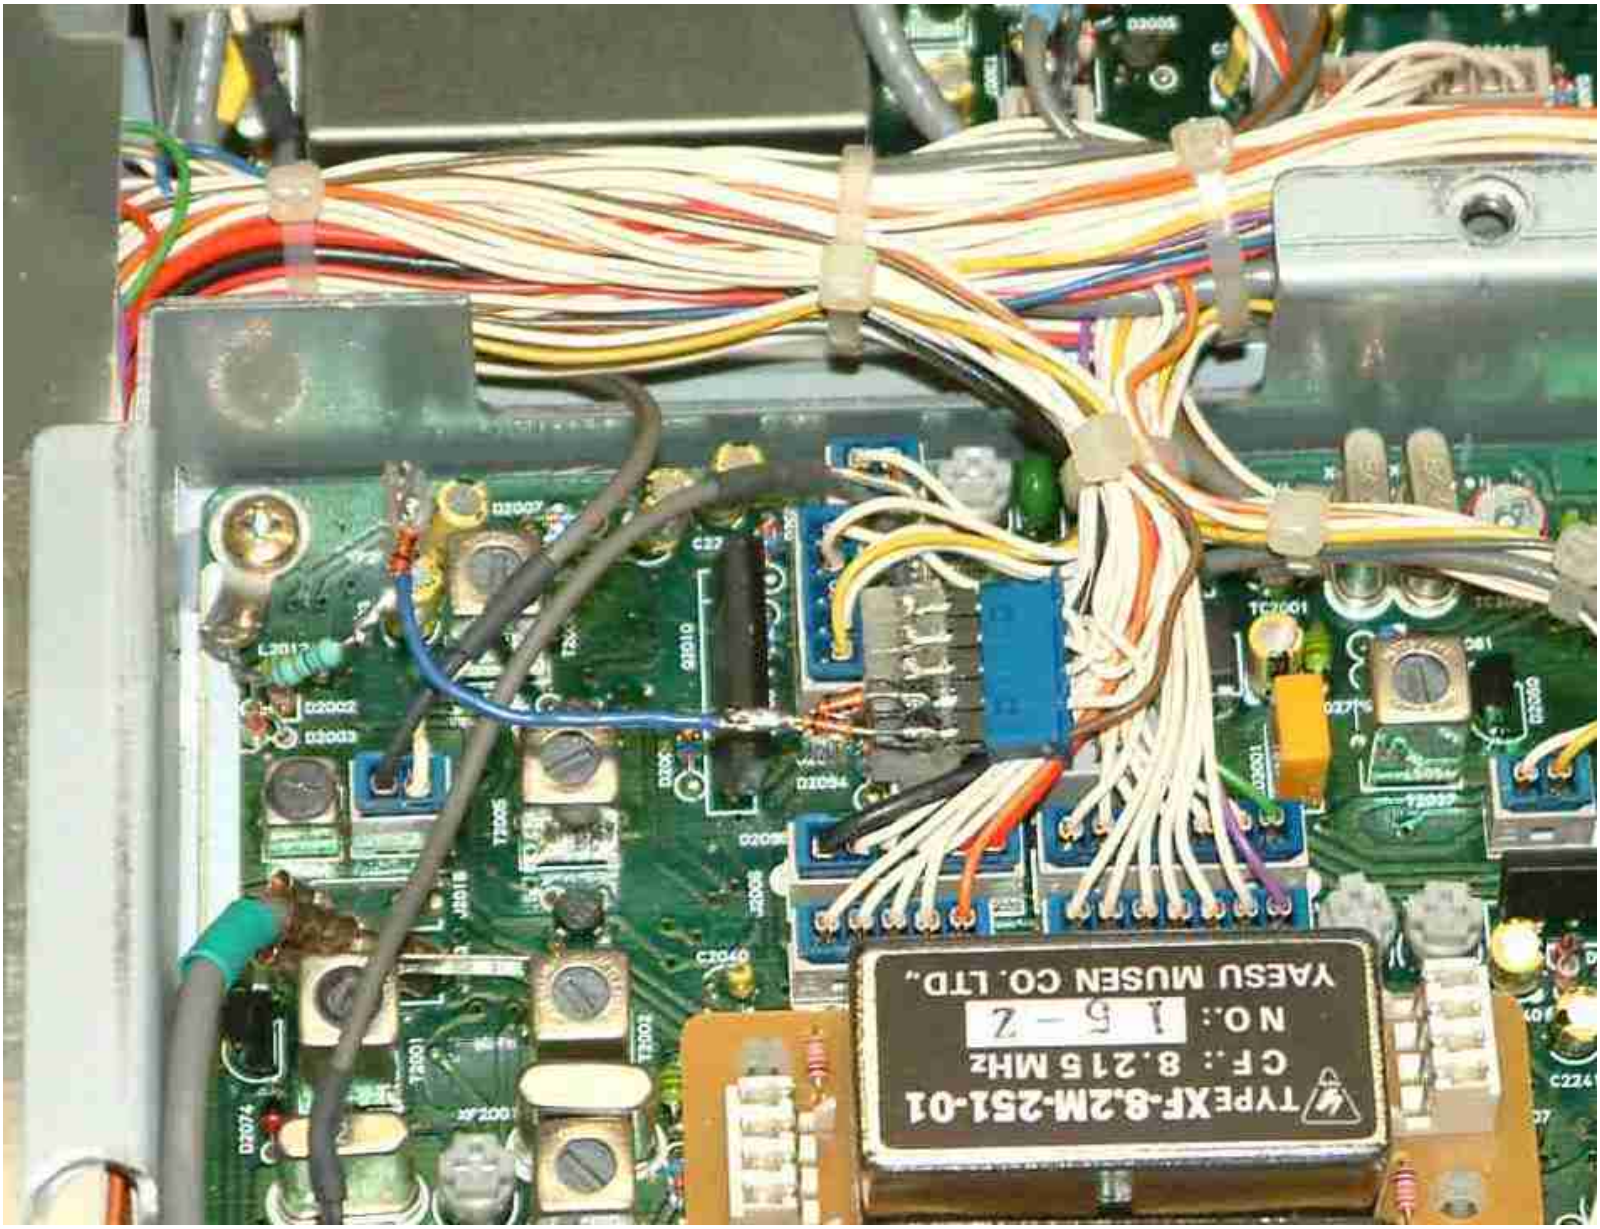
These new signals feed directly back into the 8MHz IF section, creating interference to any desired weak signals. The FET's IM creates new "phantom" signals that sound like normal CW signals. On SSB, it creates IM that sounds exactly like splatter!

This modification removes harmful forward FET bias when the noise blanker is off, and prevents the noise-blanker from creating interference to weak signals when the blanker is turned off. The NB functions normally when on.

The Mod

1.) Remove the bottom cover.

2.) Locate the noise blanker on the left rear corner of the IF board near the first group of 8 MHz filters.



Download Picture

3.) Locate TP-2001.

4.) Connect a small silicon switching diode (1N4148 is one example, although other silicon-type signal or switching diodes will work) through a 10k ohm resistor to ground from TP-2001. The diode cathode (banded end) goes towards the resistor and ground, anode towards TP-2001.

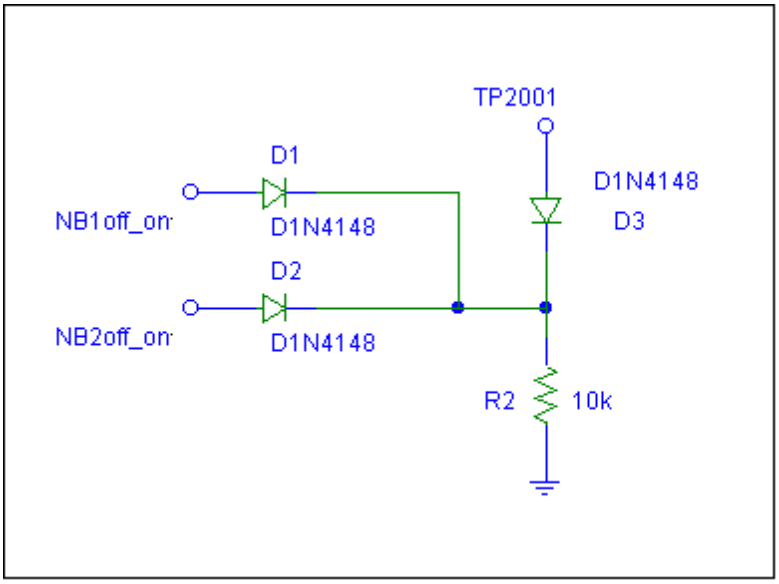
Caution: DO NOT use a high leakage germanium diodes. Use low-current silicon switching or detector diodes.

5.) Construct a pair of diodes with the cathode (banded end) tied together. Leave the leads long for now.

6.) Connect one of this diode pair's anode to pin 1 (the brown wire) of J2001.

7.) Connect the other diode anode to pin 2 of J2001.

8.) Connect the common-cathode of these two diodes to the junction of the 10K resistor and the cathode of the diode installed in step 4.



Note: I just pushed the wires down in the pin of the plug (P2001) and tacked them in place with a tiny bit of solder. You can verify these are the correct pins by measuring the voltage when switching the NB and wide NB buttons. Turning either or both NB switches "on" applies about 8 volts to either or both pins. Connect the common to the diode cathode and 10k resistor junction through a short hook-up wire.

This mod removes forward AGC bias from Q2003 and 2004 when the noise blanker is off, and prevents IM distortion fed back via C2041 and foil traces from impacting the receiver when the noise blanker is off. Other than improving IM performance when the blanker is off, it has no effect on NB performance.

Revised 1/31/04 at 0130Z

Receiver Improvement for FT1000 and 1000D

The FT-1000(D) runs an essentially unshaped CW waveform into the filters. This harsh signal generates unnecessary key clicks. The clicks are strongest from almost 1 kHz below to 2kHz above the transmit frequency.

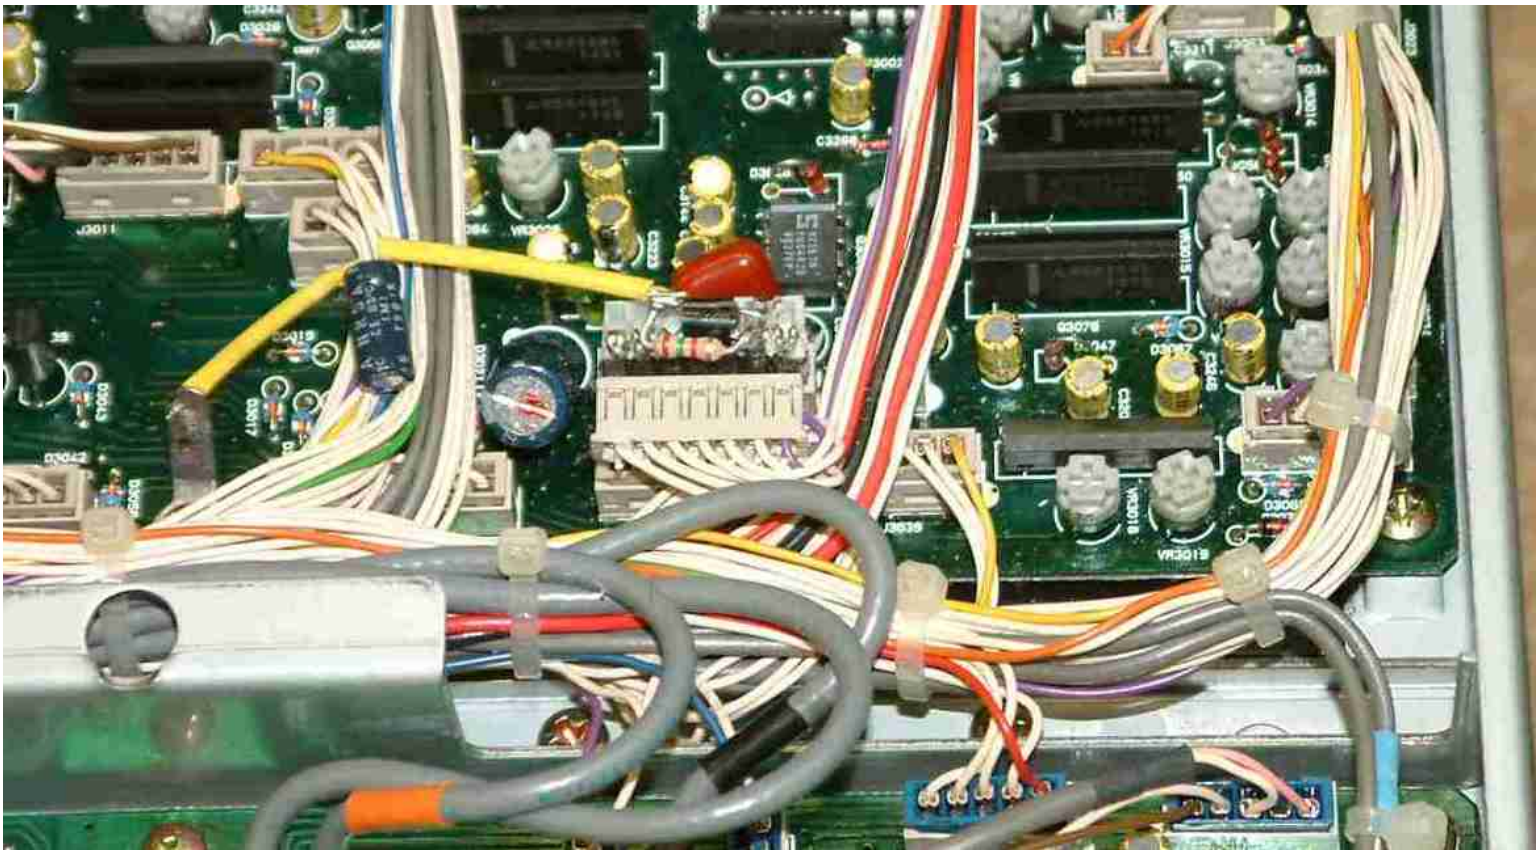
The cure:

I now have a plug-and-play 100% tested mod for the FT1000 and 1000D. This mod just plugs in, and includes the receiver NB mod.

Neither mod requires soldering! Only a screwdriver is required. The price for both mods is $45.

View plug in mods.

Locate the seven-pin connector J3024 at the middle-front of the AF board. (The AF board is the one with the audio, PTT, ALC, and key jacks as well as other connectors.)



This is a picture with a hand-wired mod in place.

Download picture

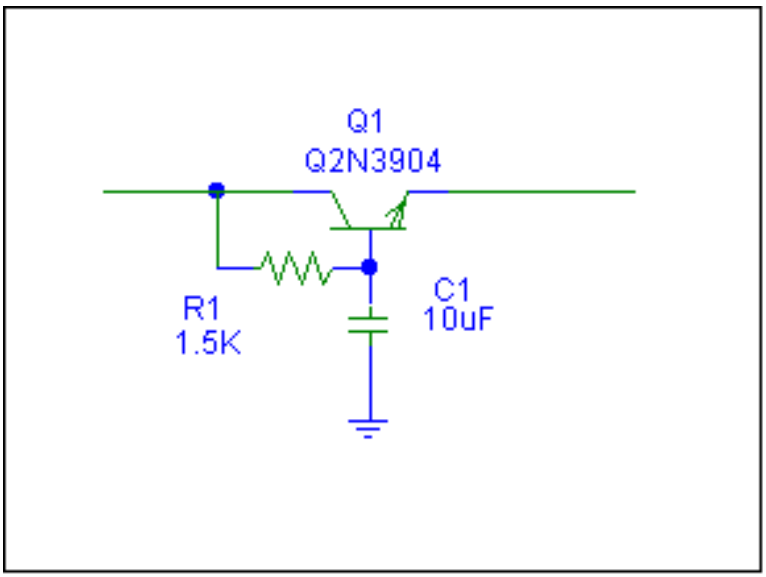
Cut the wire going to pin 2 T CNTL). This is the second terminal from the right (front of radio viewing). This is NOT the lead with 9 volts (nine volts is on pin 6). If you are unsure you counted the correct direction, measure the voltage!

Connect the collector of a 2N3904 to the flying harness wire you just cut.

Connect the emitter towards the jack on the wire you just cut. This transistor MUST be a 2N3904.

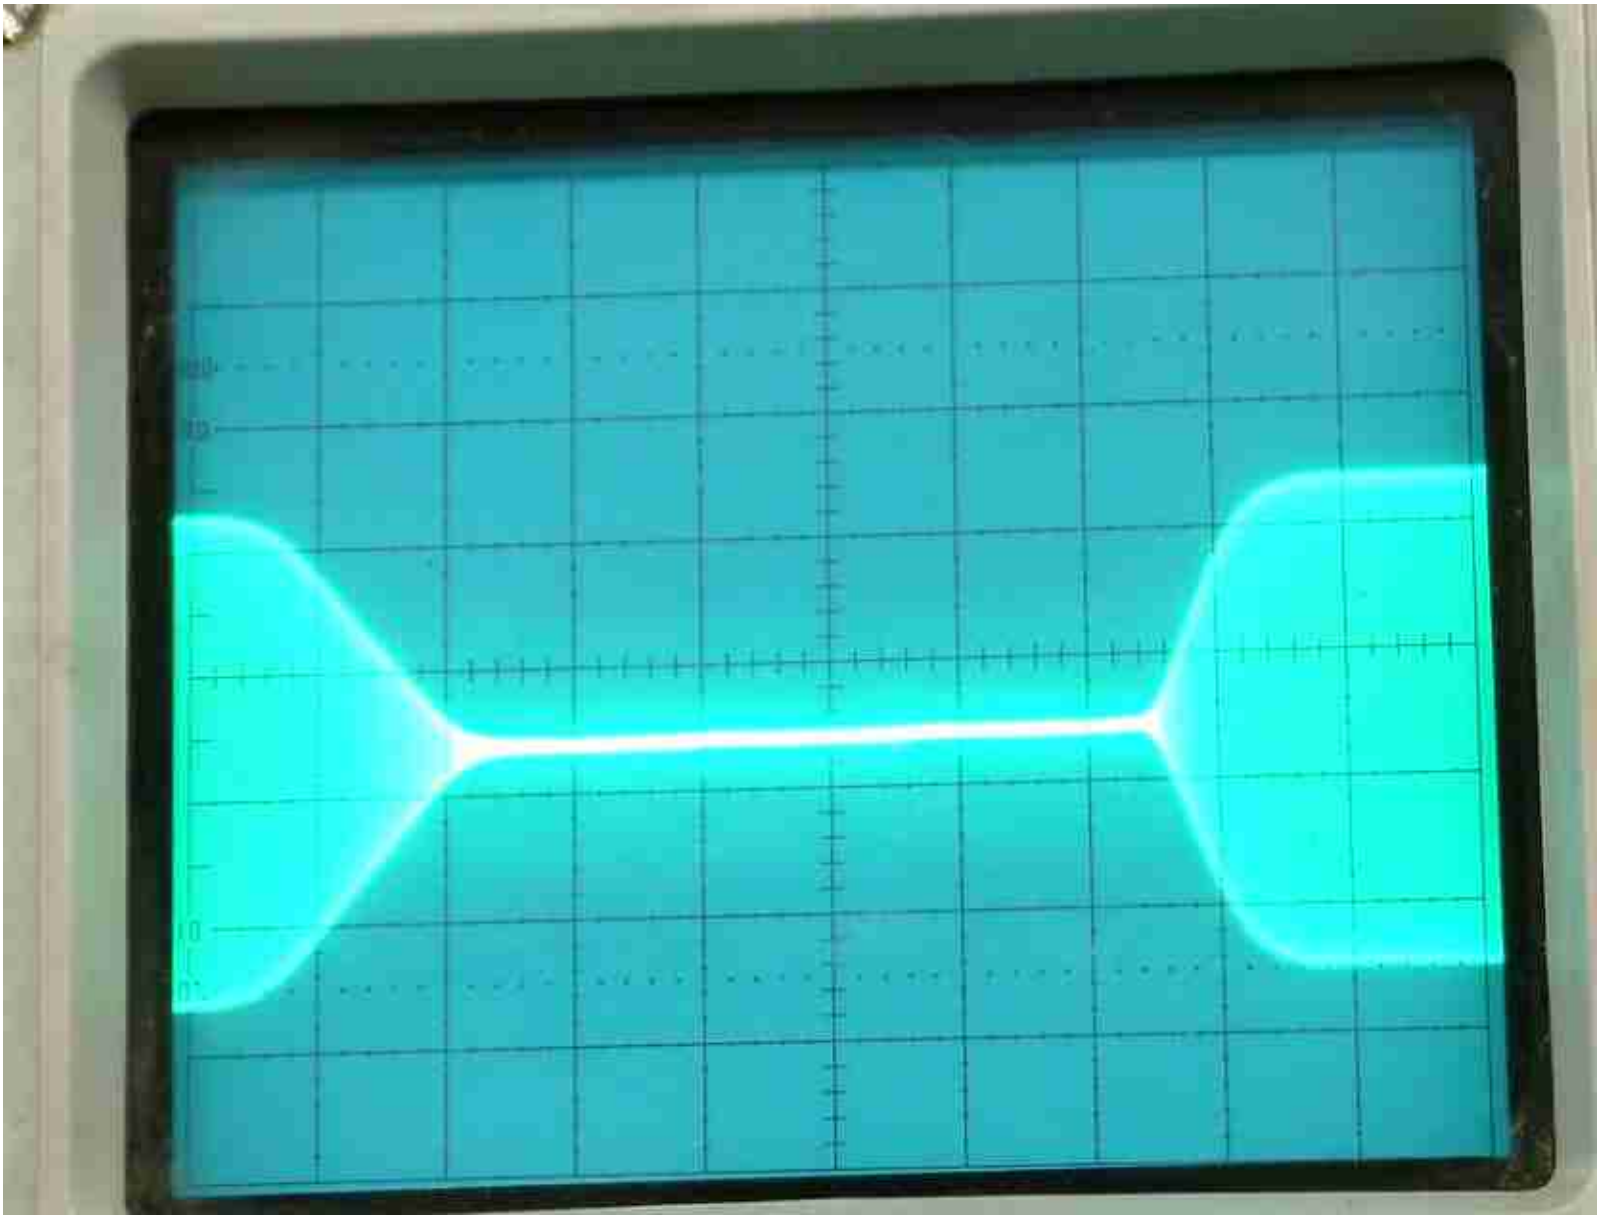
Connect a 1.5k resistor from collector-to-base on the transistor.

Connect a 10uF, 25-50 volt capacitor from base to ground. A non-polarized capacitor may be better, if you can find one. No one has reported problems with normal electrolytics as long as the positive lead connects to the base of the transistor.



The Results:

This modification slows the waveform rise and fall times at Q3030 and D3009. The result is a normally sloped CW waveshape into the SSB filter.



This is a nearly-perfect waveform with about 7mS fall and 4ms rise. The important thing is there are no sharp edges that cause clicks!

Clicks beyond 1 kHz above and below the transmitting frequency move into the composite transmitter noise, and there is about 50 dB reduction in clicks on some radios above the TX frequency!

Clicks 500Hz away are reduced about 20-35dB.

There is almost no change in "keying sound" on the transmitting frequency. The envelope shape is near ideal, and bandwidth reduction is dramatic.

Operating

Warning: This mod is NOT compatible with QSK with the full 10uF in circuit. For QSK use, I suggest adding a SPST switch from the 10uF capacitor to ground. You can place an additional 10uF capacitor across that switch, or simply add an additional 10uF in series with the ground lead from C1 (this gives 5uF total value at the base of Q1) and *not* switch the system. When not operating QSK, I recommend using the full 10uF of C1 for the cleanest signal.

The ideal wave shape occurs when the ALC is at the upper area of the blue ALC line on the FT1000 meter. With full **DRIVE**, adjust for desired power with the **RF PWR** control. After achieving desired power, back the **DRIVE** down until the ALC indication just starts to move away from full blue area (half-scale). Anything from 1/3 to 1/2 scale is a normal waveform.

For lowest clicks, adjust **DRIVE** until ALC until it just registers (perhaps 1/8 to 1/4 scale on ALC).

Keyclicks

Bandwidth rules Part 97.307

Link to W9CF. Kevin analyzes key clicks mathematically.

I noticed W2VJN has proposed using absolute signal level at a fixed test spacing for click measurements. While I agree with George's suggestion (this link) we use an established test method, I strongly disagree that a 15Hz BW signal level measurement of the peaks accumulated in dozens or hundreds of scans is any more useful that listening off-frequency on a known good receiver.

While his mod is certainly better than a stock Yaesu, clicks also can be reduced more than his method provides without affecting ability to work weak signals. We don't need to watch output power and keep duty cycle to 50%, a slight adjustment of weight control would do the same thing.

The real point is that both George and my suggestions are patches, they are not cures. Yaesu should step up to the plate and be responsible, and set an example for others to follow.

Testing

We really need to establish a standard for measurement of transmitters on both SSB and CW, and it should be the effective spurious power level on close adjacent frequencies using typical CW bandwidth. Looking at one spot with slow sweep and peak storage on a spectrum analyzer is not a good test.

It's pretty easy to see using the level (at one specific frequency) of a long-time average of signal peaks with a narrow filter sweeping by (which is what spectrum analyzers do) is a bad idea.

Some radios have a sharp click on one edge, and nothing on the other. This causes peak energy to be higher in proportion to average energy. Radios can have higher peak level and actually do less damage to adjacent channels than a lower level click that hammers on both make and break, like the FT1000MK V does.

If I look on a peak sample and storage device like my spectrum analyzer, a radio could actually

look worse yet bother adjacent CW bandwidth channels LESS than a radio that appears to be better.

A very narrow filter swept over the frequency with average storage of peaks does not account for attenuation slope modulation sidebands. I'd rather have a radio next to me with a steep drop in clicks at 500Hz than one with a single-pole gradually shaped slope even if the gradual sloped radio had less level. A peak comparison at some specified spacing misses too much.

SSB vs. CW

CW shares the same testing problems as FM and SSB. The FCC has changed some commercial voice tests to focus on spurious power level on adjacent channels, rather than using conventional but somewhat useless two-tone tests. A two-tone test shows the very ***best*** a radio is likely to do, not the ***typical performance***. The FCC now requires normal modulation and an adjacent channel ***power level measurement*** in some cases.

CW and SSB testing for amateur use should be the same way.

I think is is shameful that manufacturers can't manage to spend a few hours of engineering time to select different component values, instead of sticking us with radios that have poor keying and IM characteristics. Frankly, there is NO excuse or justification for selecting wrong component values in a such a simple design area.

Is an excessively clicking radio legal?

Most of us agree right off the bat that some radios are annoying, and MOST people actually want to have the cleanest possible signal. Of course there are a few self-centered people who care less if they bother other people. They generally use the excuse that since a radio was sold it must be legal.

Here is a link that shows the exact 97.307 FCC text.

What do bad and good signals sound like?

For now, you can listen to some recordings and judge the difference.

Key clicks are off-frequency sidebands heard when there is no trace of a tone. If you listen carefully to these recordings, you will see the "hardness" of a properly filtered transmitter on frequency sounds very little different than the hardness of a wide, clicking signal.

Here are some sound files....these files are intended to be educational. While it isn't OUR fault the rigs were incorrectly designed, it is our legal obligation under 97.307 to correct the problems we have been stuck with. This is especially true when big antennas and amplifiers are used.

First, this is a mono recording of a virtually click-less radio. This station is 20dB-over-nine, and my noise is S2. When you listen, notice the "clicks" disappear right when any trace of tone vanishes. You'll notice the CW still sounds hard, and this station regularly broadcasts high-speed CW that hundreds of people copy. This is the ***Click-free signal*** of W1AW on 160 meters.

If you own a stock FT1000, FT1000D, FT1000MP or FT1000MP MKV (or any rig with a rise and fall faster than 4 or 5mS OR with any sharply rounded corners) you have work to do!

Notice key clicks can be heard long after the tone disappears totally, as we tune across the signal, yet there isn't any trace of receiver desense. S-9 plus 10dB station from England, 40-meters, using ***FT1000MP MKV*** tuning up 2 and down 2 using 500Hz RX filters. Significant clicks in the USA from England well after sunrise in England when signals are dropping. Imagine a 40 over MKV! This appears to be typical of all MK V's

S-9 +20dB in S-2 noise tuning from 1.5kHz below stock ***FT1000D*** (sorry, I snipped the above freq tuning to avoid call sign) This is typical of all FT1000(D)'s

40-meter signal S-9 plus 15dB, background noise S-2, 500Hz filters, tuning up and down 2, recording of ***FT1000MK V***. This rig cuts a 3kHz wide swath that is S-6 or stronger.

40-meter signal S-9 plus 25dB, S-1.5 noise. Tuning up 2 and down 2, 500Hz filters in RX. ***Omni-6*** (This might or might not be typical of all Omni-6's. Ten-Tec reports an internal adjustment, when incorrectly set, causes these clicks. I've logged several Omni-6's with this problem, and some users continue to receive complaints after trying suggested mods. The characteristic I seem notice is key clicks extend downwards much more than upwards in frequency.)

160-meter, S-9 plus 15 dB signal, S-1 noise, tuning up and down 2, Inrad-mod in ***FT1000MP***

20-meter ***Kachina***. S-1 noise, signal S9 plus 10. Which signal is the "real signal"? A snip of a clean signal answering him, about the same signal level, is at the end. Spurs went down 2.4 and up 2.4, and were spaced 600Hz apart. (This might not be typical of all Kachina's)

40-meter signal, S-9 plus 10dB signal S-2 noise, tuning up and down 2kHz, 500Hz filters, stock ***FT1000MP*** (this is typical of all stock FT1000MP's. If you own one that has not been correctly modified, you can be sure it has grossly excessive key clicks)

160-meter signal, S-9 plus 20dB S-1 noise, tandem 250Hz filters in very high-dynamic range CW-only receiver, tuning up and down 1.2 kHz, stock ***IC765***

©2003 W8JI

FT1000MK_V

[Home] [Up]

Preliminary tests show very strong keyclicks +1kHz and -1kHz. The LSB clicks peak 500Hz below the TX frequency, and the USB clicks (in the LSB mode) are very obnoxious because they are at twice the rate as LSB clicks (strong on both make and break).

The FT1000MK V shows a 1mS rise and a 2ms fall with sharp edges and a very poor rise and fall slope.

Keyclick and Noise Blanker Mod for FT1000MP MK V

It's great to see a manufacturer offer improved close-spaced SSB transmit performance. The MK V Yaesu reverses other modern radio's downward spiral of transmitter SSB IM performance. Yaesu included a class-A mode.

Unfortunately close-spaced receiver performance has been neglected, and this affects all modes. The transmitter also has nasty CW clicks. Stock MK V's appear to be as bad as or worse than older 1000 series radios in two important areas:

- Clicks appear to be more severe than those from the notoriously poor 1000MP's
- The noise blanker continues with the same circuit error as the FT1000/1000D/MP series

Since a portion of the keyclick mod requires accessing the same general area as the noise blanker, it would be prudent to fix the receiver and transmitter at the same time. This article offers a combined modification that patches both problems.

Keyclick Problem

Raised- sine rises and falls would provide the fastest possible CW speeds for a given bandwidth. With properly filtered rise and falls, we would hear little or no change or softness when listening on-frequency. Tuning off- frequency, clicks would quickly vanish.

If you want to hear the sound of proper shaping, listen to this click-free signal recording as I tune across the signal. Off- frequency (even a few hundred hertz), we hear no clicks at all. On- frequency the CW is "hard" sounding, allowing copy to 60-WPM or more. When the tone disappears in the deeper receive filter's skirts, clicks also disappear.

In contrast, compare the MK V recording as I tune past the signal. This signal is from Europe on 40 meters!

There is a day-and-night difference off frequency between the no-click and loud-click signals. On-frequency both signals sound the same.

MK V clicks are caused by excessively fast rise and fall, and very poor shape of the rise and fall.

Rumors sine-shaped waveforms impact tone or readability of signals are false, as are claims clicks rolling of at some "X-dB-per-octave rate" beyond a few hundred Hz are a necessary part of life. Such statements are misleading, likely being based on the incorrect assumption the receiver has very wide bandwidth and the transmitter is filtered through a single stage simple resistor-capacitor click filter.

Unfortunately when we patch poor CW transmitter designs, we can not make perfect corrections. Without major modification we can not modulate the MK V (or most other transceivers) with properly filtered (which also means perfectly shaped) rise and falls.

This modification, like the MP and 1000D click mods, is a patch...not a cure.

Patches Vs Cures

Because mods on existing radios are patches, the radio owner must make a choice. If the user operates speeds faster than 45 or 50 WPM, the rise and fall required for legal close- spaced operation may be less than ideal. This does not mean the ability to work weak signals at modest speeds (up to 30 WPM) would be compromised even the slightest amount. It means high- speed ops (speeds over 45-50 WPM) may find the CW slightly mushy when adequate for close-frequency operation.

If a 2 or 3 millisecond rise and fall is used for operation at very high CW speeds in a single-pole R/C filter (this radio uses a simple RC filter) a transmitter is almost guaranteed to interfere with less strong signals within 1kHz or so. Transmitters with fast rise and fall times should stay at least 1.5kHz away from operators working weak signals, especially when the CW transmitter has 1930-era transmitter CW shaping.

Operators with stock MP MK V's should always try to operate at least 4kHz away from weak or moderate signal- level stations. Part 97 rules prohibiting keyclick emissions that interfere with adjacent frequency operations. The specific rule is 97.307(b) "Emissions outside the necessary bandwidth must not cause splatter or keyclick interference to operations on adjacent frequencies."

The Click Mod

The actual click mod requires changing two stages. The first stage modified is on the IF board. The IF mod slows the rise and fall of mixer transistors Q2033 and Q2038.

Note: This stage is easy to modify, and is located on the same board as the noise blanker. This allows the noise blanker to be corrected at the same time.

By itself, modification of the easy-to-reach IF board is NOT effective for substantially reducing clicks. A later stage on the RF board also has truncated rise-and-fall times with a very poor R/C edge-shaping system. This later stage continues to add clicks even after earlier stages are modified.

RF amplifier stage Q1001 has the fastest rise and fall in the RF section. Q1001 must have proper gate bias shaping and timing to reduce clicks to acceptable levels. Removing D1002 and altering components around Q1002 slightly reduced clicking, but I concluded any effort wasn't worth the result with bias rise and fall more rounded at Q1002.

As designed, Yaesu uses a square wave very rich in harmonics to drive a simple R/C filter. This poorly filtered square wave amplitude modulates the RF and IF sections. The poor basic filtering design, combined with non-linear amplitude response, requires great care in component selection. It also means we never will achieve the optimum bandwidth for any give rise and fall time and ultimate CW speed.

The NB Problem

Signals inside the wide roofing filter BW of the MK V reach the gate of Q2009 through C2043. This point precedes the narrow 8MHz IF filtering, allowing a rather wide swath of unwanted signals to reach the gate of Q2009. Q2009 is left operating even when the noise blanker is turned off, and can have substantial gain depending on bias voltages at TP2001. Bias voltages at TP2001 can be varied by changing menu settings for NB gain, but never fully turn off Q2009.

The accumulated level of all signals reaching the gate of Q2009 produce a large net voltage at the drain of Q2009. This voltage (and resulting net current) causes overload and distortion in the non-linear characteristics of Q2009 and 2010 (my manual has very poor printing, but I believe it says 2010).

New signals created by this distortion and the resulting mixing products are fed back through C2043 to the IF strip. The IM products appear as "phantom splatter" on SSB and " phantom signals" on CW. We can not actually hear the distortion on frequency of strong signals. Instead the IM products appear in the form of artificial interference when we attempt to copy weaker signals within 10kHz of a mixture of signals containing a few moderately strong signals.

The NB Patch

The NB mod is a simple effective mod, and improves close-spaced IM3 dynamic range around 10dB. A simple factory change of moving one foil trace would have made the MK V receiver noticeably better, but fortunately this mod is fairly easy for owners.

The NB correction removes the surface mounted 220-ohm resistor (R2046) from the source of Q2009, replacing it with a 220 ohm resistor connected between Q2009's source at C2027 and Q2016's (2SC4047) collector and the junction of R2049 (220-ohm also).

Making the Mod

This mod is a little more complex than the FT1000MP mod because the chassis of the MK V is a little more complex and unfriendly. Like any service work, having a clean open bench and a spot to separately store screws and other hardware removed in every step in order will make the job smooth and easy. (If someone sends step-by-step text, I'll put it on this page.)

Some may wish to remove and change parts, but I prefer to wire the click-mod to a single terminal strip. This will allow you to customize the mod, switch the mod in and out, or correct any errors without dismantling the entire radio.

You'll need the following parts:

(1) one foot each of two small insulated wires, #20-#26 one (preferably) green and one blue to make connections

(1) four-lug (with ground) terminal strip

(3) .1uF 50 volt disc capacitors (C1-C3)

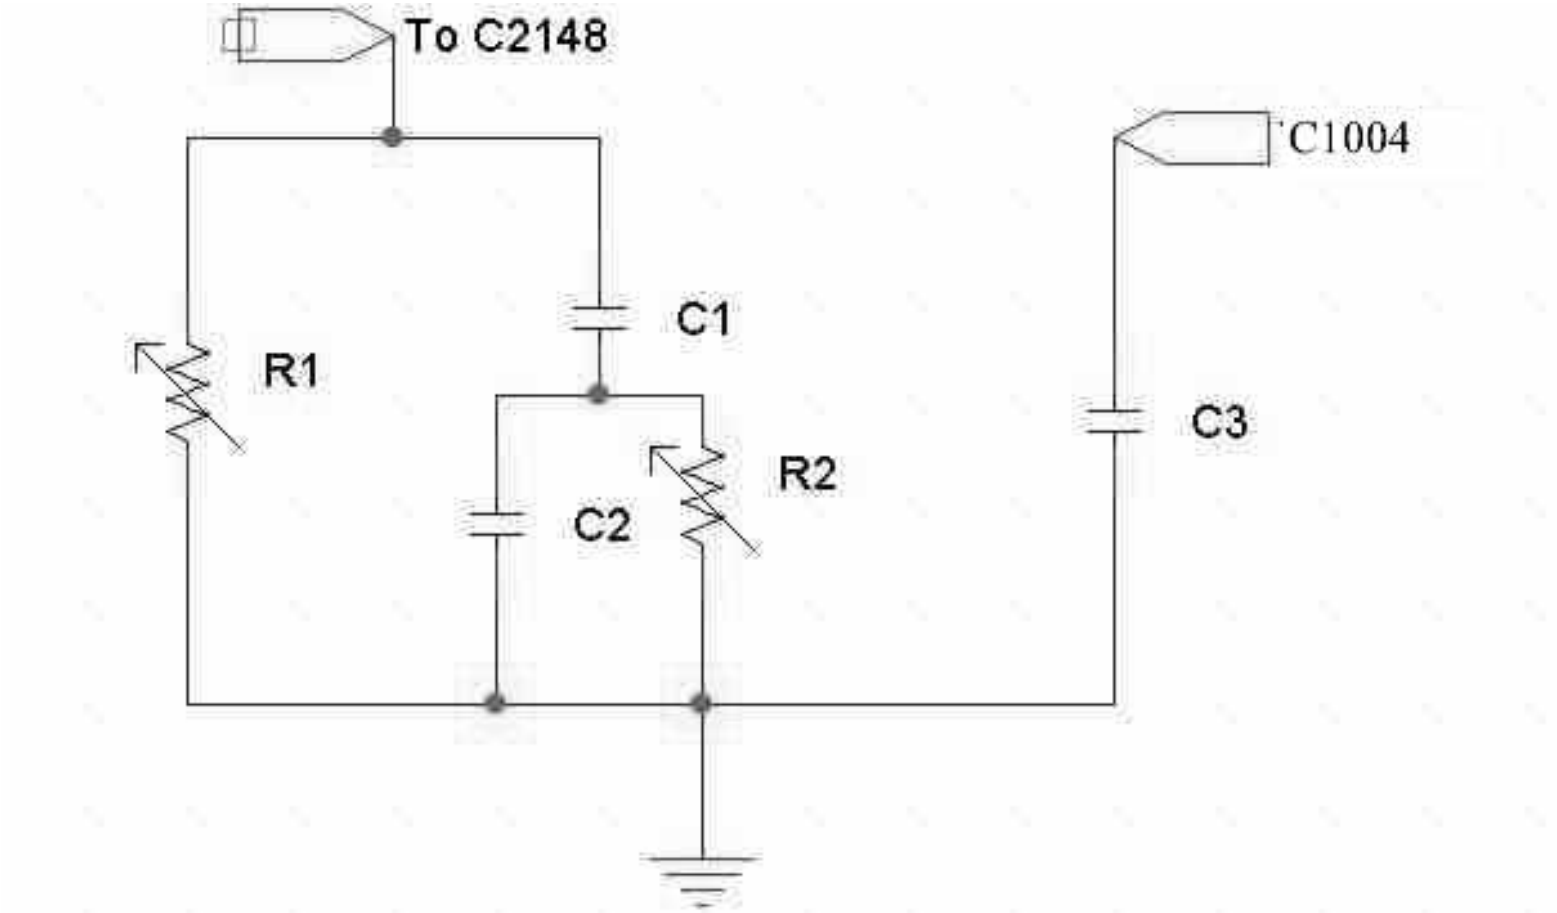
(1) 22k 1/4w fixed resistor (R2)

(1) 680k 1/4w fixed resistor (R1)

(1) 220-ohm 1/4w fixed resistor

In addition you need a well-lit bench, along with some hand-tools such as soldering pencil and solder, screwdrivers, and cutters and strippers.

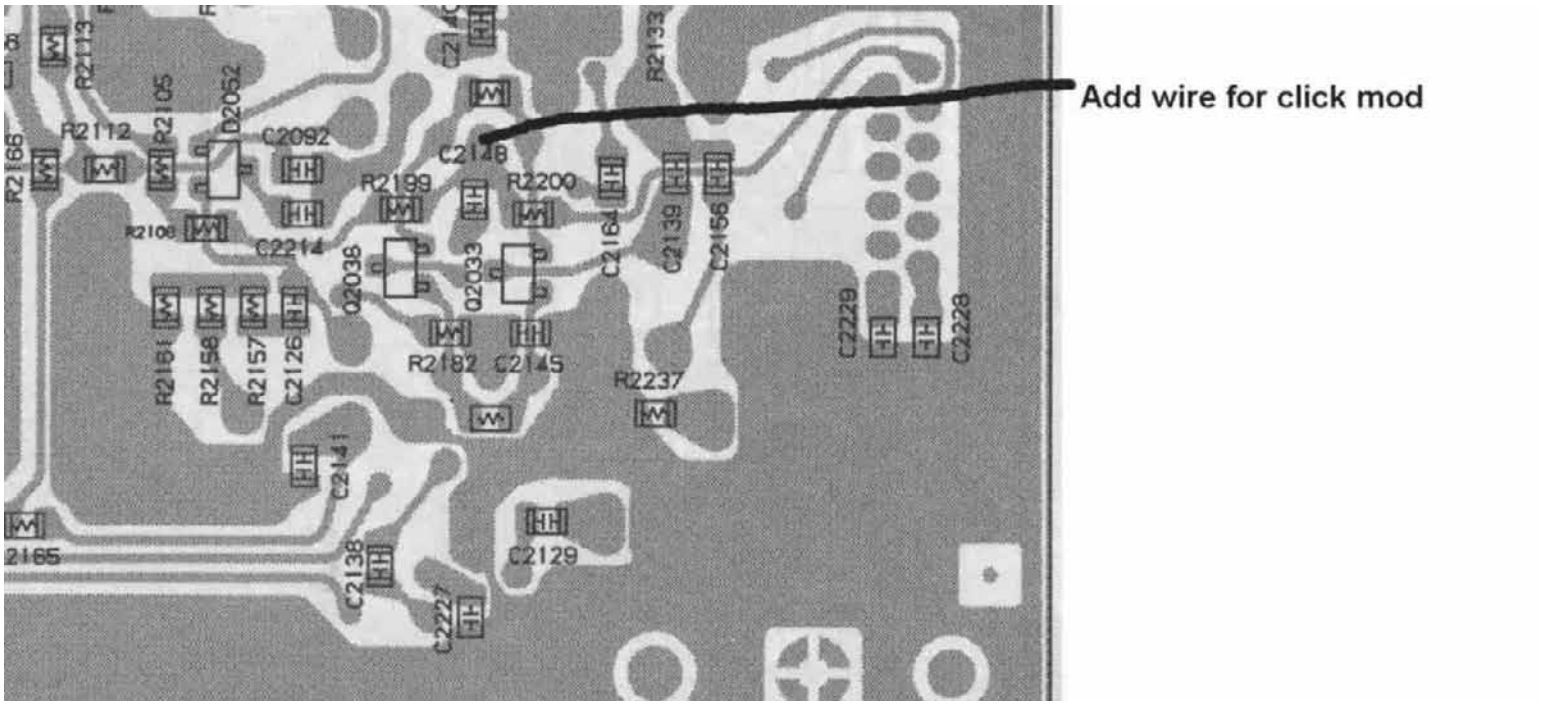
Populate the terminal strip as follows:



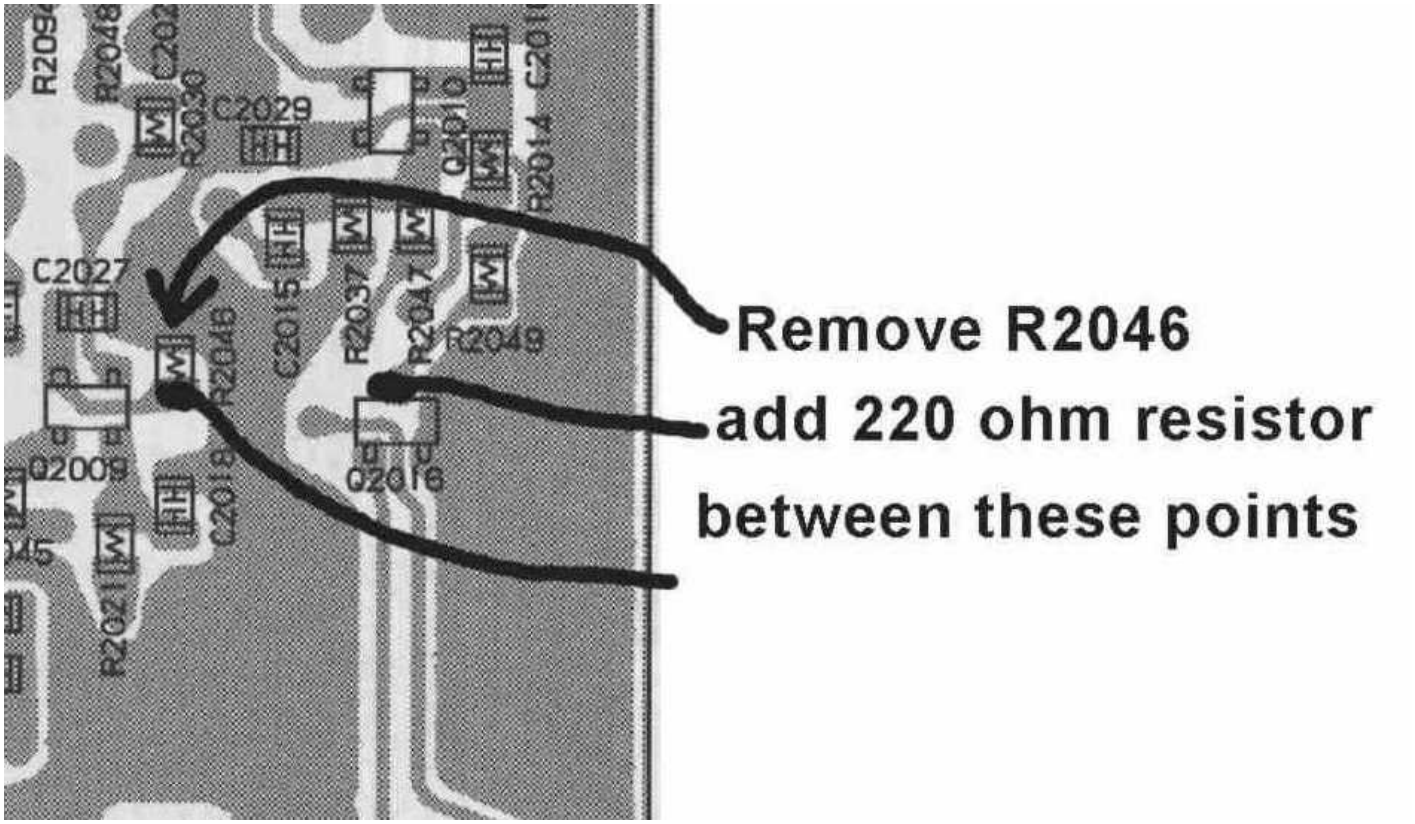
Remove top and bottom covers to gain access to internal circuitry

Remove the screws holding the IF board in place, and the minimal amount of plugs to allow flipping the IF board over. Draw a roadmap of all plugs that must be disconnected. This will help you remember where everything goes!

(click here to download expanded IF board if needed)



Attach one end of the blue wire to the ungrounded end of C2148, let the other end float



Locate and remove R2046.

Add the 220-ohm resistor to the Q2009/C2027 source and capacitor connection point

Connect the other lead of this resistor to the junction of Q2016's collector and R2048.

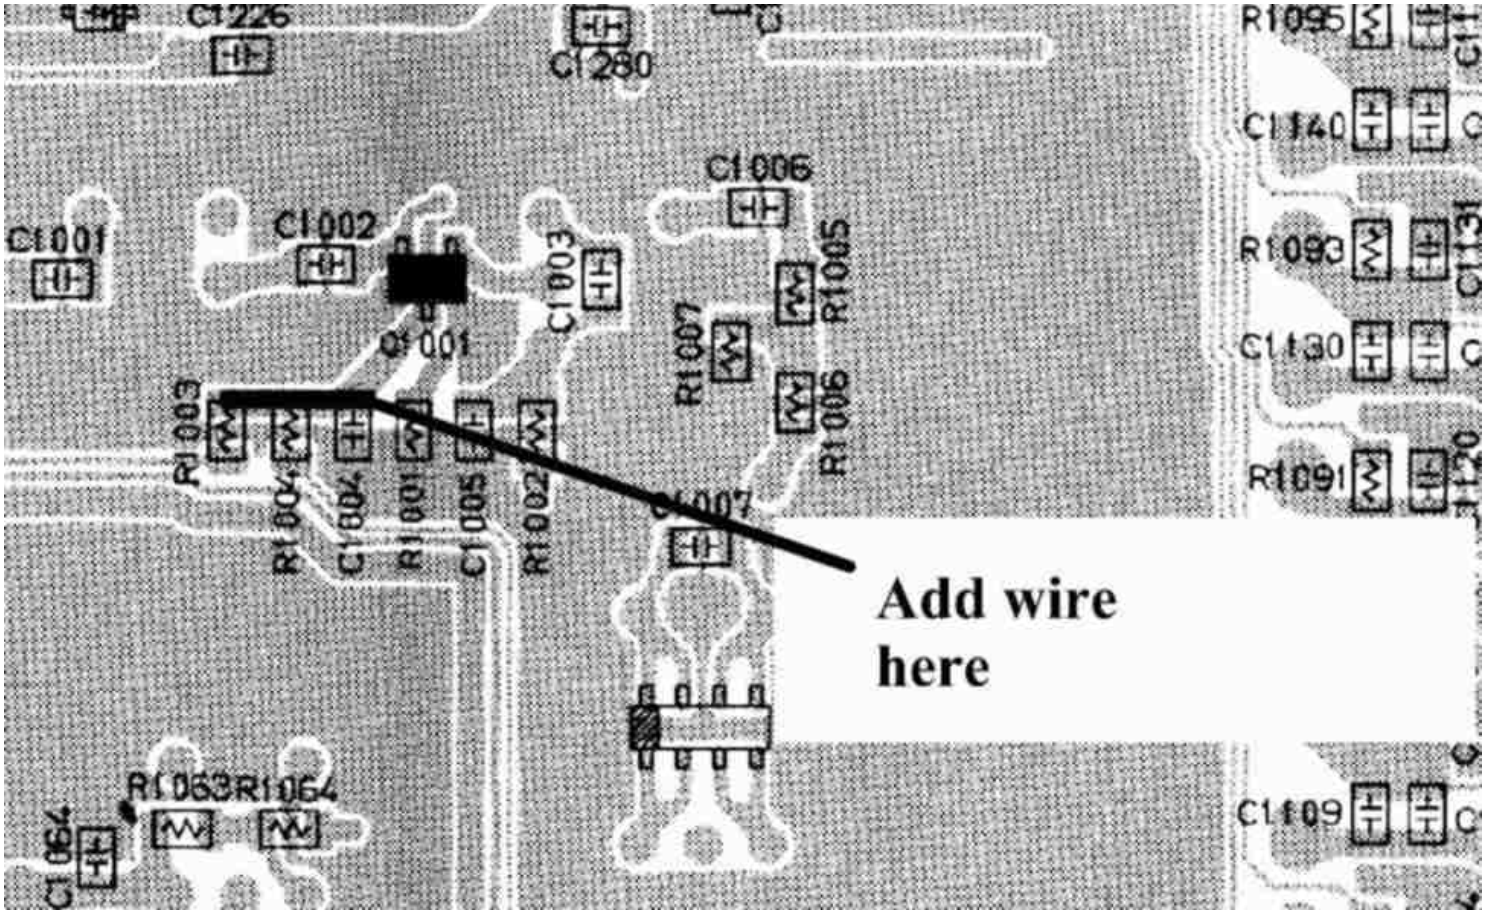
Reinstall the IF board with the flying lead exiting the closest edge of the PC board.

(Take care to avoid pinching any wires.)

Remove all hardware necessary to access the RF board

Remove the RF board

(Click here to download an expanded view of RF board if needed)



Attach the green wire to the junction of C1004 and R1003/R1004 at the gate of Q1001

Route this wire up to the area of the IF board

Reinstall the RF board and all other hardware taking care to not pinch any wires, and to reconnect all unplugged wires in proper locations

Select a clear area on the IF board and mount the terminal strip under the screws

Connect the green wire (from RF board) to C3, and the blue wire from IF board to the junction of C1 and R1. R1 is a 680k resistor, and R2 is a 22k resistor

Test the radio and reinstall the covers

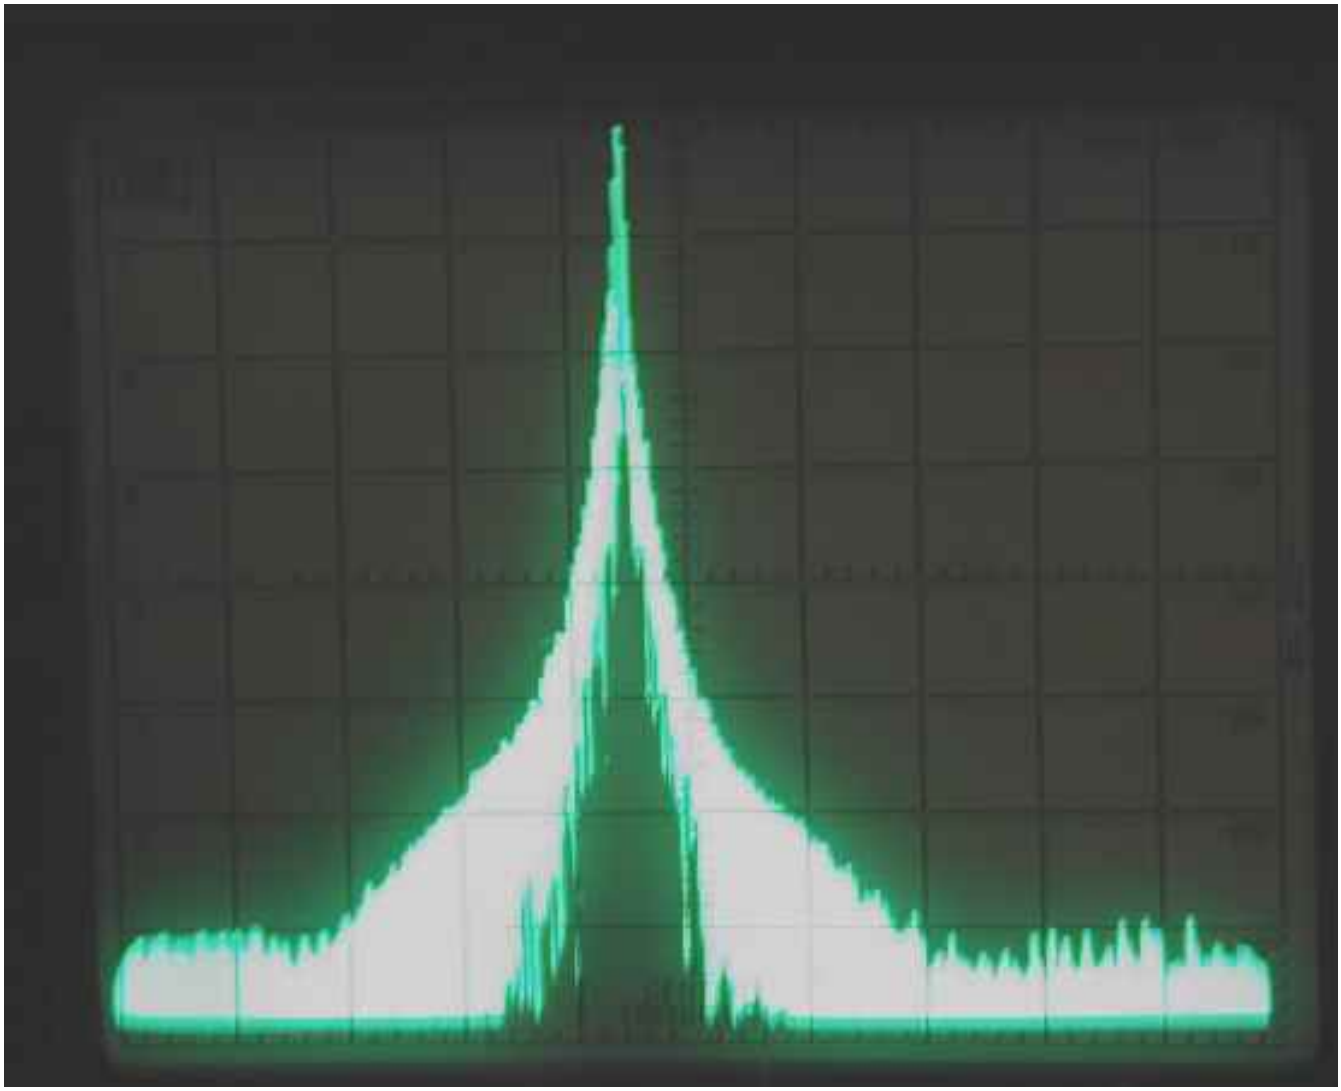
Curing FT 1000 MP CLICKS

FT-1000MP Measurements

I measured two sample FT-1000MP's (an early and a late model) by operating them into a high power fixed 30 dB attenuator pad. The output of the 30 dB pad was connected through a 3-way splitter to a step attenuator and conventional receiver, a spectrum analyzer, and an oscilloscope. The receiver used a 300 Hz eight-pole filter, the spectrum analyzer used a 50 Hz filter, and the scope was triggered from an external keying signal. Power was measured on a conventional Bird average reading meter.

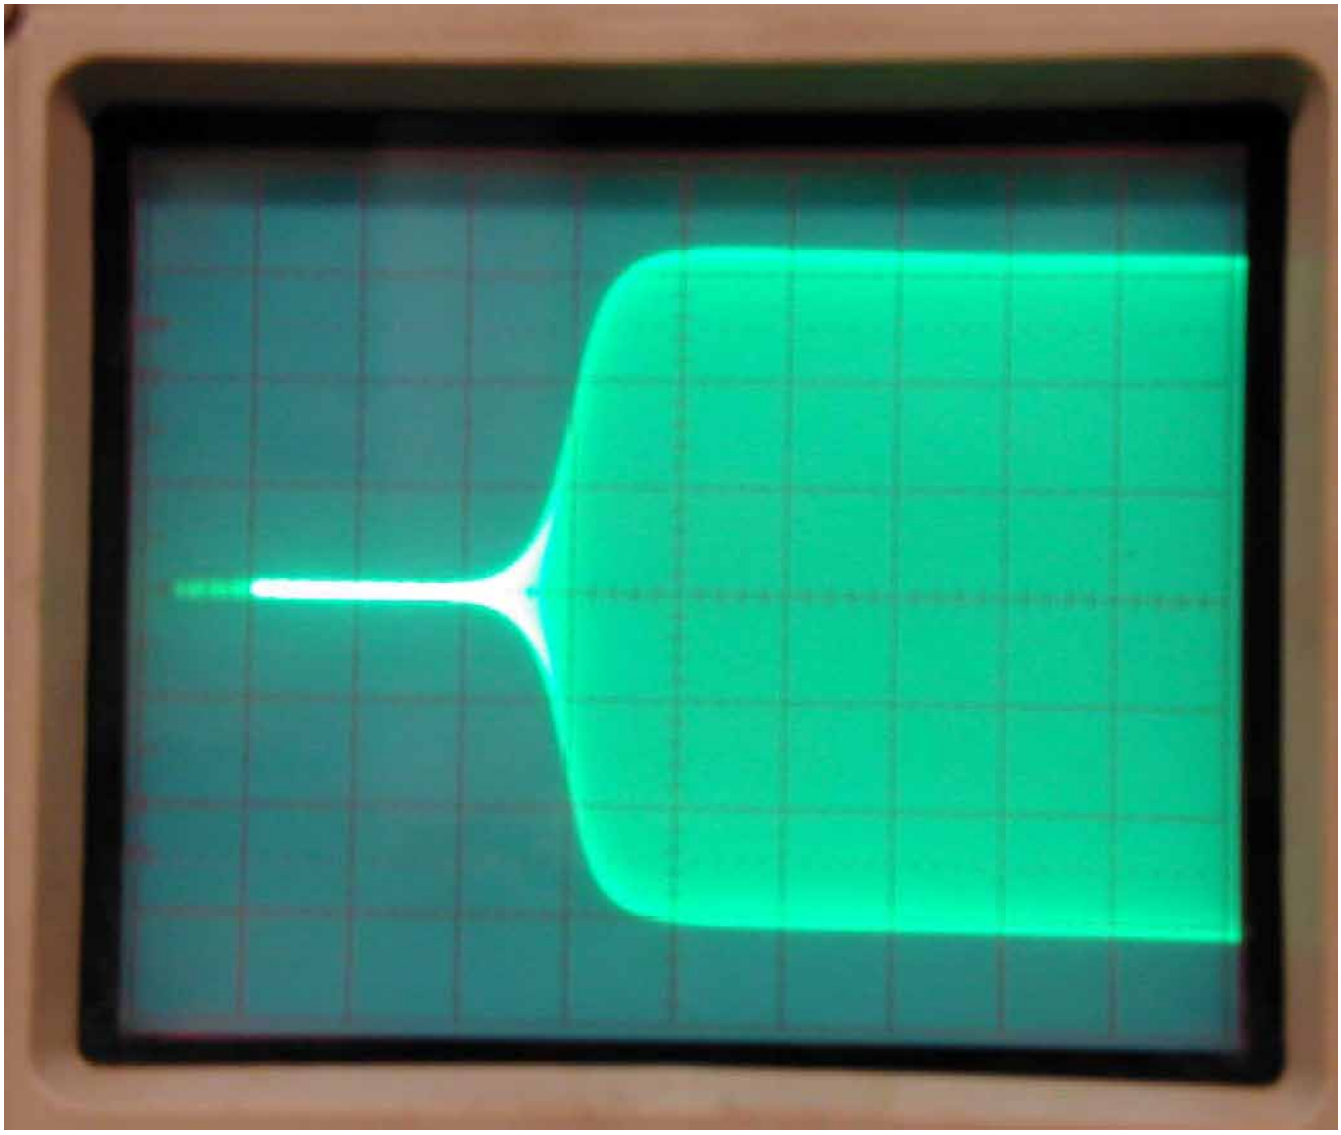
At 1kHz spacing clicks from the stock FT1000MP's were about 15 dB worse than clicks from my old test bench radio (a well-worn ICOM IC-751A) and more than 20dB worse than the clicks from my click-reduced FT-1000D!

Here is a spectrum display of my stock IC-751A using 30 Hz analyzer bandwidth and ten second sweep:

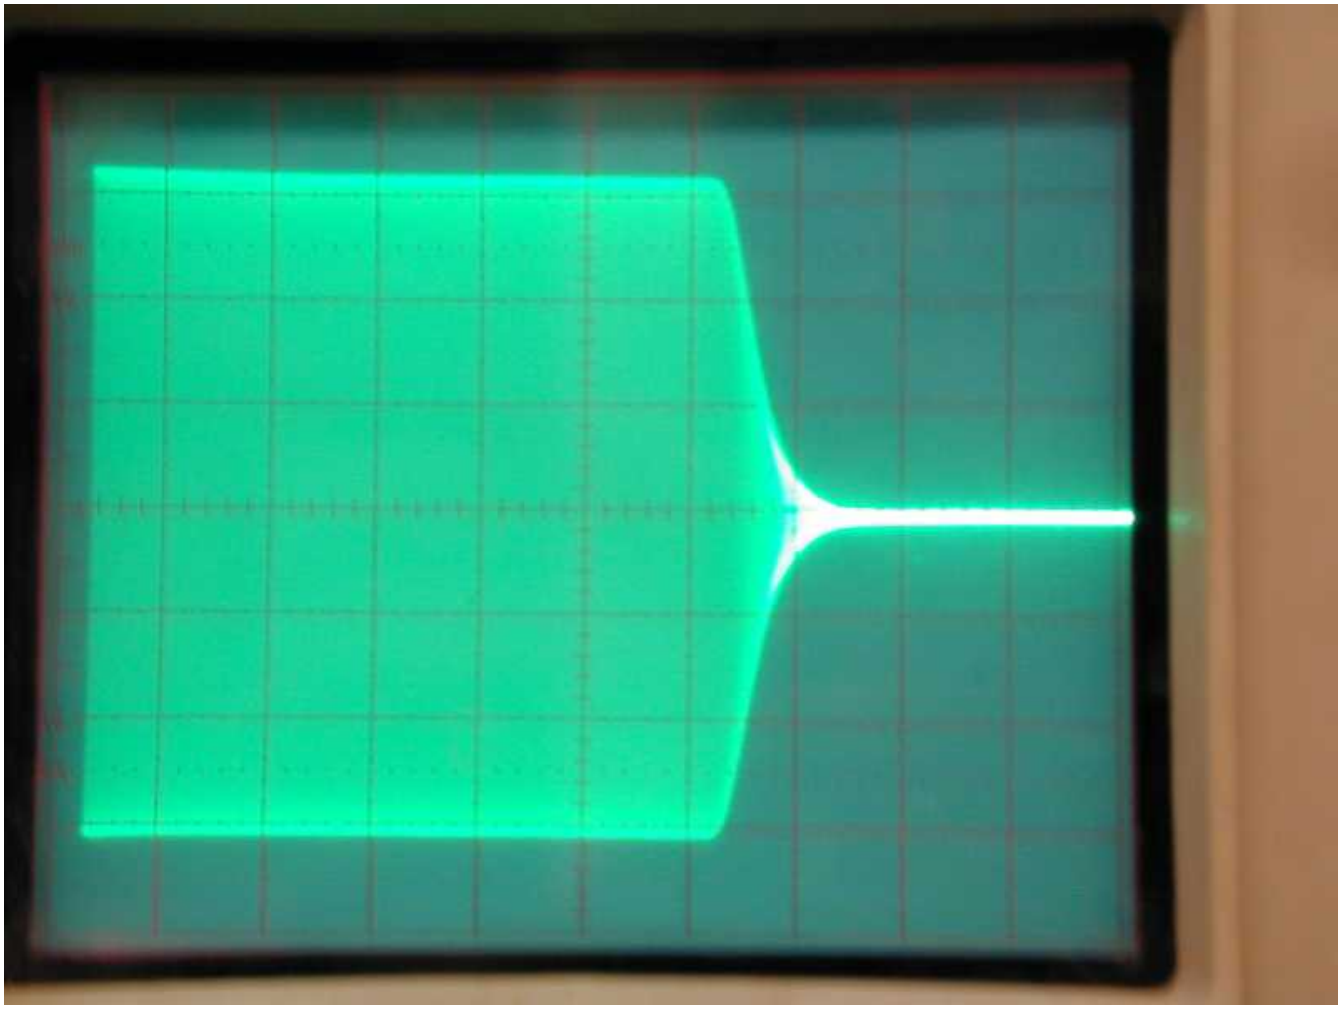


The 751A is approximately -58 dB at 1 kHz, and rolls off smoothly.

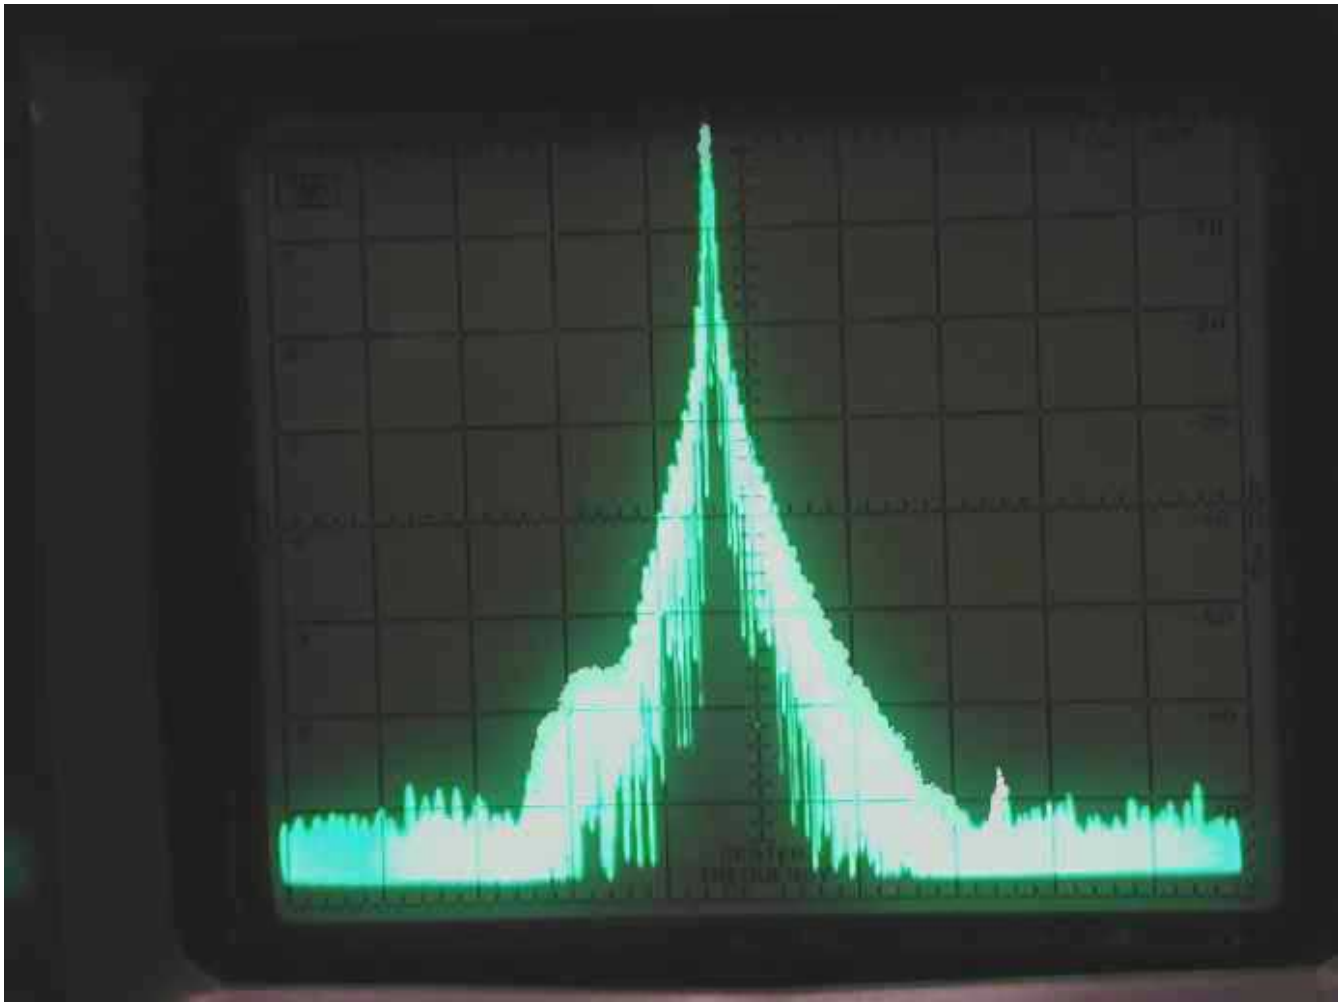
Here is the nicely sloped but too fast rise:



Rise approximately 3 mS....and the slightly sharper at the corner fall:

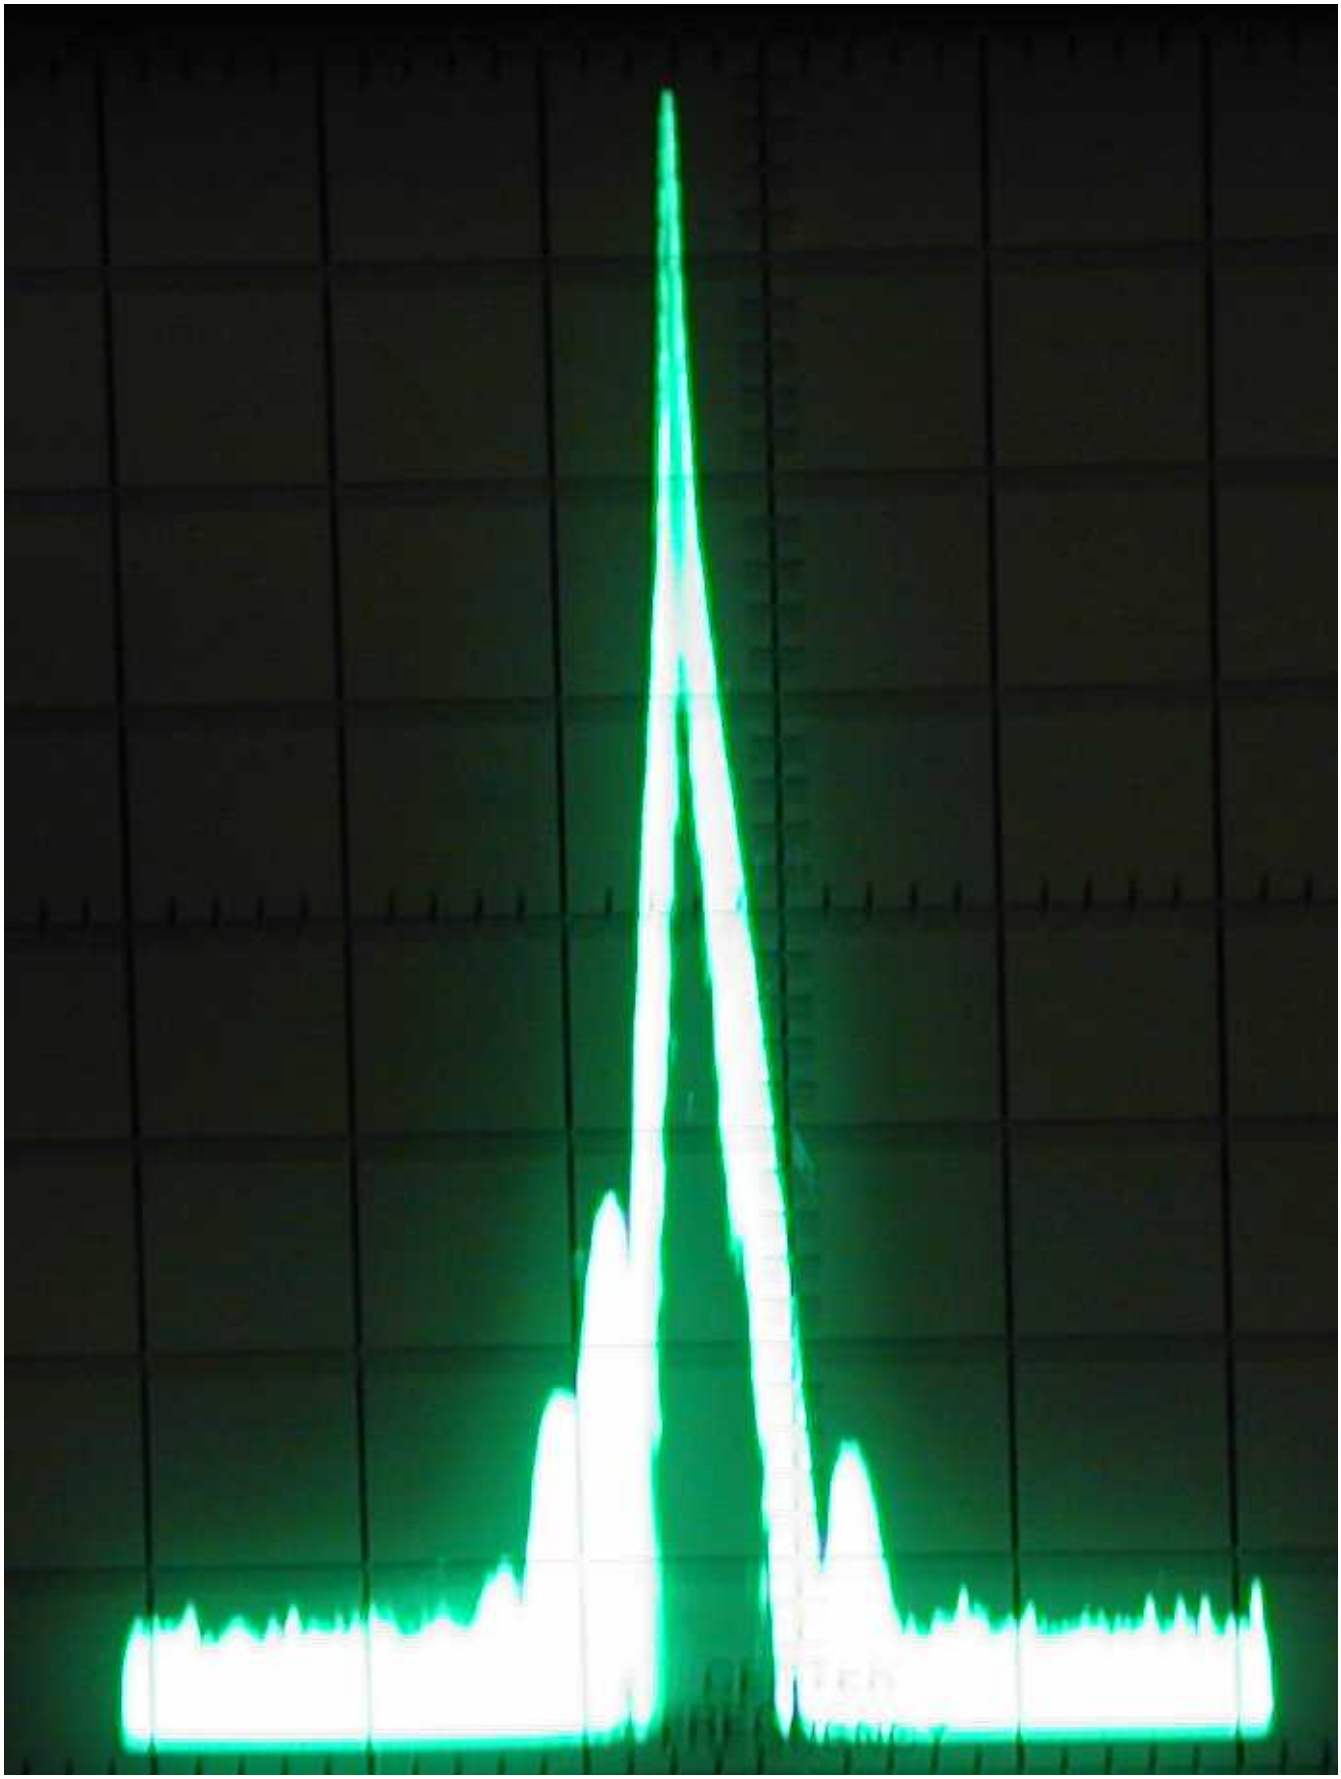


Now the stock 1000MP spectrum:



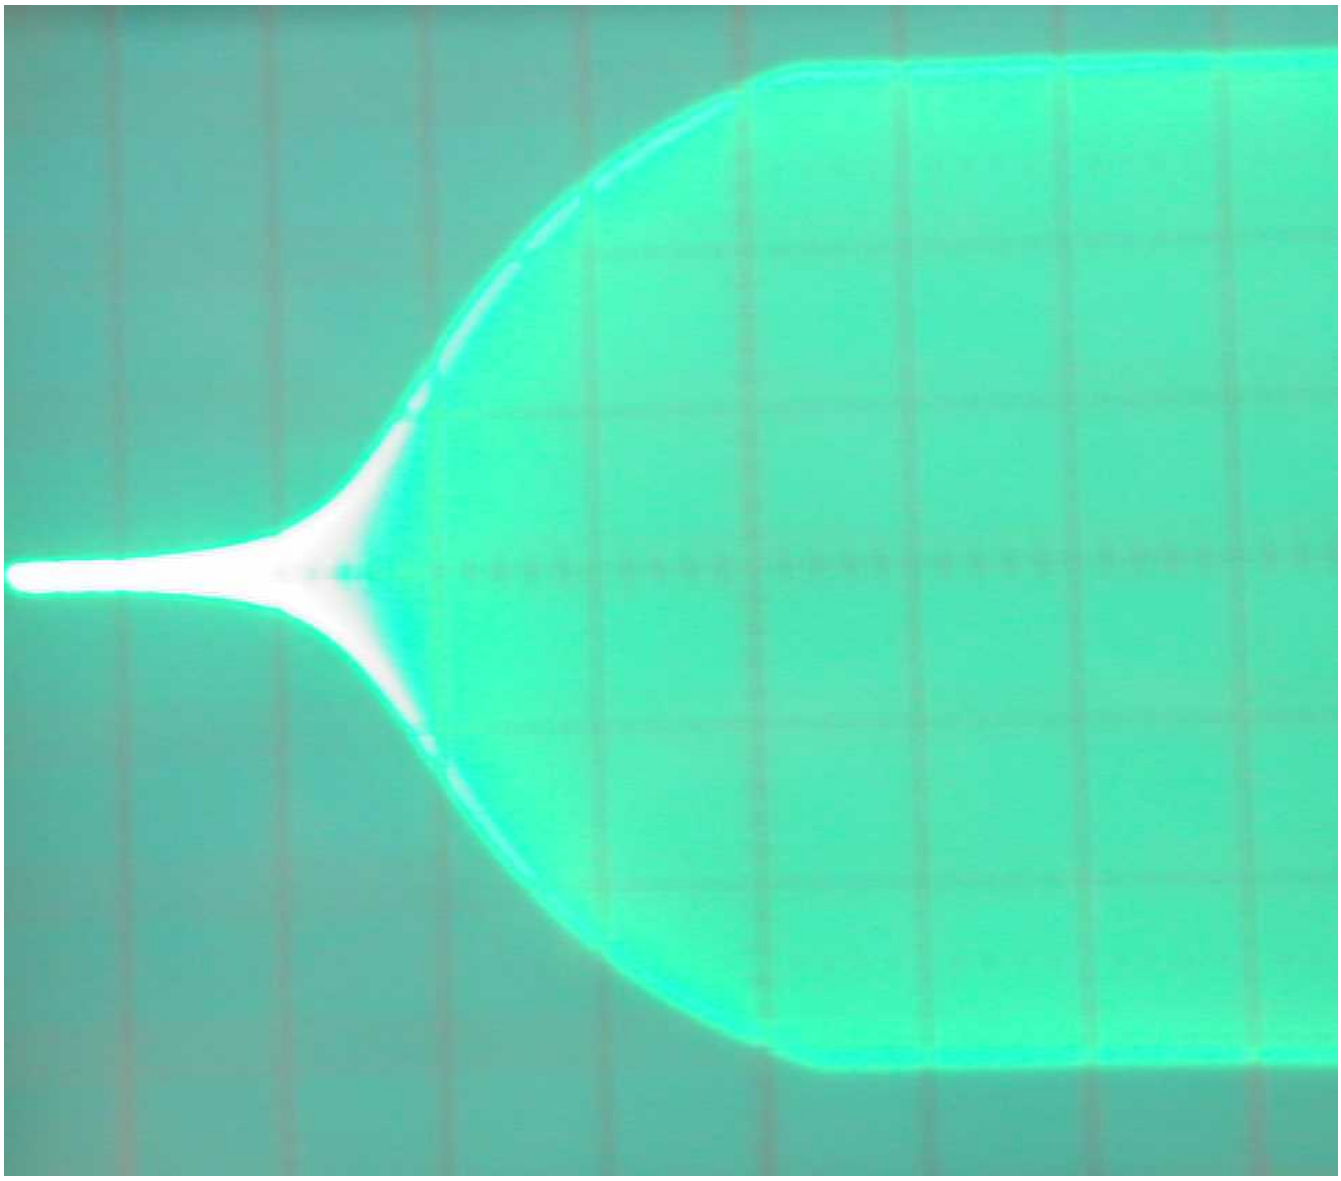
The FT1000-MP is approximately -50dB at 1kHz. It is 8 dB worse than the already "hard" 751A, and has a plateau below the carrier frequency that hovers around -55dB.

In direct comparison, here is a "de-clicked" FT-1000MP:



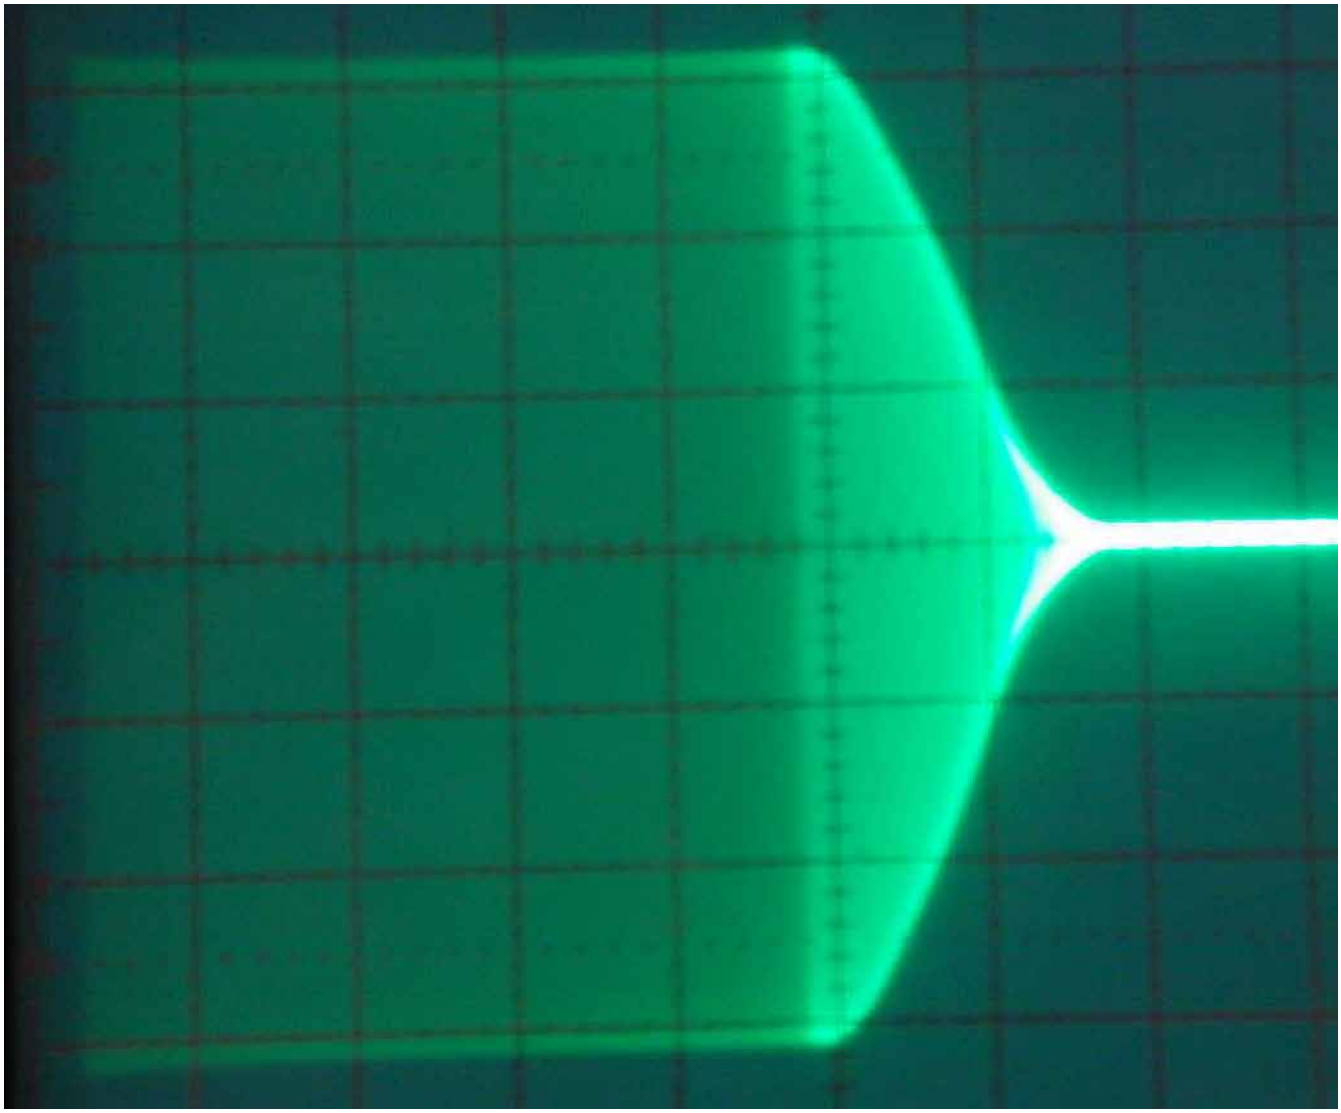
The modified FT-1000MP rivals any of the better radios I have tested, including my "de-clicked" FT-1000(D).

The modified FT-1000MP is around -85 dB at 1 kHz, over 30 dB improvement from the stock MP! Rise time is close to ARRL standards of 5mS, while fall time is around 3 mS. FT1000MP modified rise:



Rise 6 mS. The upper edge is a little sharp, but why worry....clicks are reduced 30dB or more!

Modified MP fall:



Fall time is around 3mS. While it has much more rounded edges, the slope is still not very "round". Unfortunately we are limited by what is possible to do, and this mod is already difficult enough for laymen.

Some concerned was expressed over the "power" of dots when using long rise and fall times. One simple solution is to turn up the weight control slightly. Keep in mind, even without ANY external weight adjustment, the change in average dot power at 45 WPM was only a few percent! On the air tests with VK3ZL and ZL3REX on 160 meters with fading signals and noise, revealed both could tell absolutely no difference between having the click filter in-line and out-of-line at 40 WPM CW speed. This waveform meets FCC and CCIR specifications for 60-WPM CW modest strength signals, and 35 WPM weak fading signals.

The best method of nulling clicks is by listening on another receiver with a narrow filter. Make sure you are well below overload on the receiver, and set that receiver so the carrier from the MP is just outside the passband of the test radio filter. It is almost impossible to use any other method for proper adjustment, including watching the envelope on an oscilloscope.

Work in a clear uncluttered location, I like to work with the radio on a clean small carpet on a well-lit bench, and have a container for all the hardware I remove.

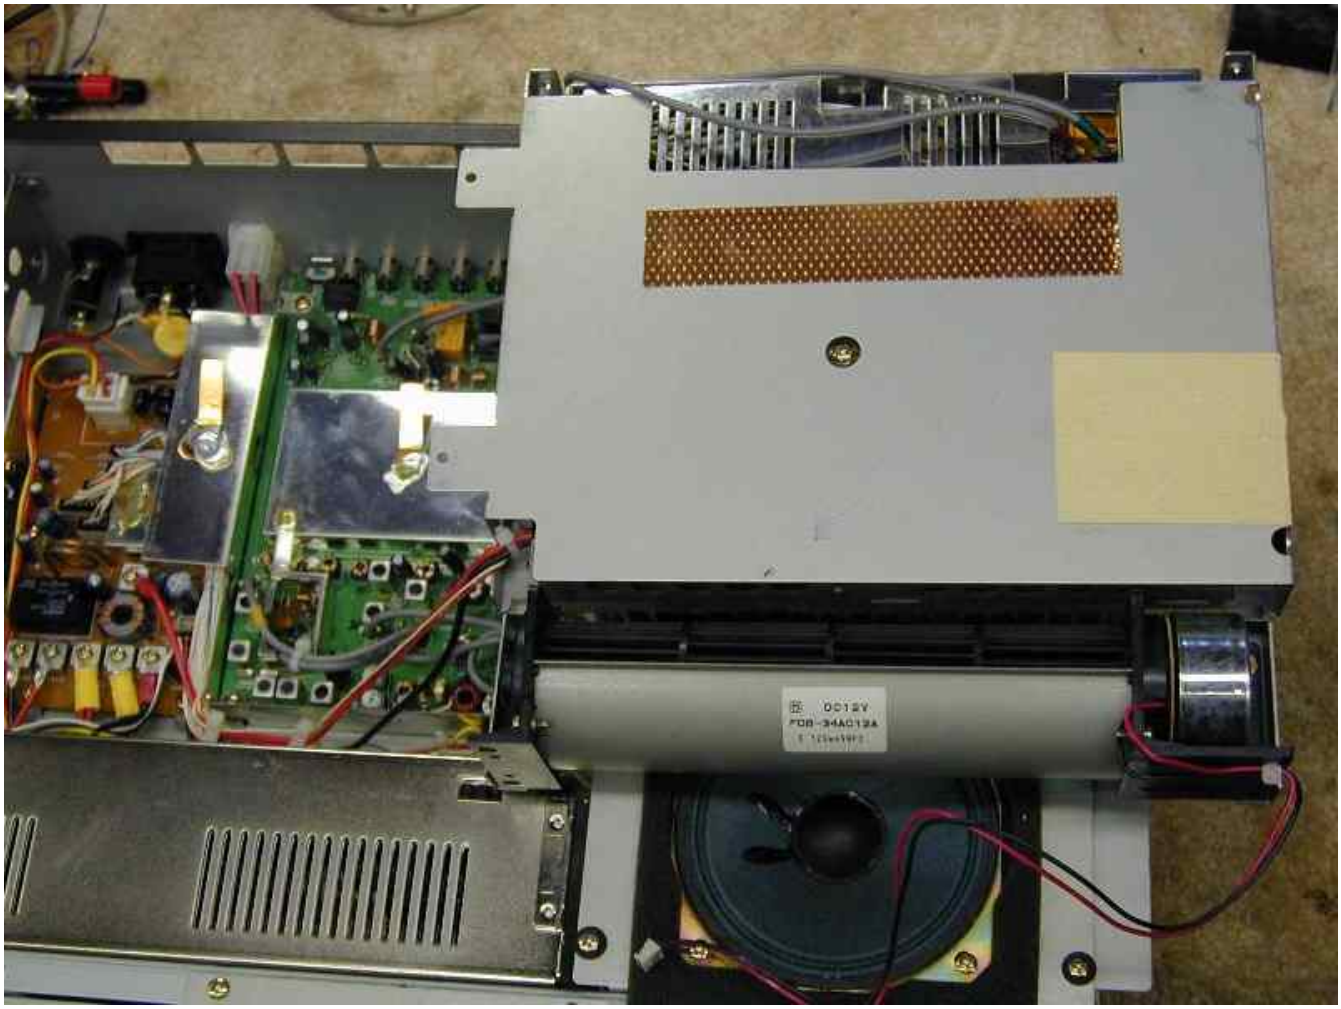
Here's how to make connections to necessary points:

1.) Remove the top and bottom covers of the radio and set them aside.

2.) Invert the radio, so you have the heatsink exposed.

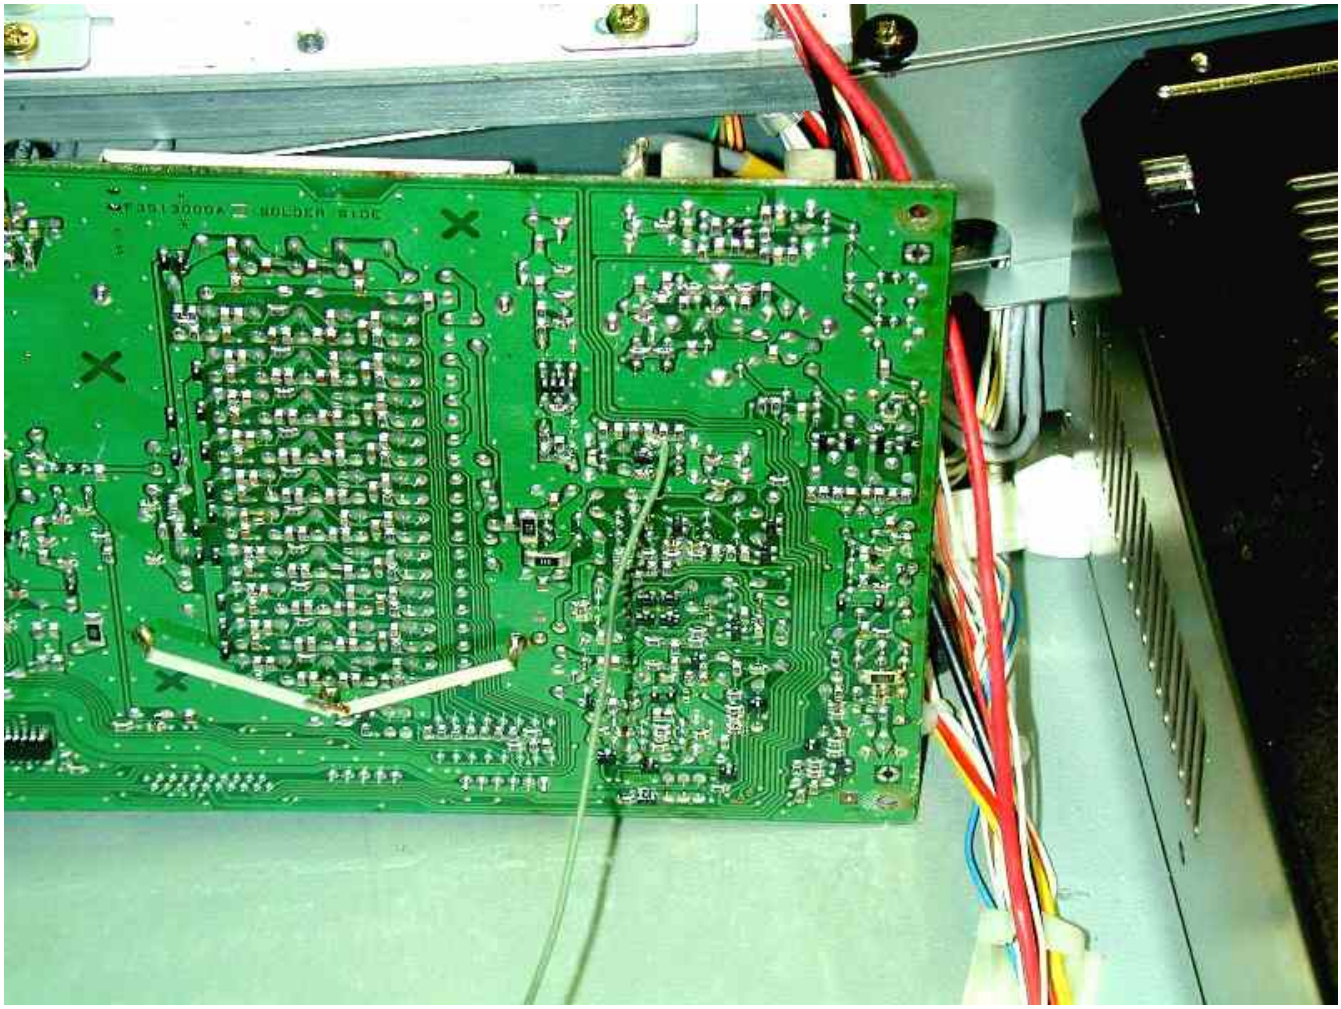
Four main screws hold the heatsink mounting bracket. Two are shown above (one under the screwdriver and one to the right of it). Two other screws are on the side of the radio chassis. You might want to remove the long screws holding the fan bracket, although I got by without doing so.

3.) Lay the fan and PA assembly out of the way, you may have to open some of the wire harness clips to get more wire. Unplug the fan so it is totally free from the unit. It should look like this now:



4.) The RF board is the green-colored board you see above. There are several screws holding that board down, and two screws on a rear panel DIN connector that is mounted on that board. The board will freely move when you remove ALL the screws. Do NOT pry or force the board out, if you have to pry you missed a screw!

5.) Flip the board over, you might have to unplug a wire harness or two...but I managed to work without doing that. The board should look like this:



6.) I added the green wire you see above. I tacked it on a foil pad by laying the wire across the point where two chip components soldered in, as shown below:

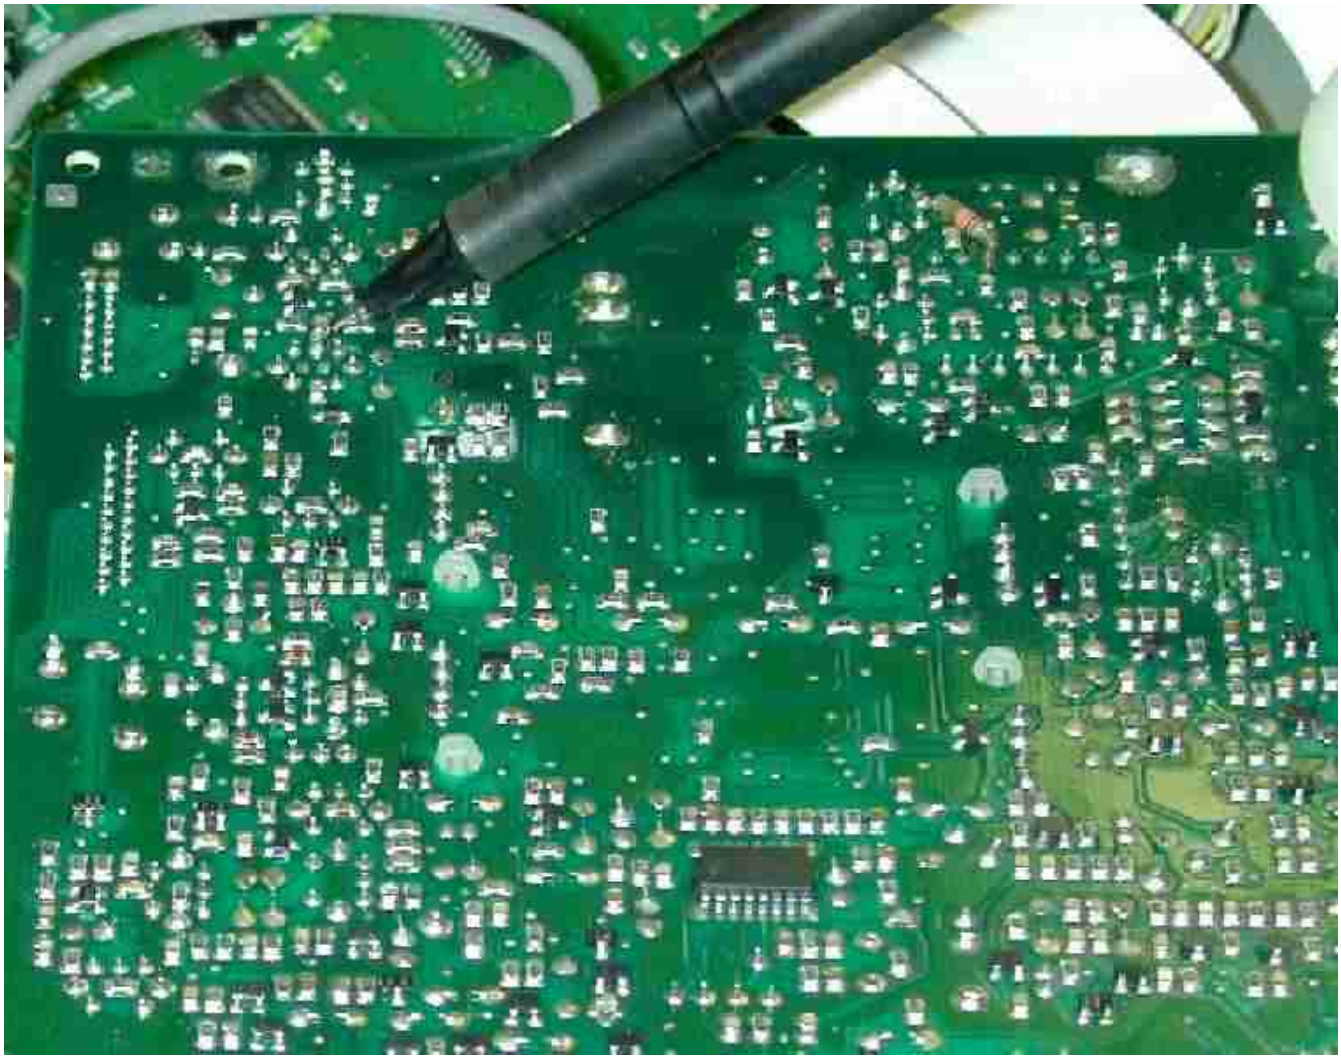
You can see the little black FET (Q1034) and the slightly triangle-shaped foil trace that connects to Q1034. I bent an "L" in the small wire I used. The wire will route topside to a terminal strip, so it needs to be several inches long.

7.) The new wire routes under the RF board to an oval slot in the chassis, where if feeds to the other side and emerges near the IF section unit. Be careful not to pinch any wires when remounting the circuit board. The opening on the right is best for getting the added wire topside:

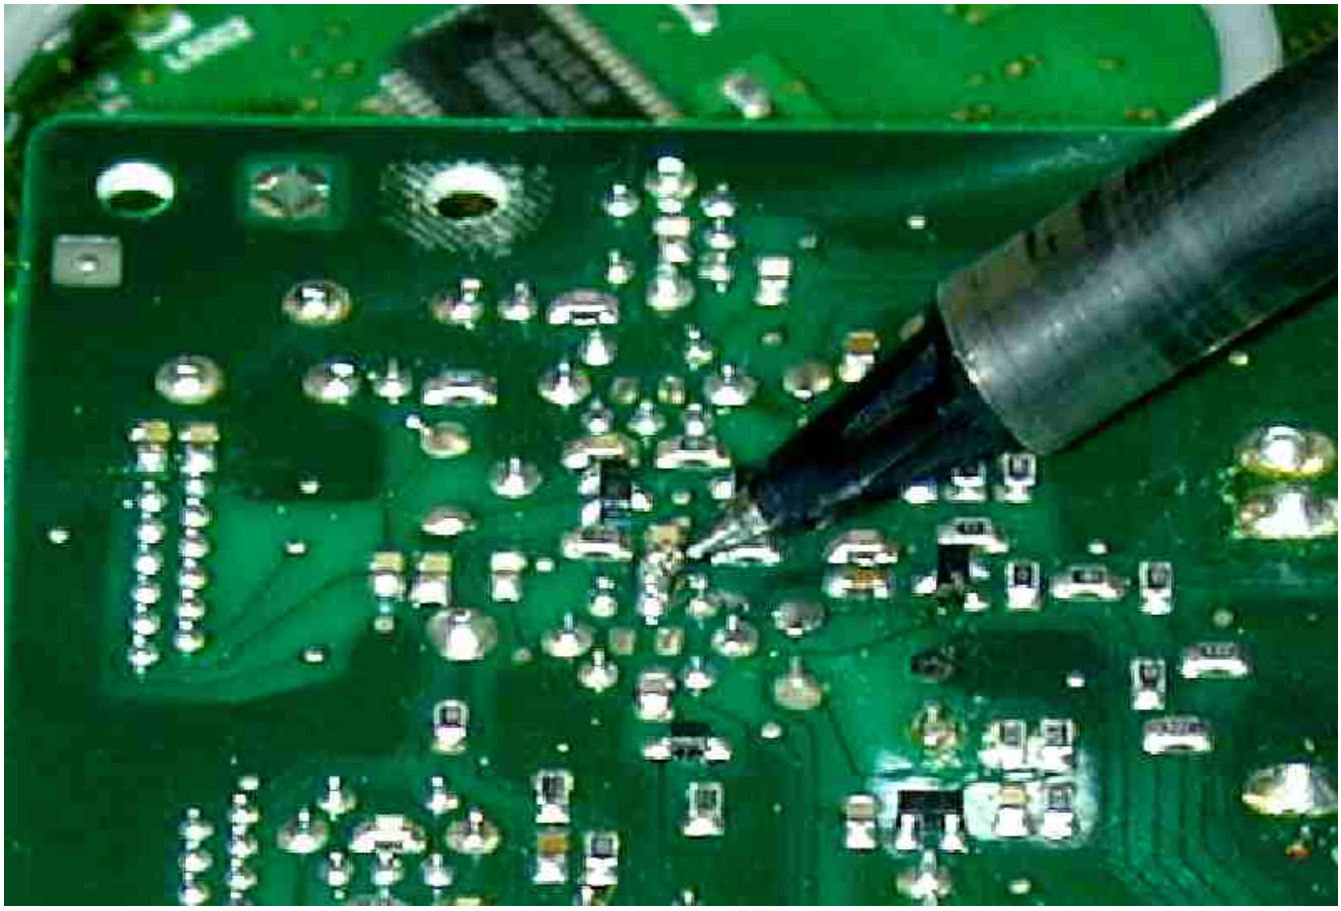
8.) While re-installing the RF section, fan, and heatsink inspect the wiring carefully. Be sure nothing is touching moving parts of the fan, and be sure no wires are pinched or left unplugged. It might be advisable to check the radio quickly on a dummy load to be sure the transmitter section works properly.

9.) Flip the radio over, and remove the two ribbon cables connecting to the IF section:

10.) Remove the mounting screws and flip the IF board exposing the bottom:



This is the area where the wire attaches to the IF board:



Note the FET above and to the left of the pen, and the IF transformer (two can shield connections and five electrical pin-outs, with an unused pad-set for a surface mount device in the center of the transformer leads) below the pen. The connection point for a new small insulated wire is the chip capacitor (C2148) pad that also connects to the center pin of the top three in-line pins of the IF transformer.

11.) Attach a small wire to the point mentioned above. It will route to the new circuitry.

12.) Re-install the board. Be sure you do not pinch any wires. Be sure you do not forget to plug in the ribbon cables, or any other wires you removed.

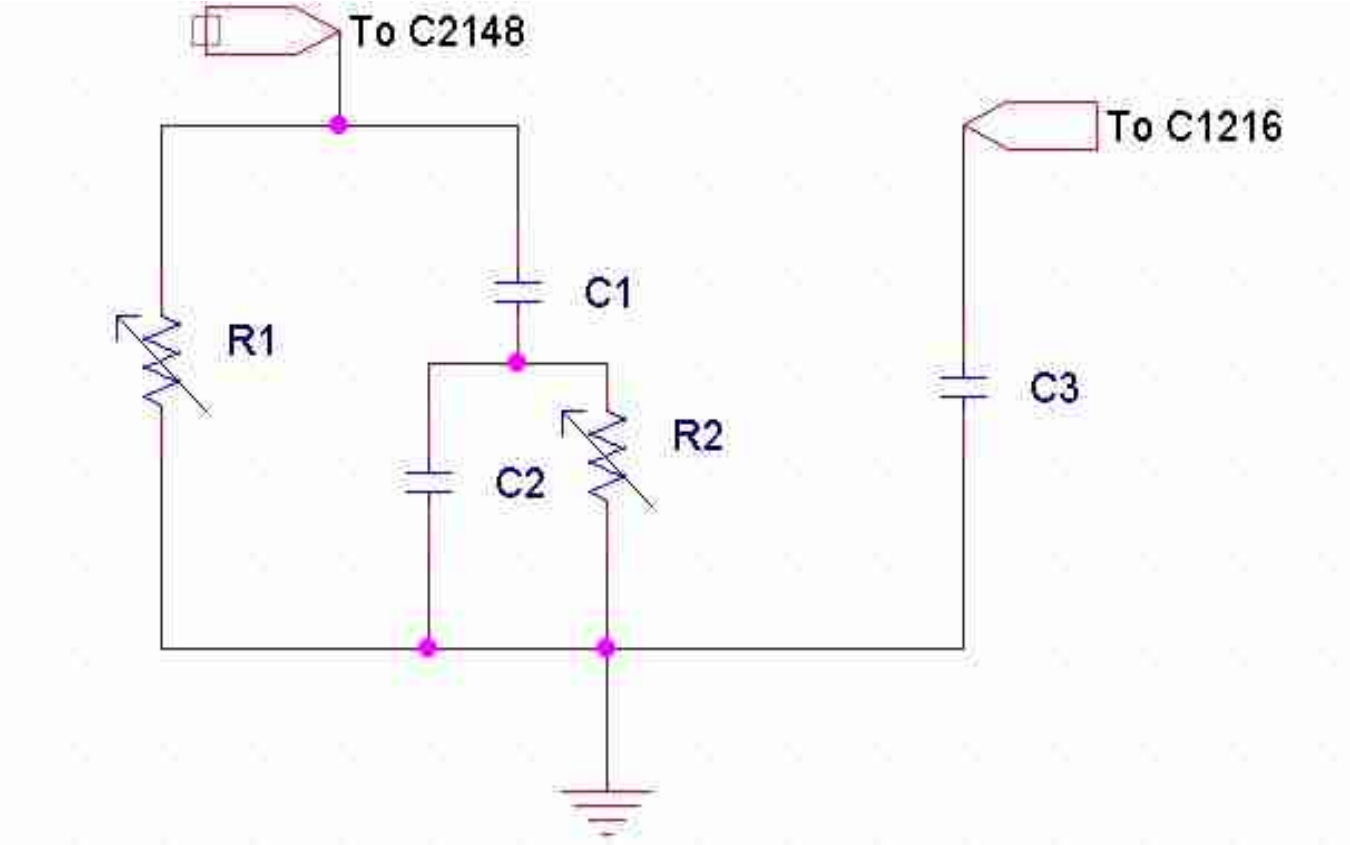
I mounted a small four lug (plus ground) terminal strip at the left front corner of this board, and mounted the components on that strip. This allows you the ability to change or adjust the mod if you find it too soft for high-speed operation.

Doing The Mod

The ideal CW radio would use a high-order filter with controlled group delay, and a reasonably linear attenuator or modulator to control the envelope shape. All other stages should be fully on just outside the output window of the CW signal. I initially hoped a CW "modulator" could be

added on, but for now it appears modifying the 1000MP to ideal circuitry would be too involved. My only option was to "hunt and peck" and find a modification that would be reasonable to do, and inexpensive. This is the best solution I could find, reduction of clicks was excellent. The only drawback is two resistors need to be hand-selected, and the radio needs some minor disassembly to reach a connection point on the RF board.

I mounted this mod on a separate terminal strip under a screw on the left front corner of the IF board. This allowed me to experiment with component values while watching bandwidth and other parameters. This is the basic circuit I used:



C3 was a .1uF disk capacitor. The value turned out to not be especially critical, it mainly seems to prevent rapid rise and fall of the low-level RF amplifier stage that is driven by a gate. There was no combination of resistance across or in series with this capacitor that reduced clicks in any of the radios I tested.

C1 and C2 are also .1uF disc capacitors. In all units tested, I could find no better combination for reducing clicks.

The only critical components appear to be R1 and R2. R1 ranged from 120k to 470k in the units I tested. R2 ranged from 1k to 10k ohms. I initially clipped in potentiometers, so I could listen to the

output and adjust the clicks at 1kHz spacing. Both pots were adjusted for a null in click amplitude. That null is rather sharp, and turned out to be around 30 dB deep. This takes the 1000MP from being one of the "clickiest" radios I have found to one of the cleanest!

Bandwidth rules Part 97.307

Clicks are often a problem on congested bands, yet with modern radios they don't need to be a problem. In the past, engineers and designers didn't have the easy ability to generate filtered waveforms. Radios lacked wide 2-3 kHz wide SSB filters, let alone narrow 250-500Hz filters. Op-amps were unheard of, and L-C filters were large, bulky and expensive. Today, every radio manufactured has the ability to be very clean.

Modern Radios

Most modern radios include 500Hz and narrower receiver filters that operate at the same IF frequency as their transmitter section. Transmitted signals are often routed through the SSB filters with intentional TX switching, when they could just as easily be routed through CW filters! We will see later in this page that TX signals could be routed through CW filters to eliminate sidebands, yet manufacturers foolishly use the SSB filters. If you examine the bandwidth of a FT1000-series radio, you will find the clicks disappear at the BW limits of the SSB filter. This is because they run an essentially unshaped CW signal through the SSB filter, and that filter sets the bandwidth of clicks.

The sad thing is once you listen to that signal through a 500Hz filter, it sounds absolutely no different ***ON FREQUENCY*** than it would if it were nearly click free. The only people who can notice the difference between a clicking rig and a clean rig are the people operating on adjacent frequencies! Claims that certain shapes produce certain "bell sounds" or high readability are not correct, they are certainly not based on engineering or actual blind A-B tests.

If you examine the audio output of your radio with a 500Hz filter in use, you will see ANY waveshape transmitter has the same nearly raised-sine shape output to your ear! That includes wide signals and narrow ones. The speed limit you can copy with a 500Hz filter is the same limit you can transmit with. It makes no difference what end of the path the filter is on, or if there is one at both ends, so far as speed is concerned! (This assumes the filters have reasonably good and easy to achieve group-delay characteristics.) We hear a few mS rise, no matter if it is a sine shape or a square, as a "tick". For demonstration, listen to the pure sine wave on WWV that "tics" every second!

What Could Be Done

At no cost to manufacturers, they could build a click free radio. Every component is in the radio, the problem all centers around poor or careless engineering.

Amplifier stages are reasonably linear (so they can amplify SSB), and virtually every radio contains power control circuitry that could be easily modified to provide wave-shaping. Even without wave-shaping, the transmitter could process transmitted CW though a 250Hz or 500Hz filter.

Sadly, most of the commonly used radios have as bad or worse keying characteristics than old rigs. It's as if the manufactures either don't understand CW, or don't care. The result is we are left with a mess, because many top-of-the-line and very popular rigs have horrible keying sidebands.

On frequency with normal CW filters, we would not be able to tell any difference between the sound of a clicking radio and one that is clean! There is no justification or reason for radios to be 3kHz wide on CW.

How to Identify Click Problems

We hardly notice clicks, and we certainly can not tell a clean rig from a dirty rig, when we are listening right on the CW station's frequency! Even an scope won't tell us much about signal bandwidth, or if the rig has excessive clicks.

In order to check clicks, we must:

1. Be sure the receiver is not overloading
2. Listen with the CW signal outside the receiver filter's bandwidth
3. Listen when the noise is low, and the signal reasonably strong

If we do not follow those three guidelines, we can't tell if a rig is clean or not. If you are testing your own rig, your second receiver must have a narrow filter and be coupled to the rig-under-test through a proper attenuator.

Why Worry About Clicks?

Clicks are most problematic when we try to copy weak signals next to moderately strong signals. If you only operate on empty bands, run low power, and never operate within four or five kHz of weak stations, bandwidth is probably not a concern.

If we contest, work DX, or Ragchew near other QSO's, and especially when we run more than a few hundred watts and have large antennas, we should be mindful of our bandwidth. If you listen to a

recording of a clicking radio, you can hear how devastating clicks are to nearby weaker signals. This signal is from Europe on 40 meters, and it is daylight over half of the path!!

For a mathematical tutorial on clicks, visit W9CF's site. Kevin's analysis deals with bandwidth requirements related ONLY to modulation of the envelope. I'll explain the same thing in verbal form, as I discuss sidebands created by rise and fall times. CW keying is really just 100% AM modulation, as you will see!

There are several INCORRECT but popular misconceptions. They are:

- **A signal has to be clicking and/or wide to send fast CW**
- **Clicks or sharp rises and falls aid in weak signal work**
- **Your CW signal bandwidth changes with the speed you are sending**
- **A certain shape gives a certain on-frequency sound**

What Causes Clicks?

While a fast rise and fall time guarantee excessive bandwidth, ***a long rise and fall is no guarantee a radio will be "click-free".*** Some radios switch into transmit while the synthesizer (VCO) circuits are still settling to a new frequency. An IC-775DSP I owned was particularly bad about this, and also had VCO leakage problems. The amount of garbage varied with how I used the radio, including "VFO" frequency settings of unused VFO's!

Radios with VCO or synthesizer settling time problems generally produce a loud "thump" on key closure on the second VCO frequency. That thump will be right on the DX station when the operator is working split. If you listen in pileups, you will hear a small percentage of rigs with this problem. If the operator uses QSK, VCO-switching-thumps can be particularly annoying. Thumps will occur every time the VCO moves from the receive frequency to the transmit frequency, sounding like a leading-edge click!

Rise and fall times are also important. ***A long rise and fall time does not always result in narrow CW transmitter bandwidth, even though a faster-than-needed rise and fall time almost certainly results in excessive bandwidth.*** Many radios have rise and fall times that are much too fast.

How fast is much too fast? For now let's ignore VCO switching problems, and consider envelope shape.

Rise and Fall

The ARRL recommends a 5 mS rise and 5 mS fall time for CW, based on data in section 2.202 of FCC rules and CCIR Radio regulations. According to professional sources, a 5 ms rise and fall time is not harmful to readability at 35 wpm under marginal (fading) conditions, and 60 wpm when signals are reasonably above noise floor. This rise and fall results in a occupied bandwidth of 150 Hz, although unwanted transient energy caused by the shape of the waveform slope may appear at wider bandwidths.

What Limits Bandwidth?

When determining bandwidth of a stable signal (no oscillator problems), two things come into play in.

- The ***slope*** of the envelope rise and fall at any point controls the band***width*** of the keying sidebands
- The ***amount of voltage change*** during the slope controls the power ***level*** of the sidebands (clicks).

The slope (bandwidth) and the amount of change in a sloped area (level) combine to determine how offensive the transmitted signal is. ***Very subtle changes in envelope shape have a profound effect on key click amplitude and frequency dispersion.*** This makes it nearly impossible to tell if our radios are as clean as they could be by looking at envelope shape.

We can be certain sharp transitions will cause problems, especially if we can actually see them on a oscilloscope. We can also be sure that a rise and fall faster than 2 or 3 milliseconds will cause a bandwidth problem.

Reference Data for Radio Engineers, in the section of Radio Noise and Interference, addresses key clicks in a manner the ARRL Handbook does not. They give an example of multi-pole shaping of waveform. The ARRL Handbook seems stuck with the incorrect notion that a single-pole R/C filter provides proper shaping, something doubtless left over from 1940's technology when better filters were expensive, large, and complicated.

Here are the bandwidth curves of three basic envelope shapes, one rectangular (some radios are this bad!), one for a proper single pole R/C filter with slightly rounded shape (The ARRL suggests this shape. Probably because it was practical in the early years and "stuck" even though it is not ideal), and one for a filtered rise and fall (this would be a sine-shaped rise and fall from a multi-pole filter). We can clearly see a large difference in bandwidth in the curves below:

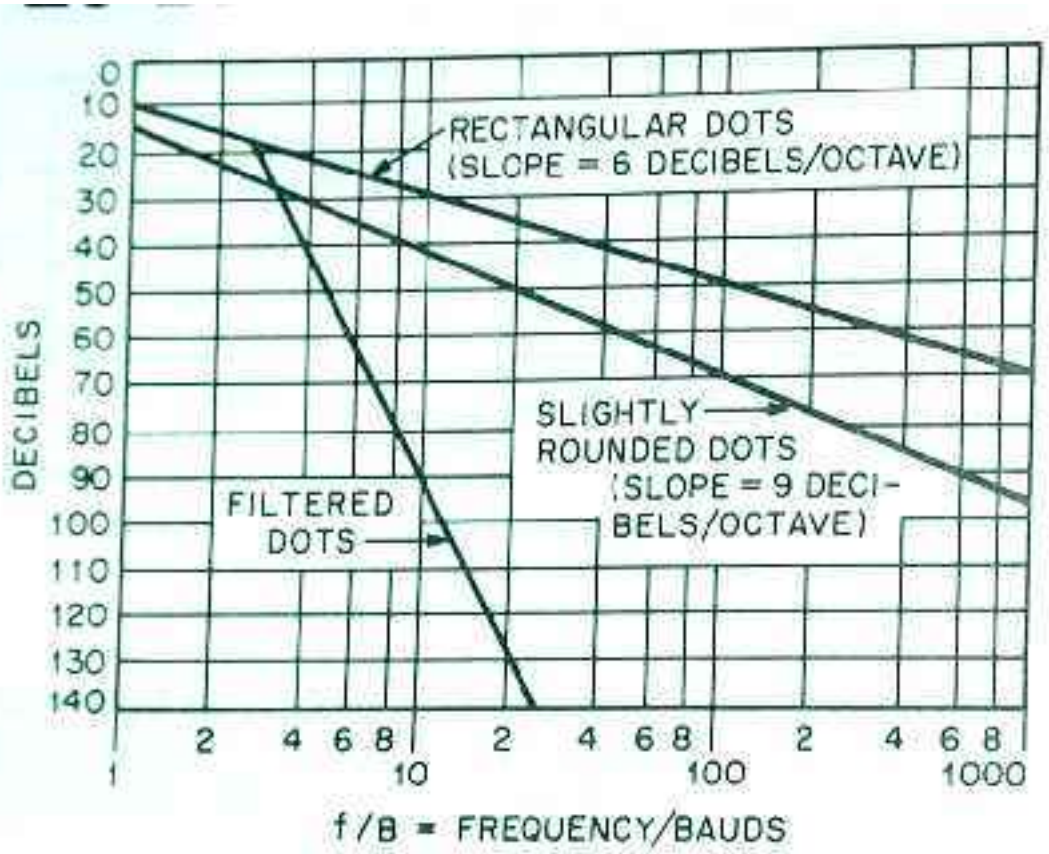

Fig. 12—Curves giving the envelopes for Fourier spectra of the emission resulting from several shapes of a single telegraph dot. For the upper curve the dot is taken to be rectangular and its length is $\frac{1}{2}$ of the period T corresponding to the fundamental dotting frequency. The dotting speed in bauds is $B=1/t=2/T$. The bottom curve would result from the insertion of a filter with a pass band equal to 5 units on the f/B scale, and having a slope of 30 decibels/octave outside of the pass band.

From Ref Data for Radio Engineers 29-10 1977 Edition

Most radios, through poor design, fit in the rectangular to slightly-rounded category!

What Can Manufacturers Do?

Radio manufacturers can certainly do a great deal more than they are. First, they created the problems through poor engineering and design. Why are we stuck fixing them? Did they take our money and run?

All of the parts are there to make radios virtually click-free, yet the only manufacturer who has taken an active interest in this (and who seems to care at all about our signal quality and frequency usage) is Ten-Tec! To date I haven't found any other manufacturer admitting a problem, or even offering technical support for bandwidth problems.

Let me give an example of what could be done with current radios:

Virtually every radio contains a CW filter that operates at the IF frequency of the transmitter, yet nearly every radio transmits CW through the SSB filter! Engineers actually ***added circuitry and parts***, in many cases, ***to steer the CW through the wider filter on transmit!*** If you listen to radios, in particular the FT1000-series, you will notice they have an ultimate click-bandwidth of about the same width as the SSB filter. That's because the poorly-shaped CW waveform with excessively fast rise-and-fall is filtered through the SSB filter.

If these same radios immediately turned on the output stages, and held them on for several mS after the key line was opened, they could send perfect filtered CW through the CW filter. A 500Hz filter would cause a steep roll-off in clicks, even if driven by a relatively "square" and very broad CW signal. The resulting waveform would be a slightly modified raised-sine envelope.

The listener would not be able to tell *any difference* **between the ON FREQUENCY sound of a 500Hz CW-filtered transmitter and an unfiltered signal with excessive bandwidth, if he used a 500Hz or narrower filter in his receiver!** As a matter of fact, I normally transmit through a 250Hz filter in my FT1000D, rather than the 2.4kHz SSB filter Yaesu selected. No one listening on frequency, even DX stations copying my signal near noise level, can tell the difference when I select 2.4KHz or 250Hz bandwidth! The only place transmitter filtering makes a difference is up or down the band from my operating frequency.

This is why we can not tell whether a signal has a proper rise and fall time, sharp level transitions, or any other envelope shape problem when we listen to the actual CW tones through a 500Hz filter. Even a very fast rise-time, with a spiked rise and fall, sounds good (and even looks perfect on a scope connected after the receiver's narrow filter)!

Claim's that a certain shape rise and fall produce a "pleasing-sound" are not true at all. First, our ears can't identify a sound only 5mS long, and second...the receiver's CW filter (assuming it is under several hundred Hz BW) reshapes the waveform to a proper rise and fall!

Why is any of this our concern? Why do we have to work on radios, and suffer with clicks? Certainly not because of a cost issue! All the parts are in the radios. It is a simple lack of good design-engineering, most likely driven by a lack of concern by manufacturers for providing rigs with good signal quality.

What Can We Do?

First, we can let manufacturers know it is ***their problem***. Let's ask the ARRL to publish useful reviews with bandwidth pictures showing a spectral display of CW (and SSB) bandwidth. Let's ask them to check for VCO problems, and publish any abnormalities. Let's rate radios as poor, fair, good, or excellent so readers don't have to be EE's to understand what they are buying (and using).

Radios are too expensive, too difficult to work on, and last too long for us to ignore this problem. We need to stop these problems at the design phase, instead of out in the field.

FCC 97.307

[Home] [Up]

Federal Communications Commission

§97.307 Emission standards.

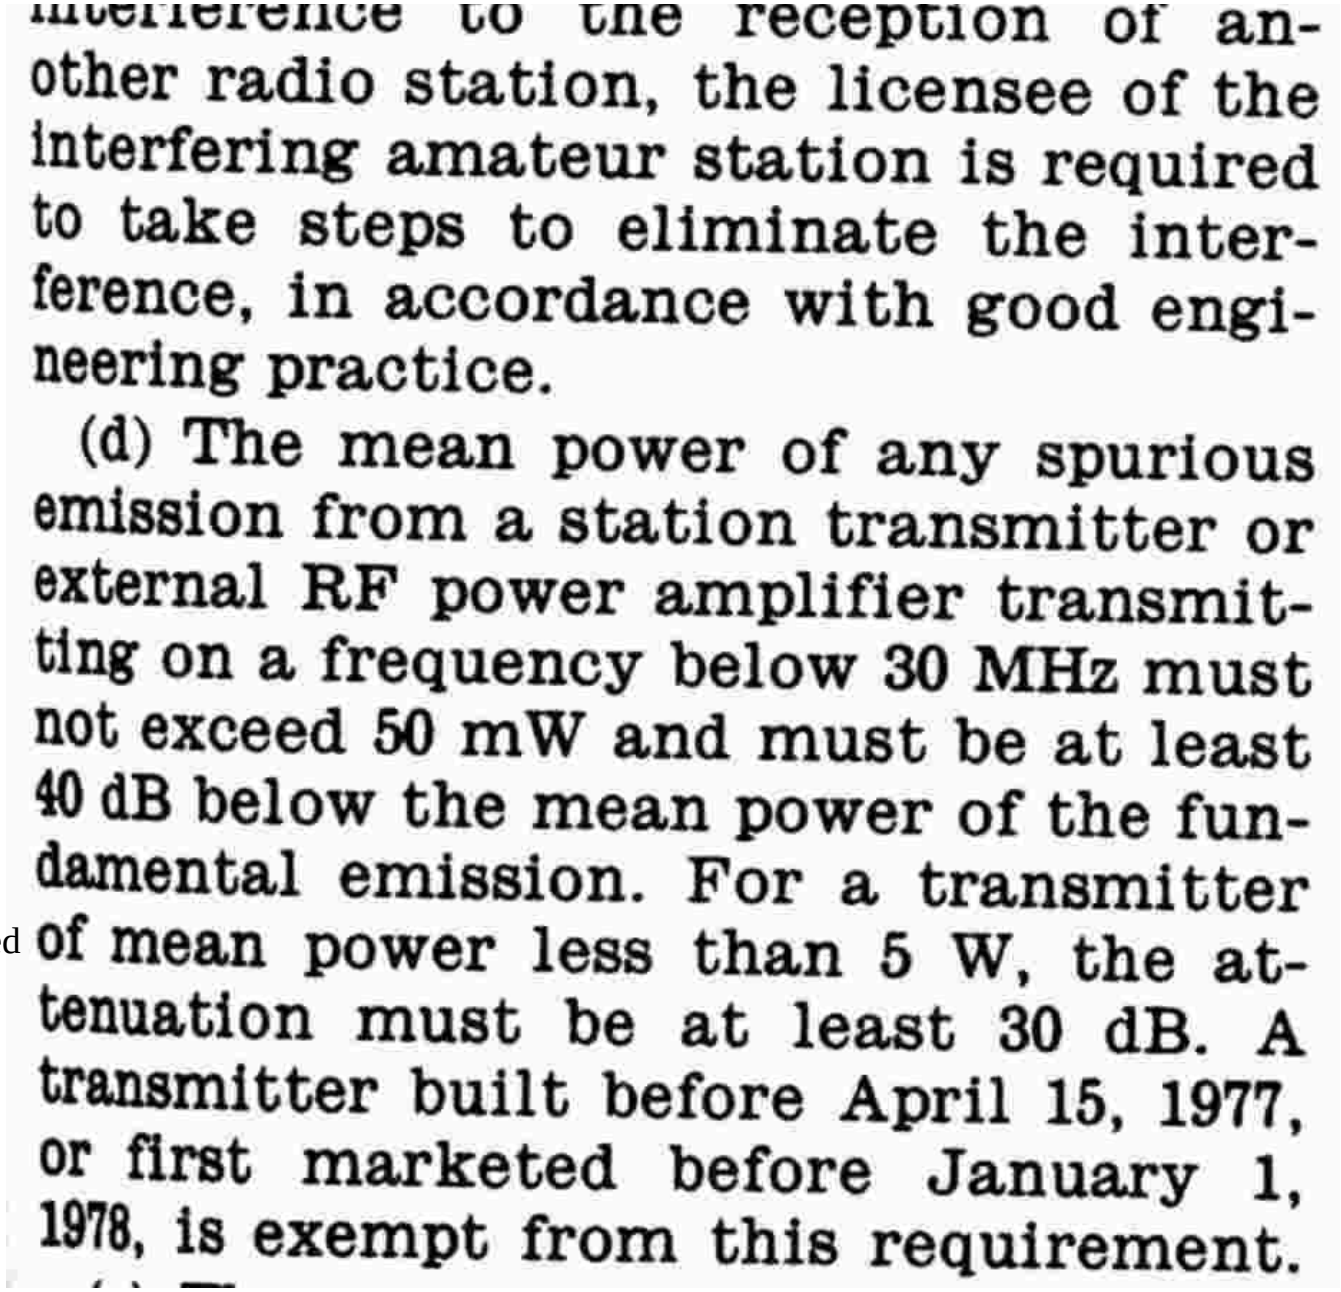
(a) No amateur station transmission shall occupy more bandwidth than necessary for the information rate and emission type being transmitted, in accordance with good amateur practice.

(b) Emissions resulting from modulation must be confined to the band or segment available to the control operator. Emissions outside the necessary bandwidth must not cause splatter or keyclick interference to operations on adjacent frequencies.

(c) All spurious emissions from a station transmitter must be reduced to the greatest extent practicable. If any spurious emission, including chassis or power line radiation, causes harmful interference to the reception of an-

Subpart (a) is very clear. If we only have to change the value of three or four components to reduce bandwidth substantially, do you think it is "good amateur practice" to not do so?

Subpart (b) is also very clear. If the stuff coming out is wider



interference to the reception of another radio station, the licensee of the interfering amateur station is required to take steps to eliminate the interference, in accordance with good engineering practice.

(d) The mean power of any spurious emission from a station transmitter or external RF power amplifier transmitting on a frequency below 30 MHz must not exceed 50 mW and must be at least 40 dB below the mean power of the fundamental emission. For a transmitter of mean power less than 5 W, the attenuation must be at least 30 dB. A transmitter built before April 15, 1977, or first marketed before January 1, 1978, is exempt from this requirement.

than needed, and if you bother someone, you are at fault! Because changing the value of a handful of parts largely corrects this problem, it clearly proves an unmodified radio is illegal to operate near other people.

Subpart (c) is pretty clear also. It doesn't say "when the manufacturer recalls the radios you should get yours fixed."

Subpart (d) doesn't apply to normal modulation bandwidth issues, but if it did we would be in more trouble. The SSB IM3 and IM5 of most radios fails this criteria! Even if a radio did squeak by, as

soon as it was operated into an amplifier it would again become illegal!

I actually had a radio that violated 97.307(d) when used with even a perfect class-A 400 watt amplifier. The radio manufacturer told me "stop using an amplifier with the radio and you'll be fine".

Checking bandwidth with receiver

[Home]

Bandwidth rules Part 97.307

Note: ***Bandwidth measurement dynamic range requirements are based on typical signal-to-noise ratios I have observed over the past several years. They are not the extremes of what I have seen, but rather are typical values. Some information on my receiving system and noise floor is available in (NOISE) and (RECEIVING).***

A receiver can be used to check BW if we understand what we are doing! The common mistakes are:

1. **Using a band-scope**
2. **Leaving a noise blanker on (some receivers have a bit of this problem even with the NB off)**
3. **Using excessive (or SSB) bandwidth while tuning to check signal bandwidth**
4. **Using an inferior receiver or a receiver with poor close-spaced strong-signal performance (many DSP-only radios are pretty poor)**
5. **Using excessive gain**
6. **Having excessive background noise or signals**
7. **Relying on an S-meter (most are not linear or accurate).**

1.) Bandscopes

Bandscopes or spectrum analyzers using wide filters can't be used to check signal bandwidth. While such devices are good for monitoring band activity, they have too much bandwidth and are too easily subjected to overload to be useful in determining signal quality or bandwidth. Bandscopes do not have narrow filters and low internal distortion.

You can prove this by looking at a pure unmodulated carrier on the display. The bandwidth of the carrier is nearly zero (it may have some faint noise or jitter), the display should ideally show a perfect single spike of negligible bandwidth.

Bandscopes (and spectrum analyzers with wide filter bandwidths) are all but useless for determining bandwidth or signal defects.

2.) Noise Blankers

Noise blankers must be OFF when checking bandwidth or working close to strong signals.

In order to remove noise, noise blankers add a form of intentional distortion to signals, They do this by turning a switch or gate in the IF amplifiers off and on. An abrupt rise in peak input signal level over average signal level triggers the switch, and shuts the receiver off. The bandwidth of the noise detector is very wide, and this means a strong signal even 5-10 kHz away will activate the NB gate and distort signals.

Some receivers (like Yaesu's) do not fully remove the effects of the NB system, even when the NB is off! In some receivers you have to turn the NB off plus turn the NB gain down, the FT1000MP and FT1000MP MK V are examples of this. In others, like the FT1000D, you actually have to modify internal wiring to correct NB problems. The mechanism is explained in the links to the receiver mods.

3.) Bandwidth

You must select the narrowest filter possible to measure TX BW, certainly less than a 500 Hz filter with good shape factor.

Receiver bandwidth and shape factor directly adds to the transmitter's bandwidth. This means a perfect brick wall 2kHz bandwidth receiver tuning across a perfect 2kHz wide transmitter makes it sound like the actual signal bandwidth is 4kHz. Theoretically it is possible to deduct the receiver bandwidth from apparent measured bandwidth to obtain real bandwidth, but this generally means you have also decreased the dynamic range of the receiver (or spectrum analyzer). In practice, deducting bandwidths often produces unreliable results.

The slope of the receiver (or analyzer) filter is also important. If the receiver response is -6dB at 4kHz and -60dB at 8kHz, you will hear stuff out 8kHz (plus transmitter bandwidth) on very strong signals if you are in a quiet location.

4.) Inferior Receivers

Some radios, in particular DSP only radios, have very poor strong signal performance. They can't be trusted to give accurate BW reports.

Look at tests here, Sherwood Engineering's tests, or ARRL tests of close spaced receiver performance. Many receiver are not all that good. Most Yaesu receivers have a built-in design problem in the noise blanker amplifier that seriously deteriorates close spaced IM performance even

when the noise blanker is OFF.

Even the Sherwood engineering test is too wide for some receivers. The Sherwood test, for example, inflates performance of R4C's with the CF-600/6 filter. This happens because they measured ***outside*** the passband (2kHz) of the filter (600Hz). The second mixer in the R4C is a horrible design, especially the early FET mixer. Close-spaced tests should always be done inside the bandwidth of the roofing filter, or the roofing filter should be considered the narrowest reliably useable selectivity.

5.) Noise

If the band is noisy you really can't check a signal for low-level IM, clicks, or splatter. The noise will cover up any weak signal defects. There must be at least 50dB headroom between the peak signal level being tested and your noise floor to check bandwidth on SSB, or 80dB of signal to noise headroom to check CW bandwidth if you operate near weak signal areas of the band. For general ragchewing away from weak signal areas 50-60dB headroom is generally enough.

Some bands are a special case because SSB operates near weak signal CW stations. 160 meters is one example. Bandwidth of higher power SSB transmitters operated near weak CW stations can be problematic. I often hear spits from Icom 756 and TS 2000 transmitters on SSB as far as 10kHz away on 160 meters.

Receiving noise floor is probably the single most common source of false "clean signal" reports to what actually are problem transmitters. If the noise or QRM floor is high, you won't hear spurious signals.

Wide-audio operators are particular victims to giving each other false assurances of how narrow and clean they are. They often use "opened-up" receivers that absorb more noise power from wide bandwidth (remember noise power is directly proportional to receiver bandwidth) and they often live in noisy environments. It takes a good weak signal narrow receiver in a quiet location to properly check bandwidth.

Results

The result of the factors above is that some people will report a nasty signal "clean" when it isn't, and some will report a signal "wide" when it isn't.

Understanding how to test will correct problems, and help us use our own equipment better. Receivers make very good measurement devices if used ***properly***.

Receiving

[Home] [Up] [Beverage Antenna Construction] [Echelon-Log Beverages]
[K9AY_Flag_Pennant_Ewe] [Magnetic Loop Antennas Receiving] [Receiving_basics]
[Slinky and Loaded Beverages] [Small Vertical Arrays] [W8JI_RX_ANTS]

Noise and common mode noise. Power line and other noise sources. Pre-amplifiers.

This page has top links to other receiving antennas such as Beverage, loop, and vertical antennas. This area deals primarily with low noise antennas, and discusses effect of antenna directivity on weak-signal reception.

Noise Floor and signal Levels at my location:

My local wintertime 350Hz BW noise (after amplifier) compared to a sample of signals on one night was:

Noise -127dBm

9H1BM -122dBm

OM0WR -95dBm

DF2PY -88dBm

WA8OLN -78dBm

W3GH -60dBm

W4ZV -32dBm

The dynamic range between noise and W4ZV was 95dB! It also illustrates how important antennas, location, and propagation are rather than power. The dB difference between signals from the same area can be profound. Many DX signals run at or near noise floor, while others can be 40dB out of noise floor. The data above is certainly not typical of every night, but it shows how large the signal level variations between weak DX and strong signals can be. Over a period

of time I've found 85 to 90 dB dynamic range about the most that is every needed. In a simple installation with a single Beverage, 80 to 85dB IM3 and blocking DR is probably enough. Receivers with less than 80dB IM3 and BDR probably compromise a reasonably good station's capabilities.

Comparison or Ranking of Receiving Arrays or Antennas

The following is a ranking of receiving antennas based on noise being evenly distributed in all directions. These rankings are most accurate in the frequency range of AM broadcast, 160 or 80 meter bands when:

1.) The receiving location shows a nighttime increase in noise level. In other words the system is not limited by local or internally generated noise, instead being limited by skywave or distant propagated noise.

2.) Thunderstorms or other local noise such as power line noise from specific directions does not dominate the receive system noise floor.

There will be occasional exceptions, but as a general rule the ratio of peak response in the direction of the signal to average response in all directions is the dominant factor in determining how good an antenna works for receiving. In virtually all installations without clearly dominant direction or directions of noise arrival, RDF (receiving directivity factor) very accurately predicts receiving antenna performance.

RDF (directivity) will be an almost perfect indicator of what you can expect from your antenna as long as:

- **Noise is not from the same general direction as the desired signal**
- **Noise field strength is not greater than the ratio of peak antenna response to depth of the pattern in the direction of noise**
- **Noise is not coming from within the antenna's nearfield or Fresnel zone**

In the vast majority of systems, the following RDF table indicates relative performance of antennas:

Antenna Type	RDF (dB)	20-degree forward gain (dBi)	Average Gain (dBi)

1/2wl Beverage	4.52	-20.28	-24.8
Vertical Omni, 60 1/4wl radials	5.05	1.9	-3.15
(Ewe Flag) Pennant	7.39	-36.16	-43.55
K9AY	7.7	-26.23	-33.93
1/2wl end-fire Beverages	7.94	-20.5	-28.44
1-wl Beverage	8.64	-14.31	-22.95
two verts optimum phasing 1/8 wl spacing	9.14	-22.46	-31.6
two 1wl Beverages Echelon 1/8 wl stagger	10.21	-15.45	-25.66
Small 4-square 1/4 wl per side (opt. phase)	10.70	-15.79	-26.49
1-1/2 wl Beverage	10.84	-10.88	-21.72
Small 4-square 1/8wl per side (opt. phase)	10.97	-30.28	-41.52
Single 1.75wl Beverage	11.16	-6.50	-17.66
2 Broadside 1.75wl Beverages .2 wl spacing	11.36	-3.51	-14.87
2 Broadside 1.75wl Beverages .4wl spacing	11.91	-3.50	-15.41
.625wl x .125wl spaced BS/EF vertical array	12.5	-19.5	-32.0
2 Broadside 1.75wl Beverages 5/8 wl spacing	12.98	-3.50	-16.48
2 Broadside 1.75wl Beverages .75wl spacing	13.48	-3.49	-16.97

If antennas are within two dB of each other in RDF, a lesser ranked antenna may occasionally outperform slightly higher RDF antennas. This is because:

1. ***Direction and polarization of arriving signals and noise constantly vary, and so the***

relative relationship of each to any individual antenna's response will vary.

2. ***Through various unavoidable errors or omissions, antennas in the real-world may not work precisely as predicted.***

Gain vs. Directivity Myth

One common rumor or myth is that higher antenna gain results in improved reception. Gain is an unreliable way to predict receiving ability on frequencies below upper UHF! A clear example is illustrated above by comparing gain of the single 1.75wl Beverage to the pair of 1.75wl phased Beverages that are spaced .2wl apart.

In this case, the single Beverage has a gain of -6.5dB. The pair of Beverages has a gain of -3.51dB, a gain of about 3 dB. Despite the gain change, antenna directivity and pattern do not change a noticeable amount. RDF only increases 0.2dB, and undetectable difference. Pattern remains essentially the same, so reception remains the same.

Spacing must be at least be 1/2 wl or more for phased Beverages to add noticeable improvement to reception. Even at 3/4 wavelength spacing the directivity improvement falls short of 3dB!

Gain of any spaced pair is about 3dB more than a single Beverage, but reception improves and antenna pattern changes only with relatively wide spacings.

Of nearly equal importance, end-fire arrays actually work better with closer spacing. For an example, compare the 1/8th wl four-square RDF with the 1/4-wl four-square array.

How well does the above hold true?

Over the years, I have had virtually all of the above systems. I always have multiple phase-locked receivers on multiple antennas listening in stereo or a very fast way to "A-B" antennas. When an antenna sits unused most of the time, I replace it with a more useful antenna. My single Beverages are now virtually all eliminated, my last phased loops were in the 80's (when I had four end-fire diamond terminated loops). Even on 80 meters, my large arrays with 300-350 foot spacing almost always beat my single long Beverages. I've migrated towards the bottom end of the chart with all my antennas ***because they actually do receive better.***

If you ask operators who visit for contests, everyone prefers the large vertical or wide-spaced Beverage arrays. Guest operators, given a choice, almost never not use single Beverages or close-spaced Beverages.

You can listen to directivity examples on my DX Sound files page.

Beverage Antenna Construction

[Home] [Up]

Link to Beverage Antenna Components I use

I installed my first Beverage Antenna (in the early 1970's). I was delighted to find a large improvement in weak-signal reception from such a simple, inexpensive antenna. Over the years I've continued to use, compare, and refine my Beverage antennas. Despite having very large vertical arrays, Beverages remain my primary DX receiving antennas. There just isn't any antenna that is as simple, as easy to construct and maintain, and as foolproof as a Beverage!

I refine my antenna systems by comparing systems against each other for extended periods of time, usually more than a year. My station has a convenient switching system allowing instant comparison of antenna systems. When an antenna system is almost never used, I abandon that system and try something else. Even though I use engineering tools (books and models), I always compare and measure actual working systems. I presently have over thirty Beverages in three different clusters of arrays, the end result filtered through years of measurements and A-B testing of systems.

A great much has been written about Beverages. Unfortunately much or most information is a repeat of previously published information (and misinformation) from verbal discussions or from other articles or handbooks! It is time to set aside some of the myths that have been handed down and repeated so much they have become "fact".

Types of Beverage Wire

The most commonly used wire types are single conductor hook-up or electrical, electric fence wire, and special antenna wire such as copperweld. The only significant and easily noticed difference between these commonly used wires is in physical properties, such as ease of soldering, strength, and life

Insulated Wire

Sporadic claims have appeared indicating insulation prevents charged droplets of water from making an antenna "noisy". I've never been able to verify that rumor either in A-B tests of actual antennas or through planned experiments. Other reports, many from reliable sources, also seem to discredit this rumor.

One of my experiments was to charge a stream of water (against earth) with an extremely high voltage supply, and spray the water on a wire. Other than corona noise from sharp points, the type of wire made no difference at all in "noise". The water droplets obviously were not hitting the wire like hundreds of random charged capacitors, they generated no noise at all. This is really what we would expect, if we consider that each drop contains only a very miniscule amount of change and also has nearly perfect insulation (distilled water is a very good insulator).

Controlled observations also tend to support the idea corona, and not charges in individual droplets, cause precipitation static.

In Ohio, my long Beverages stretched across open farm fields. Snow would whip across the fields, rain would pelt the wires, yet insulated and bare wire Beverages running in the same direction always had the same noise level. Beverages that picked-up corona (or "p-static") noise were always near or aimed at tall towers. With corona sizzling at 40-over-nine on my tall towers, Beverages (and even small "magnetic" loop antennas) aimed at the towers would "hear" the same precipitation noise.

The same was true for tower-mounted antennas. The largest noise problems came from antennas mounted high on towers, and generally were with antennas that had "sharp" ends jutting out in the air. Lower antennas, even those of identical construction, were either significantly quieter or totally free of precipitation static. This effect was reported many times by contest operators and DX'ers with stacked antennas. They universally switch to low antennas to eliminate or reduce p-static, even though the ***same moisture is hitting the lower and upper antennas.*** This strongly indicates precipitation static is from corona discharge, and ***not*** from charges in each individual drop of moisture hitting the antenna.

After my move to Barnesville, Georgia my first antennas were all insulated wire. Hook-up wire was pressed into service in my first group of temporary Beverages. As non-insulated conductors permanent antennas were added, there wasn't any observable change in inclement weather noise. As before, the antennas nearest or aimed at tall towers picked up some p-static noise. Antennas located away from the towers remained free of precipitation static, whether bare or insulated.

There is also some chance, if the antenna wire is not under significant tension, that insulation may sometimes hide a broken conductor.

Insulated wire may reduce leakage currents if a substantial part of the conductor is in contact with resistive paths, such as wet brush or tree branches, but you may be better off trimming back any substantial foliage in contact with the wire.

While insulated wire has no major performance disadvantage, it also has no advantage.

Type of Conductor

Copper wire is a good choice if supports are close. Copper wire lacks the mechanical strength of steel-core wires, but is very easy to work with. It is softer, making it easier to bend. Copper wire can be repeatedly scraped or re-soldered without worries about piercing a thin copper coating and exposing a rust-sensitive steel core, and it is readily available and relatively inexpensive in large quantities.

Copperweld wire is much stronger and has about the same RF resistance as 100% copper. Like copper, it is easy to clean and solder after it has been exposed to the weather as long as you are very careful to not scrape through the thin outer coating of copper. It is considerably more difficult to work with than normal pure copper wires, any kink or sharp bend will substantially weaken the wire.

Most fence wire I've found is cadmium plated, rather than zinc galvanized. Using RF current meters, I have measured increased losses when using zinc or cadmium plated steel wire. Beverages already have substantial current loss due to the close proximity with lossy earth. I've measured about 60% of feed point current remaining (~4.4dB loss) after passing over around 700-feet of electric fence wire, and about 10% more current (~3.1dB loss) using copper-clad steel wire. Steel fence wire would aggravate losses that already limit the benefits of using long Beverage antennas. *In a very long antenna, the small*

additional loss of steel fence wire might slightly reduce performance.

In my Beverages, the important consideration is antenna maintenance. I use copperweld wire or electric fence wire, because strength is a primary concern. With spans exceeding 200 feet, my antennas need a large strength to weight ratio.

Don't use welding wire! It is a very poor material choice. It rusts (and as with aluminum) you'll have connection problems in no time.

Beverage Supports

Some would have us believe we need non-metallic supports for our Beverages, but there is not the slightest technical justification for such suggestions.

The only requirement for the support is it must hold the antenna up, and it can not connect the antenna to ground. A metal pole with a small PVC stub for an insulator is every bit as good as a full non-metallic pole. Trees make good supports, especially if you use nail-type electric-fence insulators for use with wooden posts.

I've never seen a problem allowing a wire to contact a branch, although I do trim out the branches and avoid any contact with trees.

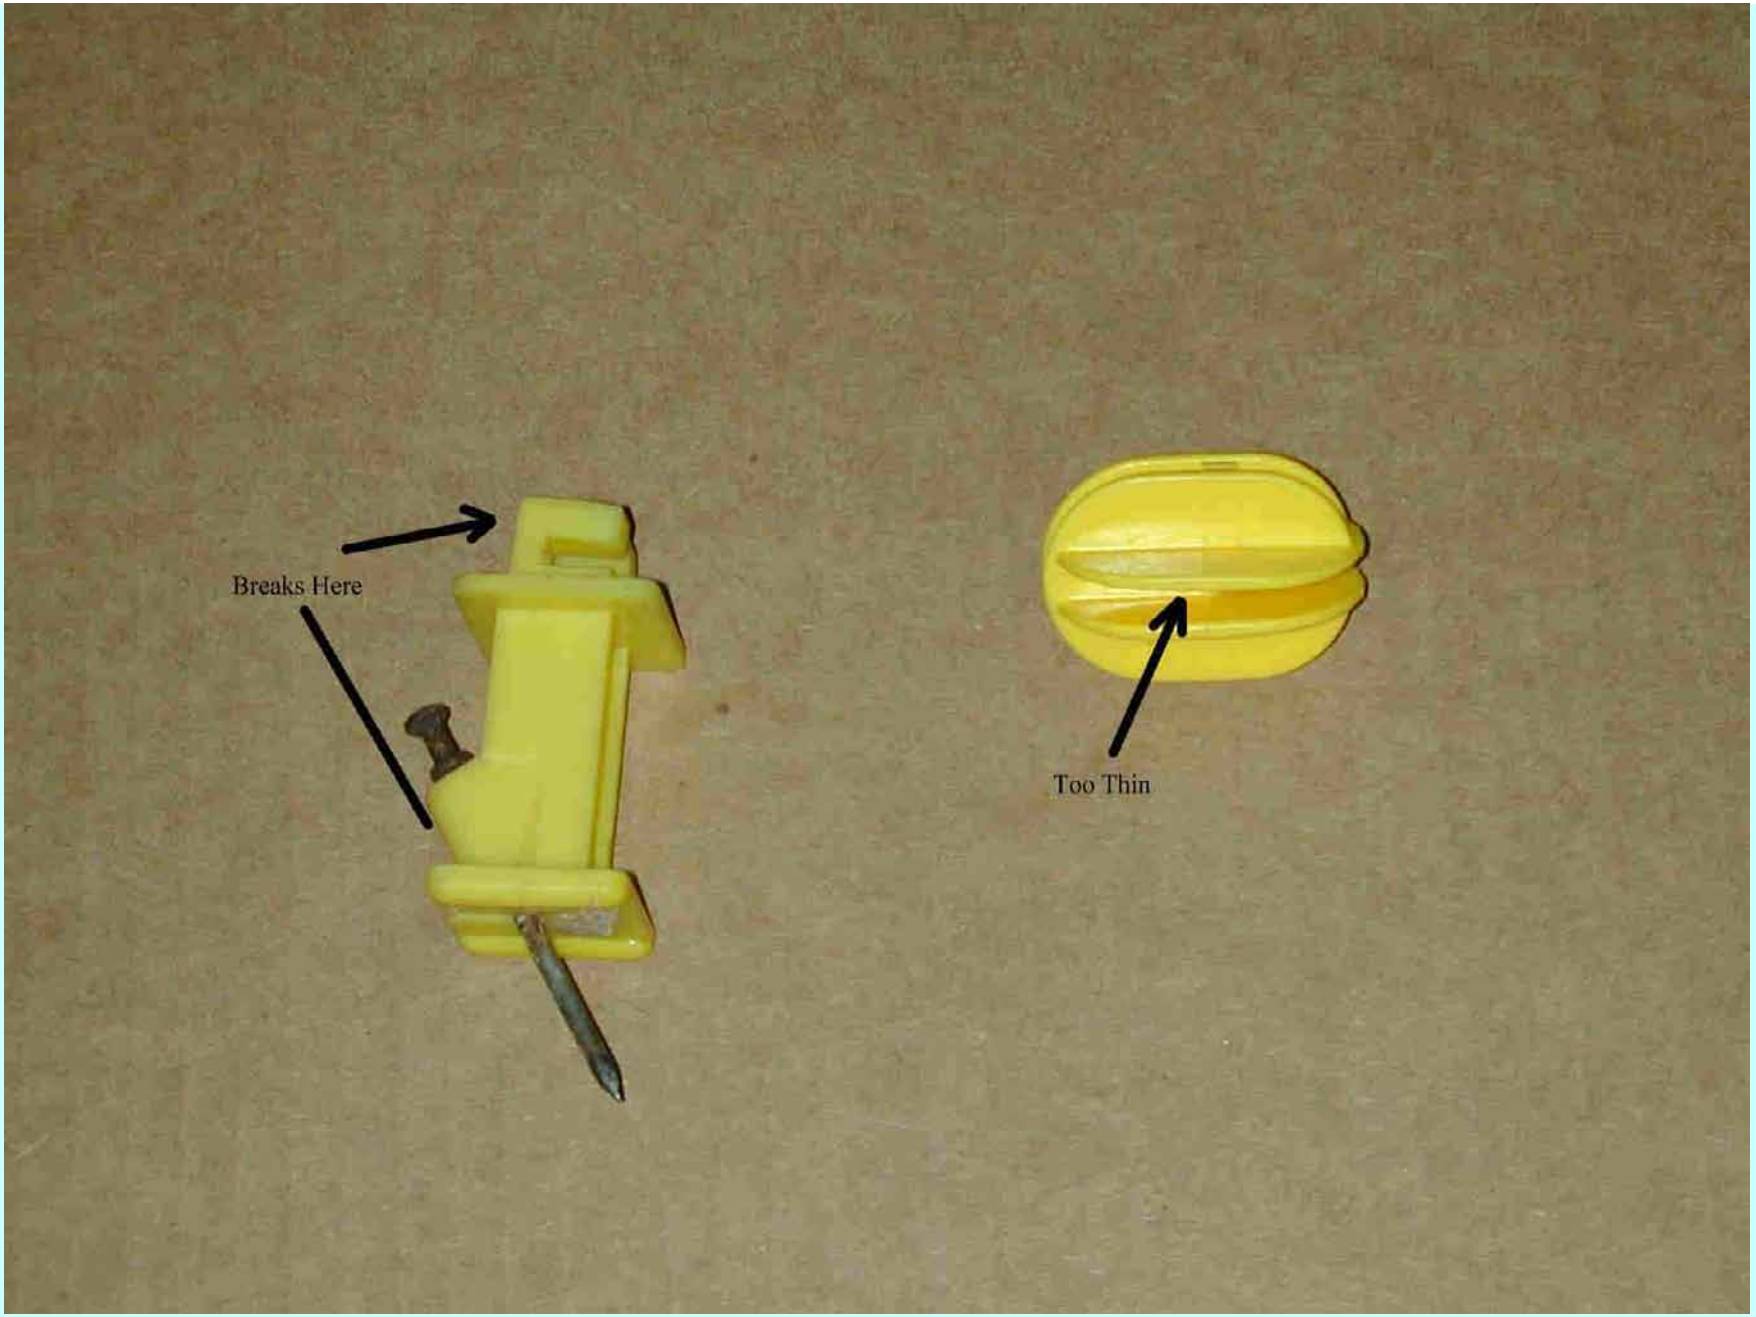
For end supports, I use trees, pressure treated lumber, or landscaping timbers. With a lot of tension, I backstay the poles to a dead-man (generally an old brick) buried in the ground. When I set end-posts with my power auger, I line the hole with copper flashing. That becomes part or all of the feed point (and termination) ground connection.

I never anchor or wrap the Beverage wire around insulators, except at the ends. I always allow the wire to "float" through the insulators. When the wire floats, you can tension the entire antenna from either end. If anything breaks the wire, you can see it at any point! A "floating" wire is much easier to repair if it is damaged, because you only need release tension on one end to splice the wire. Re-tension that same end, and everything is restored. It takes no more tension to support a 1000-foot Beverage with supports every 100-feet than it does to support a 100-foot wire between two rigid supports, but it is a much more difficult to break the longer wire. A longer "floating" wire will often take-up enough slack to remain up after deflecting a large tree branch, where a shorter rigidly-anchored span will almost certainly break either the insulators or wire.

Beverage Insulators

If you expect a long-lasting antenna and have a long antenna, be careful when choosing insulators! Some types of electric fence insulators will not last long. The unreliable types of post insulators have two square folds to hold the wire, a square shaped base, and nail through a small molded plastic angle. The weak points of this insulator are the square retaining tabs, and the molded nail tube at the insulator base. When this type of insulator is mounted horizontally, the wire's weight will stress both the molded nail tube and a single tab. I typically find about 10% of the insulators fail within a few months. After three years, the few dozen installed here have virtually all failed.

Avoid these types!



Round yellow or back plastic insulators with the nail going through the center, like the examples below, are much more reliable post insulators

Ceramic post insulators may look great, but they do not allow floating the wire across the insulator. Even if you do manage to find a ceramic insulator that allows floating the wire, the ceramic will quickly wear away at the constantly moving wire. Avoid ceramic insulators, unless you are prepared to "buffer" the wire through a UV resistant soft plastic bushing!

Good end-insulators are becoming difficult to find. I always use compression types, but the material has to be either ceramic or very thick plastic. Some very thin plastic compression insulators will actually cold-flow and allow the wire to pass through the insulation. This is particularly true with thin steel wires that are tensioned over 25 pounds. Heavy-walled egg insulators are much more reliable, and not subject to wire migration through the thin insulation.

My favorite insulators are large these rather thick Fi-Shock yellow plastic insulators. They are slippery enough to allow the dead-end wire or rope to loop over the insulator, and create a 2:1 mechanical advantage when tensioning.

Height

I've found very little performance difference with height, unless the Beverage is more than .05WL high. As the height exceeds .05wl, performance seems to be reduced. Small rolling hills or ravines also seem to make any difference. Follow the contour of gradual slopes, and go straight across ditches or narrow ravines without following the contour.

Sloping Ends

There really isn't a logical reason to slope the ends of a Beverage. After all, six-feet of vertical drop is six feet, no matter if the drop is over 50 feet or straight vertical.

Consider, for example, the K9AY or Pennant antennas. Both have sloped wires, yet virtually all of the response is from the vertical slope of the wire in the antennas. As a matter of fact, the actual shape makes very little difference in the way each antenna works. Why would anyone, knowing how a Pennant or K9AY works, think that a Beverage somehow magically breaks tradition and stops responding to vertical signals in the wires when we slope them a bit? What difference would it make in noise anyway, since the entire antenna responds to vertically polarized signals?

There isn't any possible way, including use of shielding or additional conductors, to prevent the end-wires from having the very small effect they have. Save yourself time and worry, and avoid a needless hazard. Just drop the end-wires vertically right down to earth.

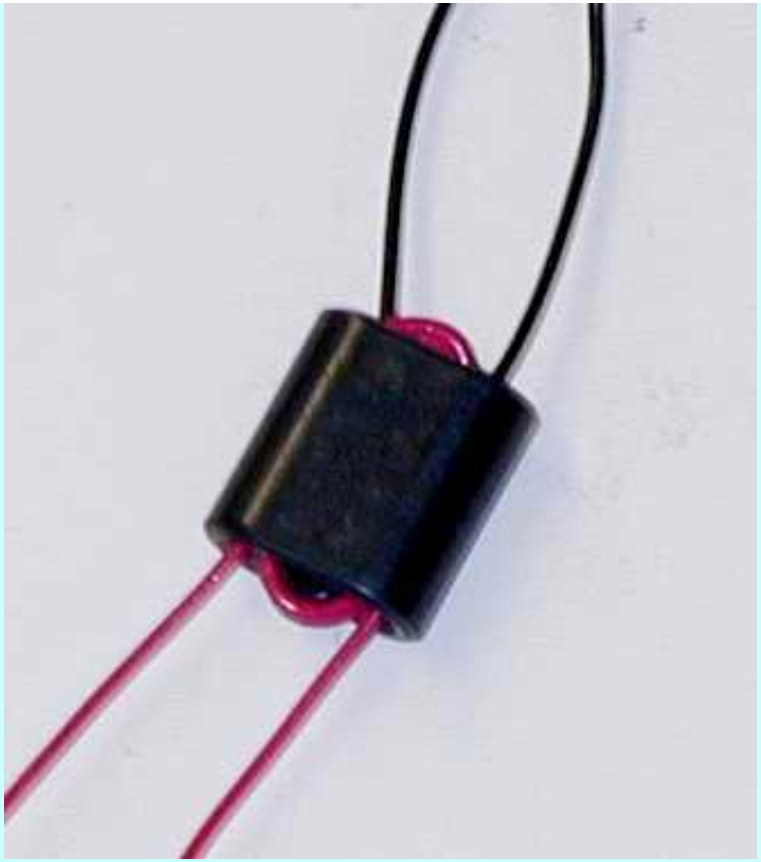
Multiple Antennas Crossing

Crossing of Beverages has little effect if they are not parallel or nearly parallel. Try to cross at an angle of 90 degrees if possible. Even a few inches of spacing is enough for right angle crossing. With shallow angles, assuming they can not be avoided, increase wire spacing to a few feet.

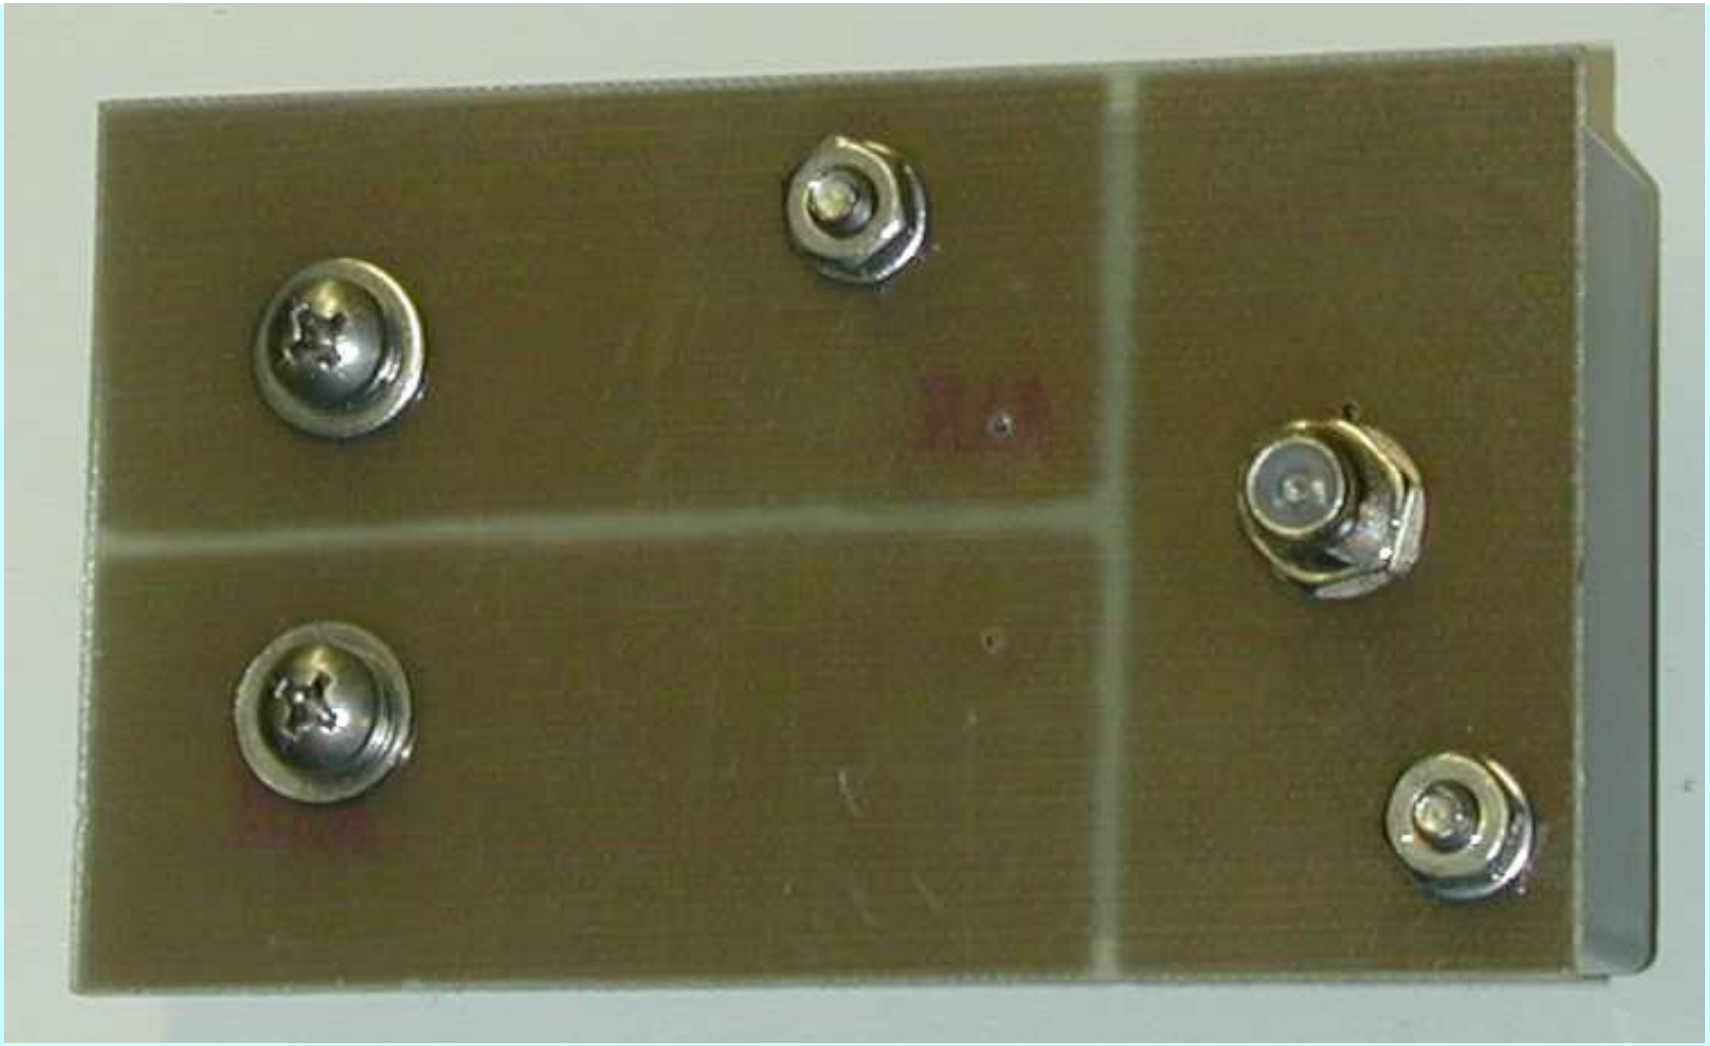
Transformers

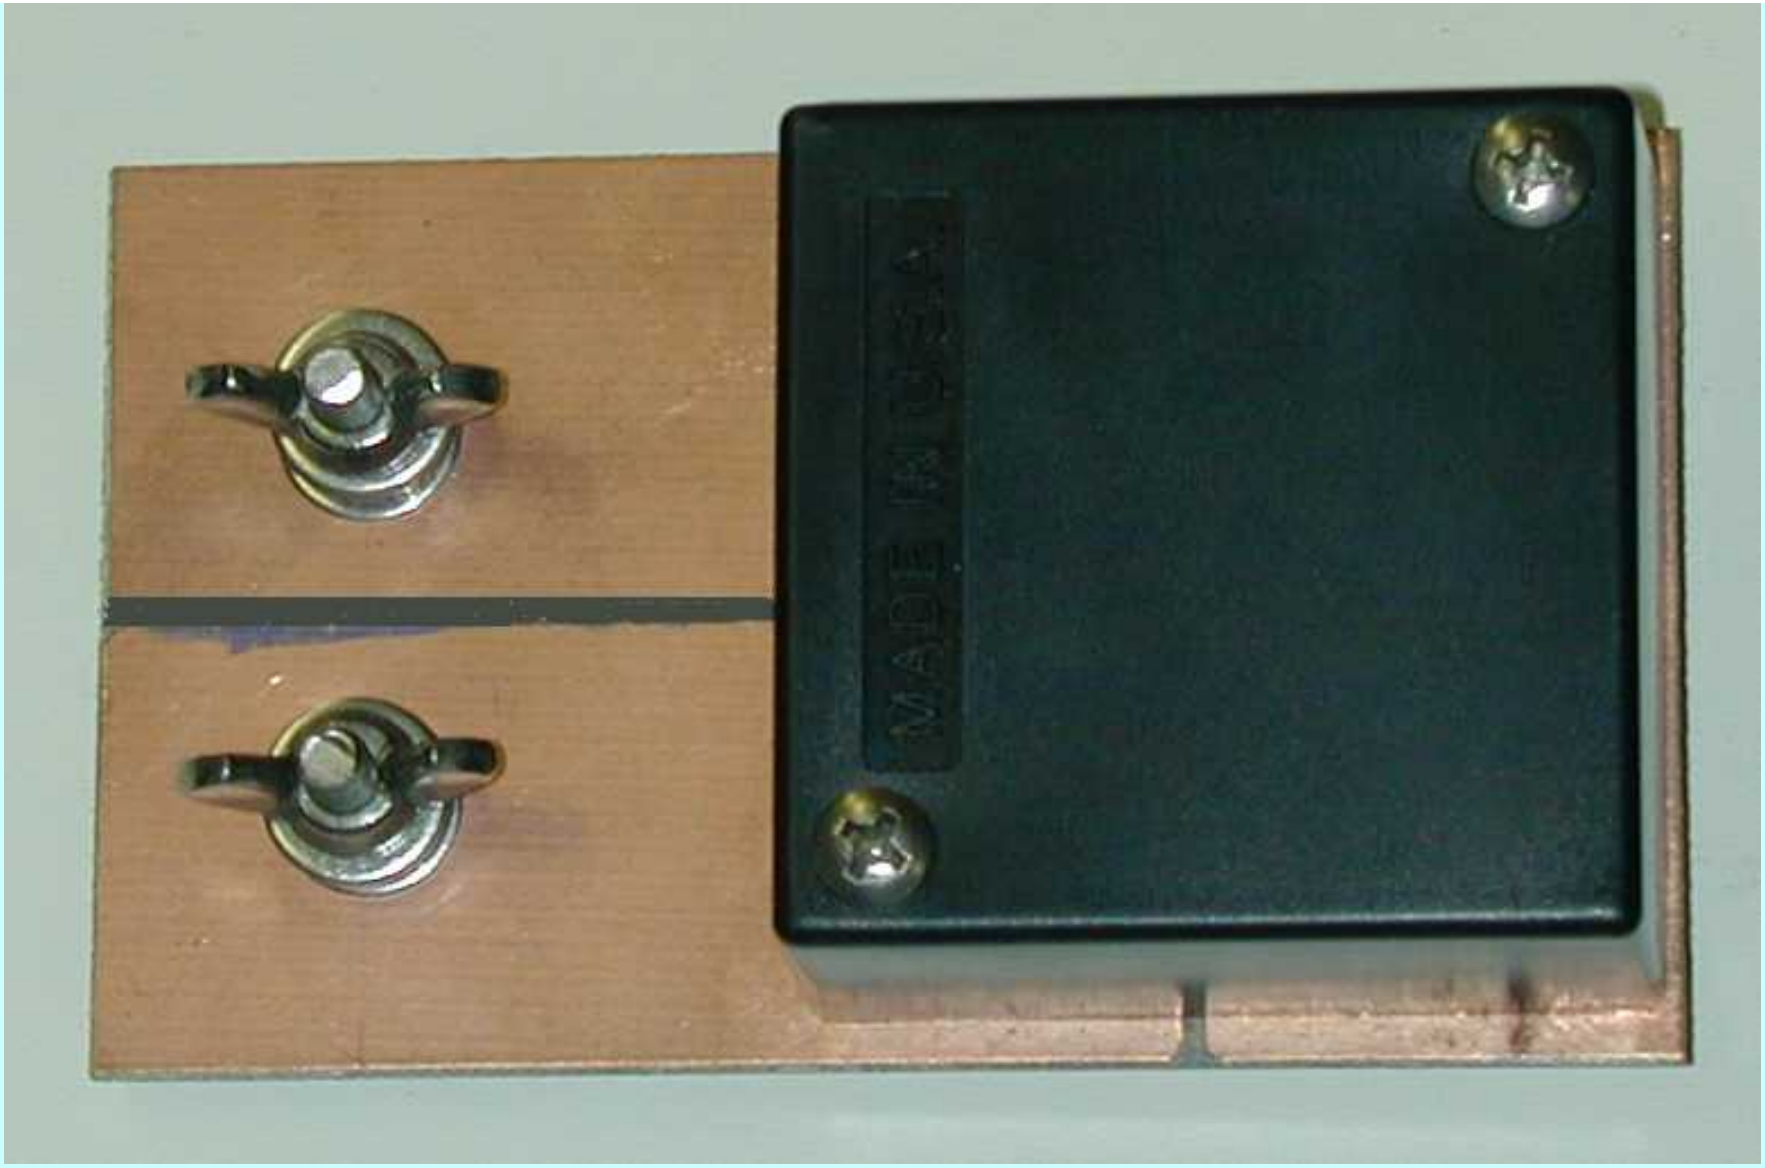
Always use isolated transformers for feeding Beverages. It is cheap, simple, easy insurance against unwanted common-mode ingress of noise and signals into the antenna from the feedline shield. See the Common Mode Noise page for an analysis.

I use 73-mix FairRite Products 2873000202 cores (about 1/2 inch square and 1/3 inch thick 73 material) in my transformers. These cores require a ***two-turn 50-75 ohm winding.*** The high-impedance winding is ***5 turns for 75-ohm cables*** (6.25:1 Z ratio) or ***6 turns for 50-ohm cables*** (9:1 Z ratio). Small insulated hookup wire is actually better than enameled wire. The thicker insulation is much less susceptible to developing shorted turns in rough service.



While my early transformers were waterproofed with Krylon and coated with insulation foam, I have finally laid out enclosed transformers and terminations with internal lightning protection. The transformer sections have F-fittings, and all use stainless steel hardware.





For a Reversible Beverage, I use the following:

Multiple Antennas at One Feedpoint

Never bring multiple antennas to one feedpoint, especially when they share one common ground. I've noticed a definite deterioration in pattern with multiple feedpoints arranged with only ten feet of spacing, even when they had separate ground systems. One set of Beverages installed with 5-10 foot of feedpoint separation has noticeably poorer patterns than other identical length antennas with wide separation at the feedpoint.

Multiple antennas actually may be the only case where a sloped feeder can make a difference, the slope will actually move the effective feedpoints further apart. The best idea, however, is to separate the feedpoints by several times the antenna height.

Termination Value

Having precise termination values isn't necessary, but get as close as you reasonably can. There are some impedance measurement suggestions circulating that absolutely do not work. One is to just use a tuner to match the terminated (or unterminated) antenna, and work backwards with loads to measure tuner impedance ratio after matching. This won't tell you a thing about proper termination, unless you repeat the measurements on dozens of frequencies spread over a wide range!

There are three fast, simple ways to test for proper termination:

With an Antenna SWR Analyzer

1. Connect the antenna analyzer at the Beverage feedpoint through a good matching transformer
2. Sweep the analyzer frequency from 1.8 to 7 MHz (or over a ~4:1 frequency range near the frequency intended for antenna) while watching SWR
3. Adjust termination for minimum SWR ***variation*** (not minimum SWR, minimum SWR variation!)

When installation (including grounds) and termination is proper, ***SWR VALUE*** will remain nearly the same regardless of frequency

With an Antenna Impedance Meter

1. Measure the feedpoint impedance (right at the feedpoint) of a roughly terminated antenna at the frequencies of ***highest and lowest*** resistive impedance. You can do this through a known good transformer by correcting impedance for use of the transformer
2. Multiply the lowest measured impedance by the highest, and then find the square root of that number. This will be the correct termination impedance of the antenna

With a Clamp-on RF Current Meter

(This does not work well with voltage, because of measurement method error problems)

1. Apply a small amount of power from a transmitter, do not exceed antenna system component ratings!
2. Measure current at the termination, and several points up to a distance of at least 1/2 wl from the termination
3. Adjust termination resistance so current shows a smooth current decline as you move the meter towards the termination

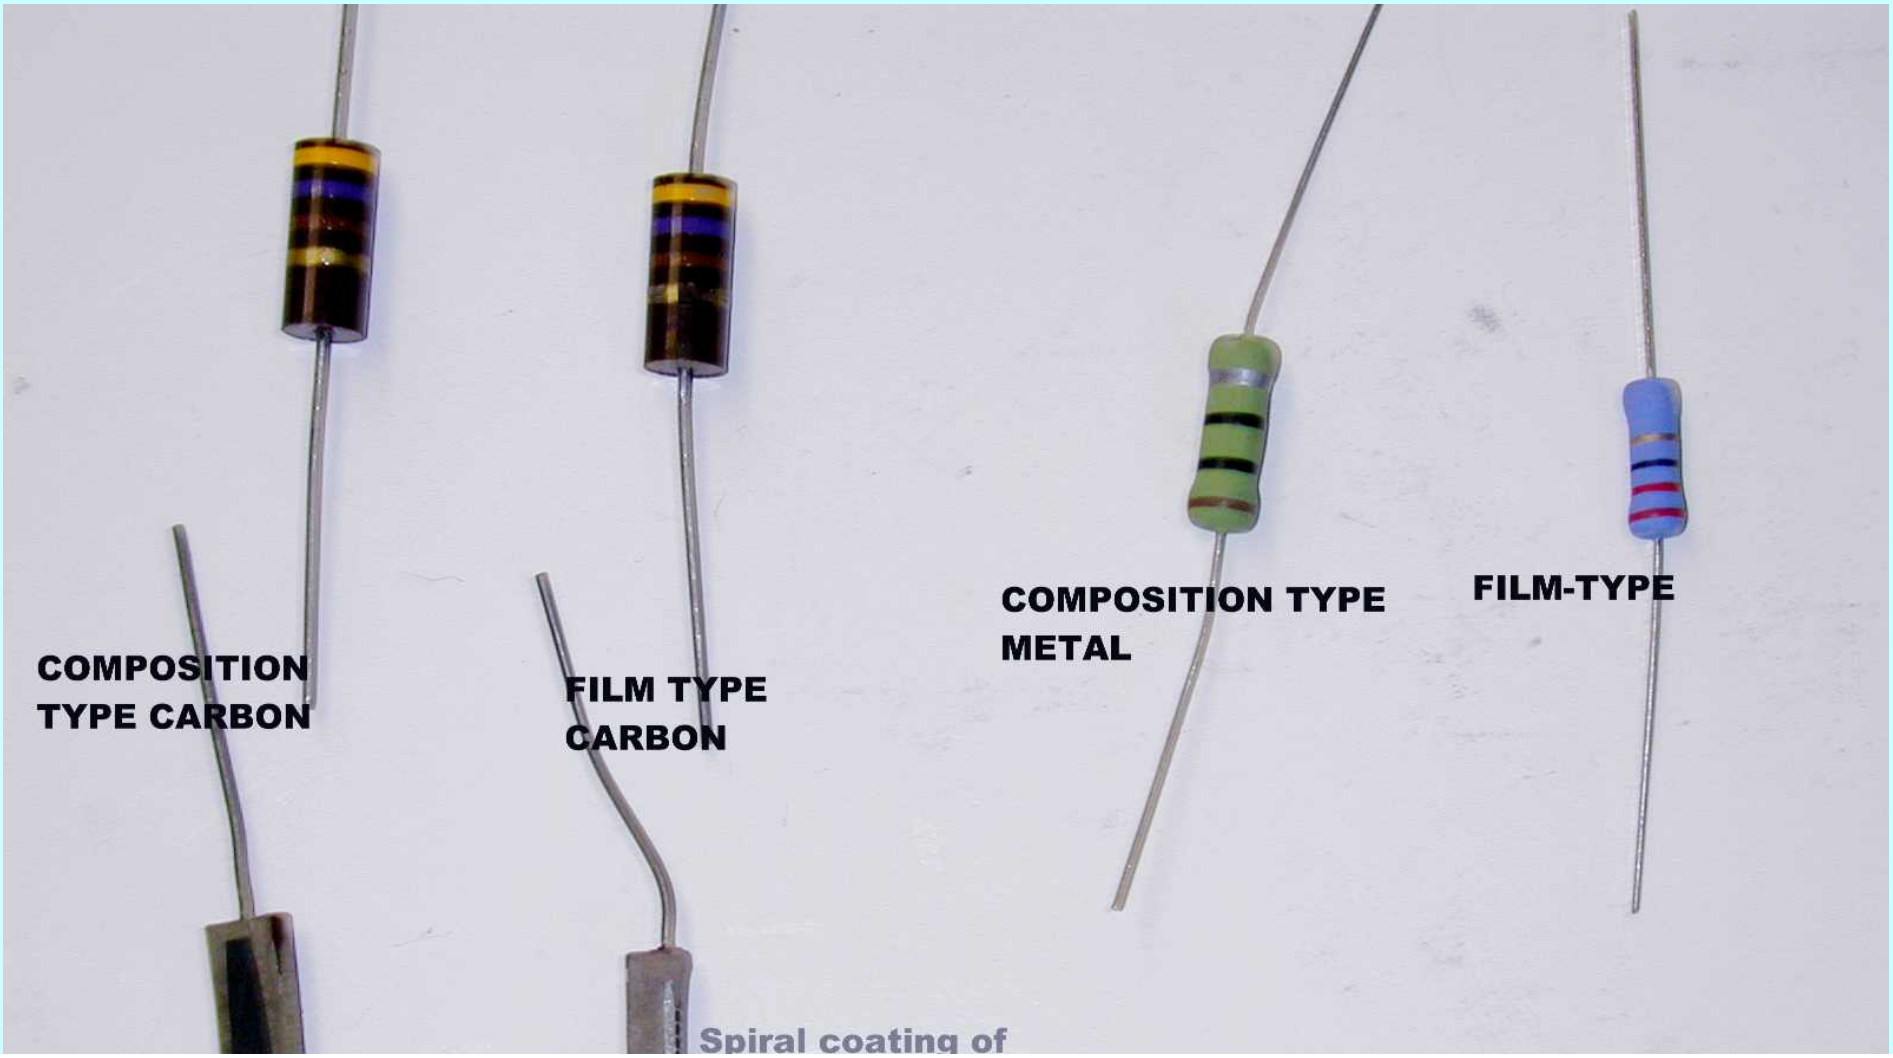
Note:

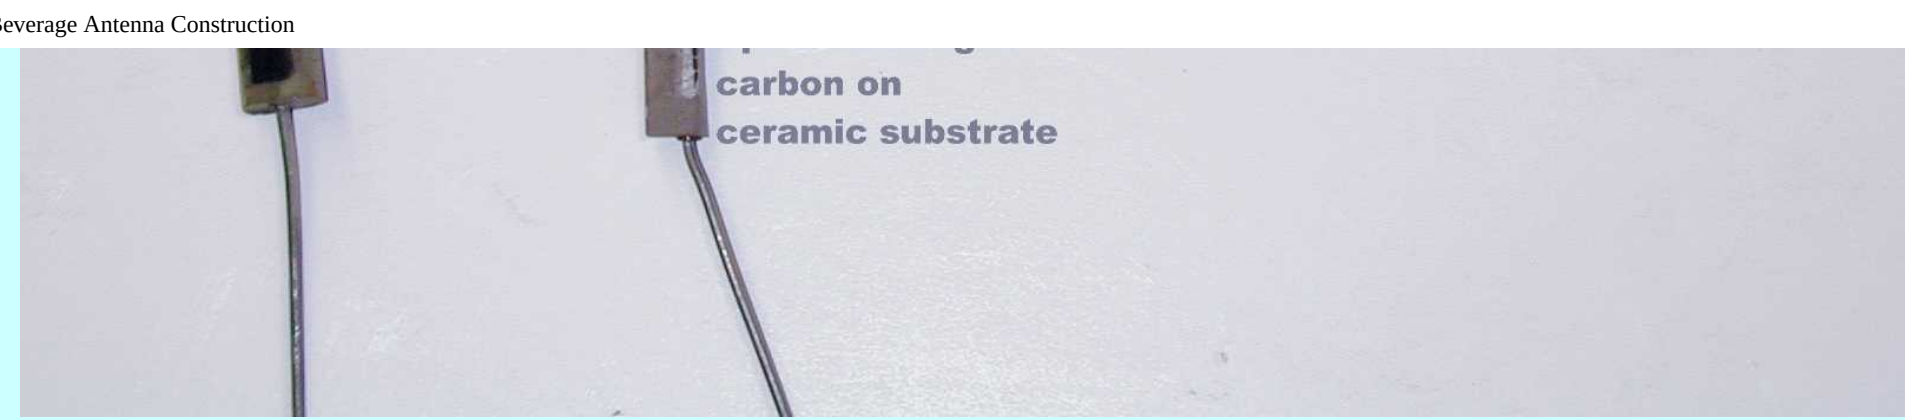
In about 500-800 feet of distance, power loss in a Beverage is around 3dB. This corresponds to a 1/3 reduction in current. If you attempt to adjust for equal currents (or voltages) over any distance, the antenna will be MIS-terminated!

Termination Components

Identifying a Composition Resistor

We commonly assume any brown phenolic resistor is a carbon composition resistor, but that isn't true. Most of the smooth brown-colored phenolic cased resistors manufactured after 1960-1970 have actually been carbon film resistors. There are only a limited number of manufacturers supplying carbon composition resistors. One is Allen-Bradley. They are expensive special-order parts, and the buyer must specify composition types.





As we see from the photo, it is impossible to identify a composition resistor by external appearance.

The only sure way to identify a resistor, short of ordering it from a reputable source, is through a destructive test. We can, for example, apply a large momentary overload and look for a resistance change. A resistance change indicates a film-type element. We could also cut the resistor open, and look for a non-conductive core. A non-conductive core indicates the resistor is a film style component.

Why Composition Types?

We need composition resistors in any application where the resistor is subjected to very-large very-short overloads, or where the system demands a nearly pure resistance at a very high frequency (F>100MHz).

Obviously, in the case of a Beverage at a few MHz or lower, we could get away with using many styles of wire-wound resistors or spiral-film resistors. A small amount of inductance would not be a major problem, and virtually ALL carbon or metal film resistors (constructed with resistance elements deposited or cut in a spiral on an insulated core) would not have excessive inductance. The thing we can not tolerate is the sensitivity of non-surge rated components to damage from lightning storms, even distant storms.

The life of a carbon or metal film resistor, when used as an antenna termination, is relatively short in most locations. Just a few coulombs of energy, when applied in a few milliseconds, will cause a carbon or metal film resistor to change value. Worse yet, the resistor will not be altered in appearance. (Carbon also has a strong tendency to change value with heat. Even modest operating temperatures, over a period of time, will cause a carbon resistor to change value. Metal resistors are more stable.)

Unless you want to make a full-time career out of testing your antennas and replacing resistors, use a energy absorbing composition type resistor!

I install a small lightning gap of about 1/8th inch across my antenna's ends, both at the feedpoint and the termination. This helps immensely with very close strikes. I use either Ohmite OY-series metal compositions or A-B carbon composition resistors. You can buy metal composition resistors at DX Engineering.

Ground Systems

The ground system mainly provides an RF and lightning ground. Having a very low ground-resistance is not especially important, unless an Autotransformer or Un-un is used! Autotransformers and Un-un's don't isolate the feedline for common-mode. The antenna needs a stable ground, not necessarily a low-resistance ground.

In my tests over the years, a 3/4-inch copper pipe driven five feet or deeper into the soil typically measures between 50-150 ohms of RF resistance on 160-meters. (DC or low frequency AC measurements will NEVER give the correct earth resistance for RF, and they certainly can not tell us ground conductivity.) Unless you have exceptionally poor soil, going deeper than five feet will not reduce RF resistance on frequencies above 1.8 MHz. Skin effect limits the depth of RF current in the soil, so the extra rod depth does nothing. Lower resistance values (about 55 ohms) were obtained in a wet marshy area of NW Ohio, with a very rich black acidic sandy loam soil. The higher resistance were obtained in rocky clay soil typical of the Atlanta, Georgia area.

My present location has rolling pastures and wet clay soils, providing under 100-ohms of RF resistance at 1.8MHz with a five-foot rod.

The general guideline I follow is to use at least two five-foot copper rods (I use 3/4" copper spaced 5 feet apart). If I can not get full depth, or if the soil is particularly poor, I add a few 30-60 foot buried radials. The idea is to obtain a reasonably stable ground, so termination does not change.

CLICK TO LOOK AT ACTUAL MEASURED GROUND TERMINATION RESISTANCES!!!

If you are unsure if you Beverage's ground is adequate, measure the impedance of the beverage with an antenna analyzer with your operating ground systems. Note the reading. Add two temporary radials 1/4 wl long suspended above earth at right angles to the Beverage, and re-measure the impedance. (It is OK to have them there at right angles to the antenna and not have them connected, and them connect them while taking readings.)

You can measure the impedance on the low-Z side of a good transformer. Under almost any condition, the wires would have 100 ohms or less impedance. If you see a very noticeable change in impedance, you probably should consider improving the ground system. Impedance changes of 15% (or larger) indicate a potential ground stability problem, because the ground resistance would be nearly 100 ohms. This test should be done when the ground is dry, or any time you think you might be having a ground problem.

Always remember to keep the shield of the cable isolated from the Beverage ground! Never use un-un or autotransformers.

Length

For length considerations, see the directivity factor text. It is not necessary, nor does it do any good, to go beyond 1-1/2 or 2 WL. By the time the antenna is that long, current is so low any addition length makes the pattern worse. I limit my 160-meter antennas to 800-feet, and use multiple antennas when a sharper pattern is required.

Directivity can actually decrease if a longwire-type array is made too long. This is true with Rhombics and Vee Beams, and it is also true with Beverages.

Zigzagging Wire

While a nice clear straight wire looks great, it does more to make us feel better than hear better! Minor ups and downs in height or dips or valleys don't really seem to have any noticeable impact.

Although it probably is a good idea to keep the wire as straight as possible, it is the overall direction and length that is most important because each small area contributes on a similar small portion to the overall directivity and signal reception.

Verticals and Baluns

RF in the Shack

Many people assume that RF in the shack or (worse yet) RF burns are tied to problems from poor station grounds. With properly operating coaxial feedlines or balanced feedlines, the operating position should have minimal RF even absent a shack ground. Only bringing a longwire or some other single wire feeder directly into the shack should cause RF burns or RF feedback in the shack.

There is one exception to the above. Direct radiation from the antenna into station wiring could cause high levels of RF to appear on equipment or wiring, but even in that case the station ground is not the problem or cure!

Contrary to popular belief that only dipoles need baluns, verticals and longwires can require baluns (more correctly called common-mode chokes or isolators in this application) also. This article shows why baluns (or common mode chokes) might be required, and what the balun can do.

What causes common-mode current?

Current flows because there is a voltage difference between two parts of a system along with a return path for the current flow. The path can be "special currents" without actual electrons flowing called

"displacement currents", or it can be actual charges moving through conductors. Displacement currents flow through the dielectric of a capacitor, between a vertical or single wire fed antenna and the "ground" for that antenna, or currents that flow between a mobile's antenna and a car body.

Displacement currents commonly complete the entire current path in antennas. They are the sole reason current in physically large coils can vary from end-to-end, and are especially problematic in mobile antenna installations. They are the reason an open-ended antenna like a dipole, longwire, or vertical is able to have current flow!

When we force charges up into a Marconi vertical or longwire antenna (making current flow), we have to move an equal number of charges out of some ground system or counterpoise into the feedpoint. The ground can be a single conductor or many dozens of wires, and it can (and often does) involve equipment in the house and/or the coaxial feedline shield. The bottom line is we always must have the same current coming back to the feedpoint as moves up into the antenna! There is no way around that rule.

This creates two problems:

1. **We may not be able to handle all the charge displacement with a few radials without having significant voltage driving those radials**
2. **The feedline has to connect to the antenna, the outside of the shield may be excited by this voltage, and become part of the return path for "collecting" displacement current**

Another way to view this is the feedline has to have something to ***push against*** to force current into the antenna. It is like pushing a car. If you have very poor footing, your feet will move and slide. The same is true for a ground system, as feedline power "forces" current up into the antenna the other terminal of the feedline has to be held steady.

The Feedline

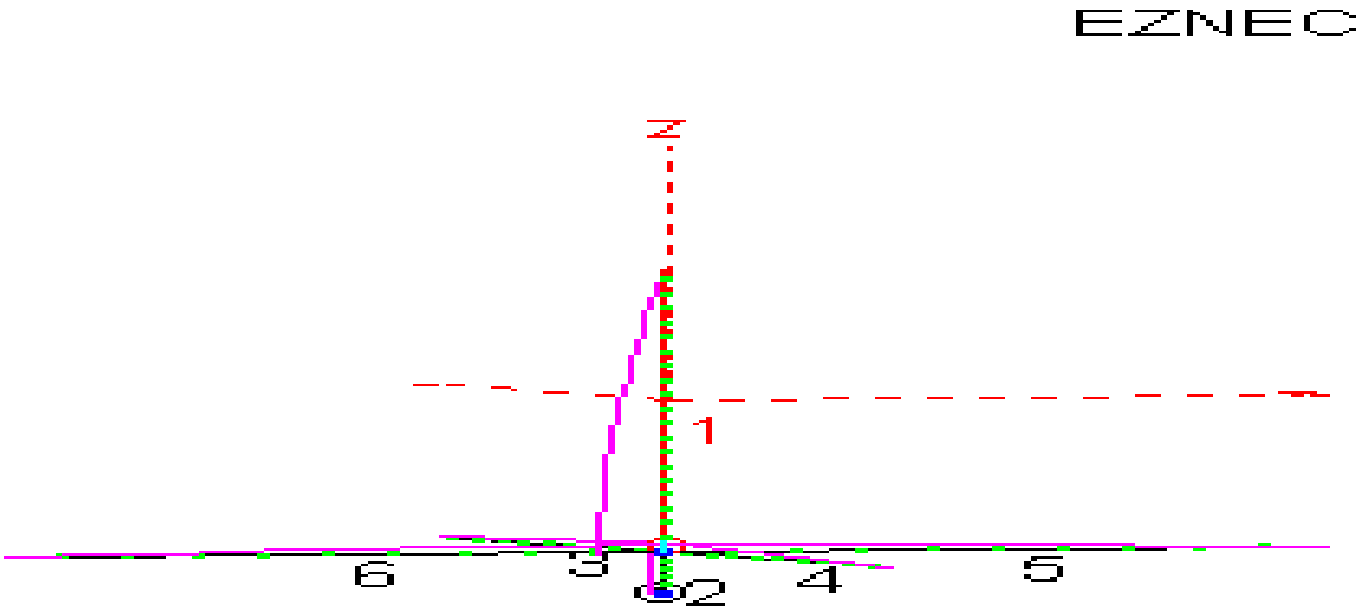
If you are not familiar with how coaxial cables work, you might want to look at a simple explanation on this site or one of the ARRL Handbooks.

In order for a conductor like the outside of the shield to ***not*** have current flow at Radio Frequencies, it must have the same electrical potential and phase all along the length. If it has a high series impedance or if the potential difference along the conductor is low, very little current will flow. As seen in coaxial cable operational descriptions, any coaxial feedline can have unwanted common mode currents.

Does a vertical or longwire present common mode voltages to the feeder that can cause common mode currents? You bet! The only vertical (or longwire) that would not cause such problems is one with a very good or nearly perfect ground system, and that means something that looks like a large infinite groundplane. Even then, the cable must exit ***below*** that groundplane to be "shield current free".

Aren't Four Elevated Radials Perfect?

Here is a model of a groundplane with four radials:



EZNEC ver. 3.0
Balun 80 vertical 1/3/04 7:19:05 PM
---------- CURRENT DATA ----------
Frequency = 3.6 MHz.
Wire No. 1: 6.700
Wire No. 2: 1.359 (This is your feedline or mast)
Wire No. 3: 1.985 (These are the radials)
Wire No. 4: 1.985
Wire No. 5: 1.985
Wire No. 6: 1.985

We can see significant current flows over wire 2, which would be the coax shield, a mast, or both.

There is a trick with Eznec. By inserting an additional source in the mast or feedline and setting current to zero, we can observe the radial common point to earth voltage required across a balun to force current to zero. In this case the voltage across the balun would be:

Source 2 Voltage = 145.5 V. at 67.97 deg.
Current = 0 A. at 0.0 deg.
Impedance is infinite

Amazing isn't it? At 1500 watts the ground common point for the radials actually wants to have ***145.5 volts to earth*** to prevent current flow and unbalance of the system!!! If we elevate the common point to 145.5 volts at 68 degrees phase angle, we now have the following currents at 1500 watts:

Wire No. 1: 6.4 A
Wire No. 2: 0 A (coax shield or mast)
Radials: 1.58 A each

Other Systems

With fewer radials the situation becomes much worse! (As a matter of fact, this is a good reason to use as many radials as we can even if the radials are resonant.)

Claims that four elevated radials form a "perfect ground better than 120 radials" are obvious nonsense! If it was a perfect ground, there would be no potential difference to earth and no common mode current flowing to "real ground" !

If the antenna has a high base impedance, it will have less current at the feed connection. (Sorry, but we cannot do this by using a folded unipole!)

Longwire and Windom antennas really aren't much different than verticals. They are a form of Marconi antennas, and require a counterpoise or ground of some sort. As with verticals, common mode current flowing into the antenna must be balanced by current flowing into a ground system.

Instead of bringing the longwire directly to an antenna tuner, a better solution is using an RF ground system independent of the station safety ground, and keeping that ground isolated from the station safety ground. That can be accomplished by adding a good heavy-duty 1:1 choke or current balun a few feet from the tuner, and connecting the RF ground to one output terminal and the antenna to the other terminal. With a two-wire feed Windom (really an OCF dipole), the two wire should connect to the choke balun.

The balun MUST be a current balun, rather than a voltage balun.

Summary

The cure for common mode problems caused by less-than-perfect grounds is inserting a 1:1 choke balun in the system at the antenna feedpoint. The coax should also be kept away from the radials as it exits the area of the radials and the antenna. An antenna with a poor ground using few radials cannot have a support mast grounded to the radial common point (at least it shouldn't if designed properly). There is no exception to this!

For comparisons of baluns see balun test.

Testing Transmitting Baluns

One of the most popular Ham-lore rumors is a balun's performance can be tested or evaluated by grabbing the coax and watching for an SWR change. This is probably one of the worse test-rumors circulating!

An observable SWR change when touching, grounding, or altering length of a feedline (with the same Zo at the test meter) indicates severe common-mode current problems.

The opposite response, however, means nothing. Lack of SWR change does NOT prove the balun adequate and the system free from common-mode currents.

I was first exposed to this wild idea when asked to evaluate a problem with a commercially manufactured antenna. The antenna's design engineer decided a bead balun was adequate, based on this "grab and touch test". The antenna/balun combination passed the "grab test" with flying colors, even though the system had gross common-mode current levels. Despite extending the bead balun from the original foot to almost three-feet of beads, I couldn't remove common mode excitation of

the feedline by the grossly unbalanced antenna.

If we think about it, we would never consider it likely that our hand would have significantly lower impedance than the shield on a long length of coaxial cable! We also would never expect, just by dumb luck, to always grab the high impedance point of a random wire like the feedline.

A hand-grab-test will cause an SWR change only when the impedance of your hand is very low compared to the common-mode impedance of the cable at the point where you are "grabbing" the cable. The portion of impedance attributed to feedline radiation (compared to overall antenna impedance) must be a significant portion of antenna terminal impedance or the SWR will not change.

It is possible, if we alter antenna feed-cable lengths, to observe SWR changes as an indicator of common mode currents from poor system design. But such methods are never nearly as accurate as an absolute current measurement, and are actually only a little bit better than the useless "hand test". They also can give false answers if the feedline impedance is not the same as the SWR measurement device impedance.

An Accurate Test

The most simple and accurate way to test the effectiveness of a balun is to actually measure the common mode currents on the feedline with a suitable RF current meter that does not perturb the system. Such meters are inexpensive to purchase and are also easily manufactured at home. The meter would consist of a closed core that snaps around the cable, a terminated winding on that core, and a meter that measures RF voltage across that winding. The coil's load resistor should be low enough in value that the impedance of the cable shield is not perturbed.

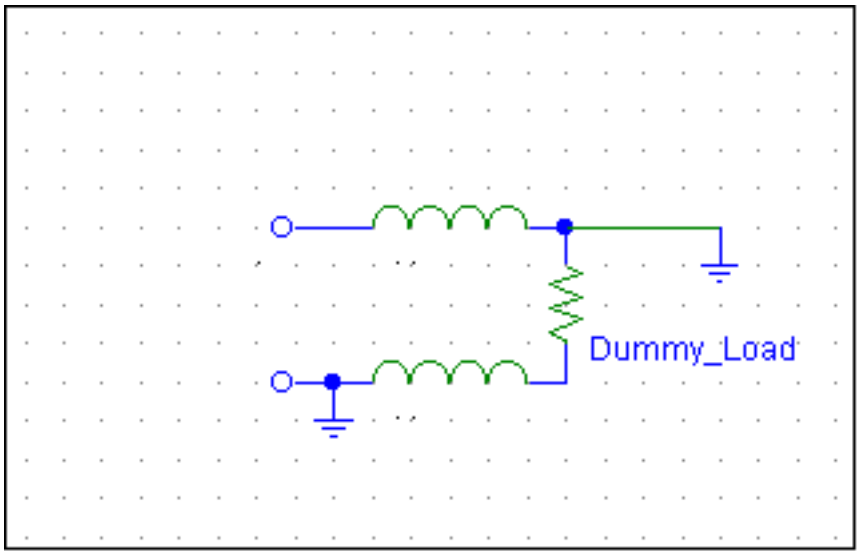
By sliding the meter along the feedline, we could get a good idea of the common mode currents. The meter should be moved along at least 1/4wl of feedline. It normally would be sufficient to sample just four points along that distance.

Feedline radiation, like antenna radiation, is a function of the linear ampere-feet of conductor. The important distance is the spatial or linear distance, not the length of a coiled conductor. It is the charge acceleration over a linear distance of space that accounts for the radiation. A one foot box packed with 500 feet of cable is still just a one-foot antenna!

There are many cases where adding a balun will actually INCREASE common mode currents. Be sure you either fully understand the system or have modeled the feedline and antenna correctly.

Power Testing

A choke or current balun can be tested by inverting the ground on either end, and using a dummy load. Actual operation may produce more stress than this test, or less stress, but such a test gives a reasonable idea of the power rating under reasonable conditions.



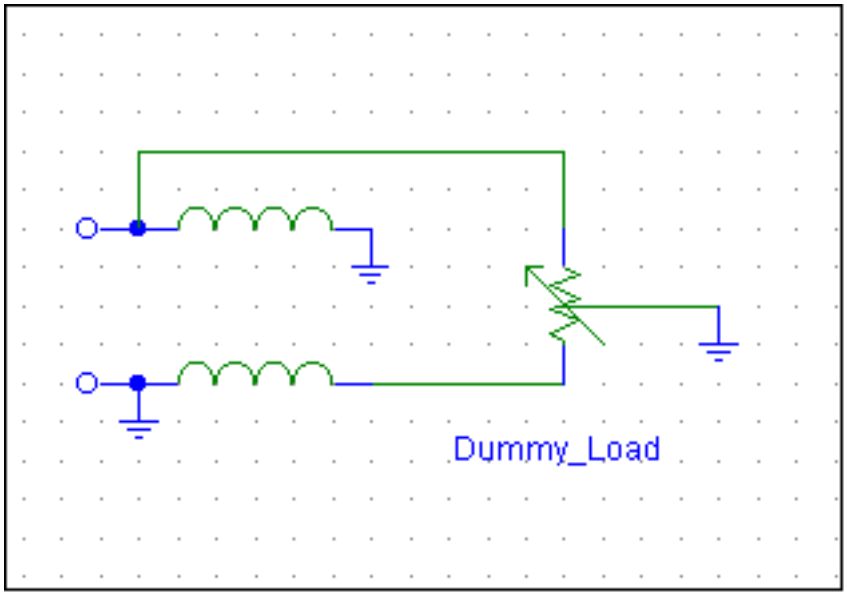
The balun should not overheat or change impedance with application of full power for the expected duty cycle in the expected maximum operating temperature (be sure to include sunlight heating).

Impedance Testing

Using the above test configuration, SWR can be measured. SWR should be flat, and should not change when the ground by the dummy load is moved from side-to-side. This should be true at full sustained operating power.

Testing Voltage Baluns

While voltage baluns are the least desirable types in most applications, they still have some useful applications. Using this configuration:



By moving the tap point along the dummy resistance, an idea of balance can be obtained. The balun should show perfect performance with the tap-point at the load center, and should show an SWR increase as the tap moves to the top or bottom.

Crossed Split Windings on Toroids

Some articles and handbooks show a Split winding method. This method is supposed to reduce winding capacitance by moving the ends of windings further apart. The proposed theory is by reducing shunt capacitance that "leaks RF around the balun", balun performance is enhanced.

This method very often hurts the performance! Check this article

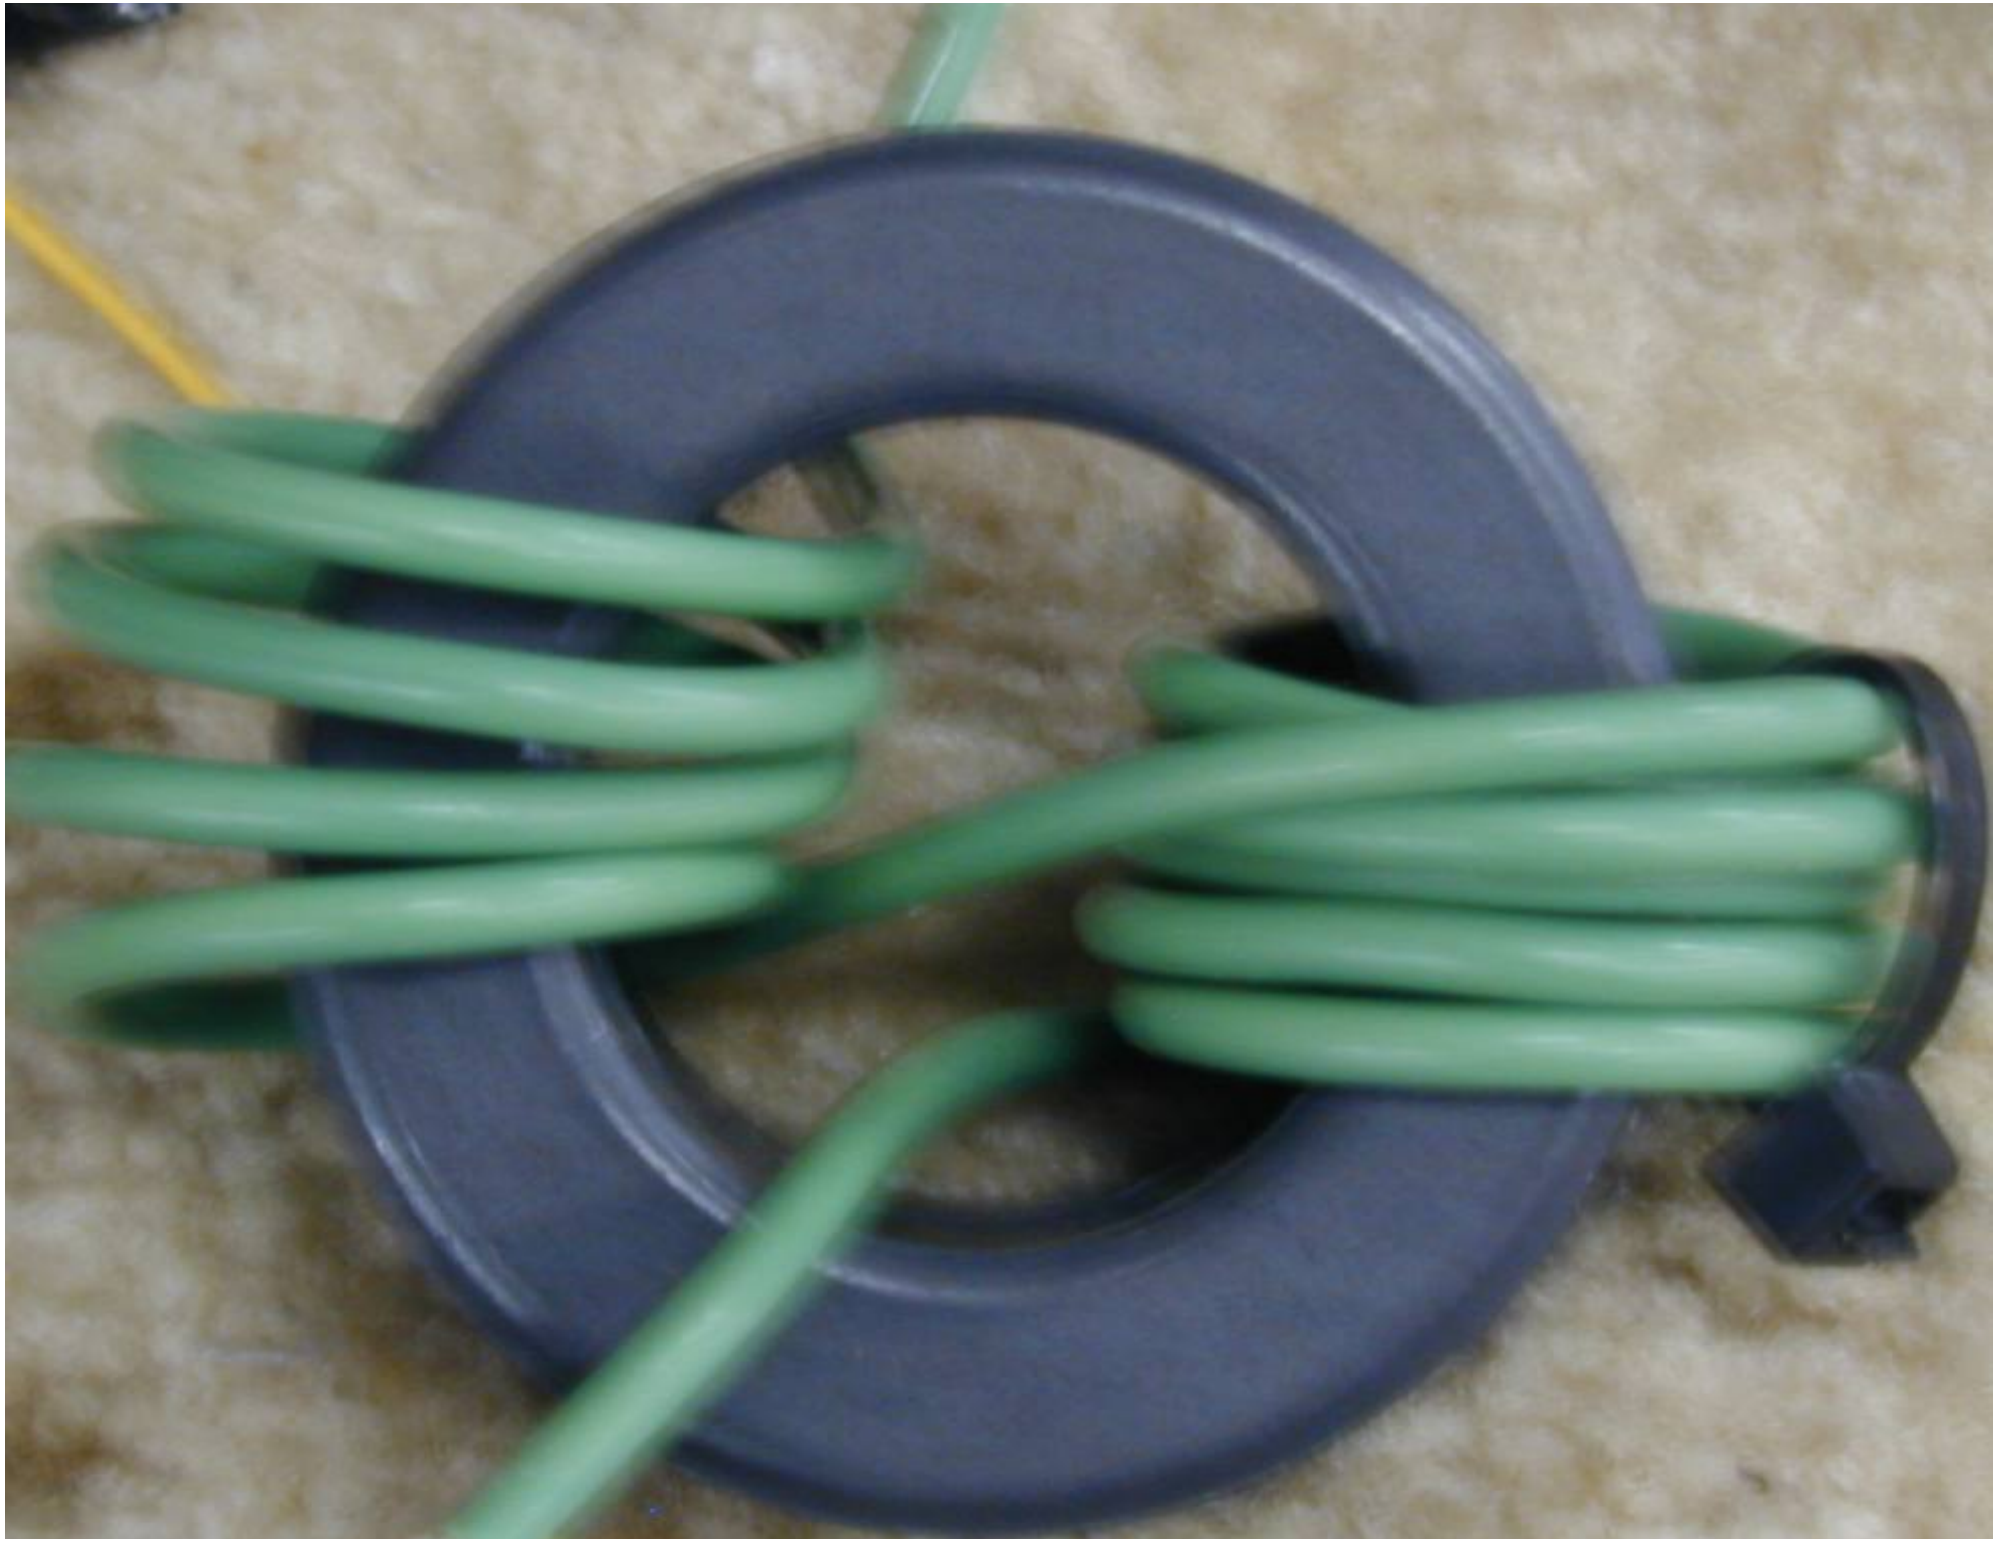
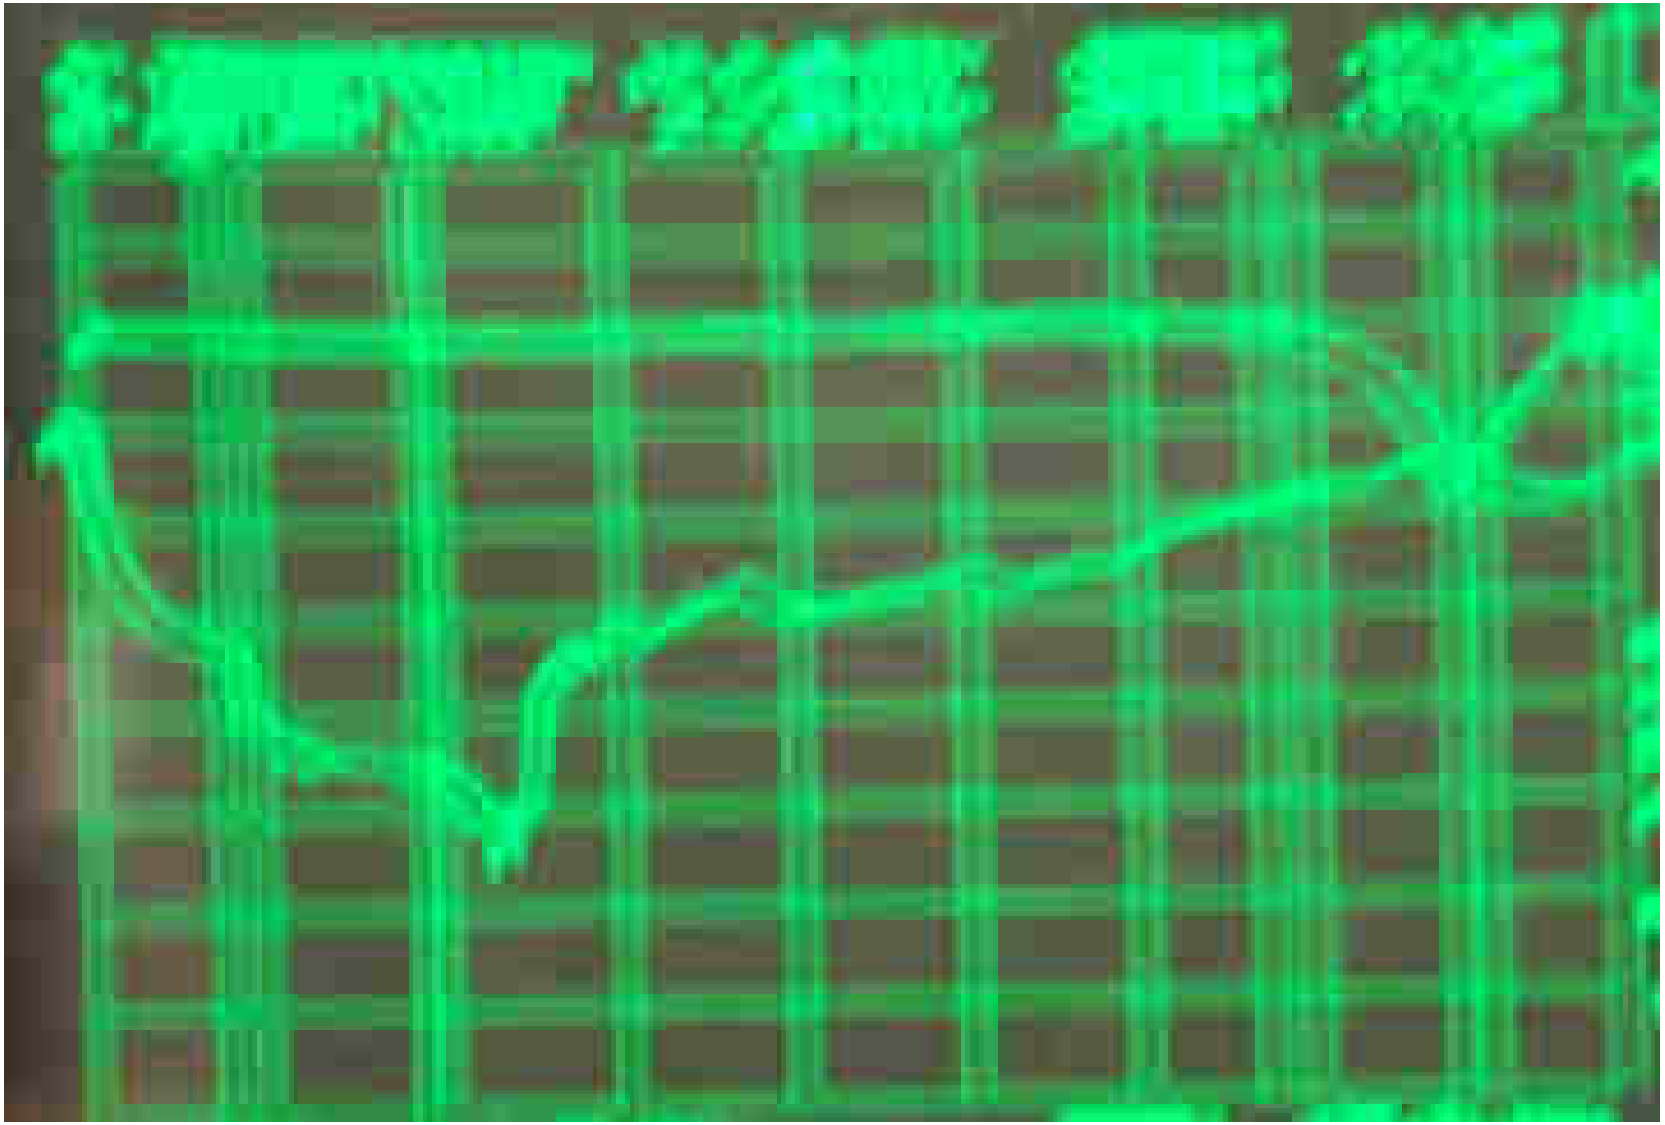
Toroid Chokes and Baluns

Commonly published information tells us winding a choke or 1:1 balun on a toroid with this special winding technique increases common mode impedance (choking isolation) of an 11-turn balun on a pair of #65 material ferrite cores:



The common mode rejection sweep, assuming a 50-ohm common mode source and load is:

(pardon the camera jitter)

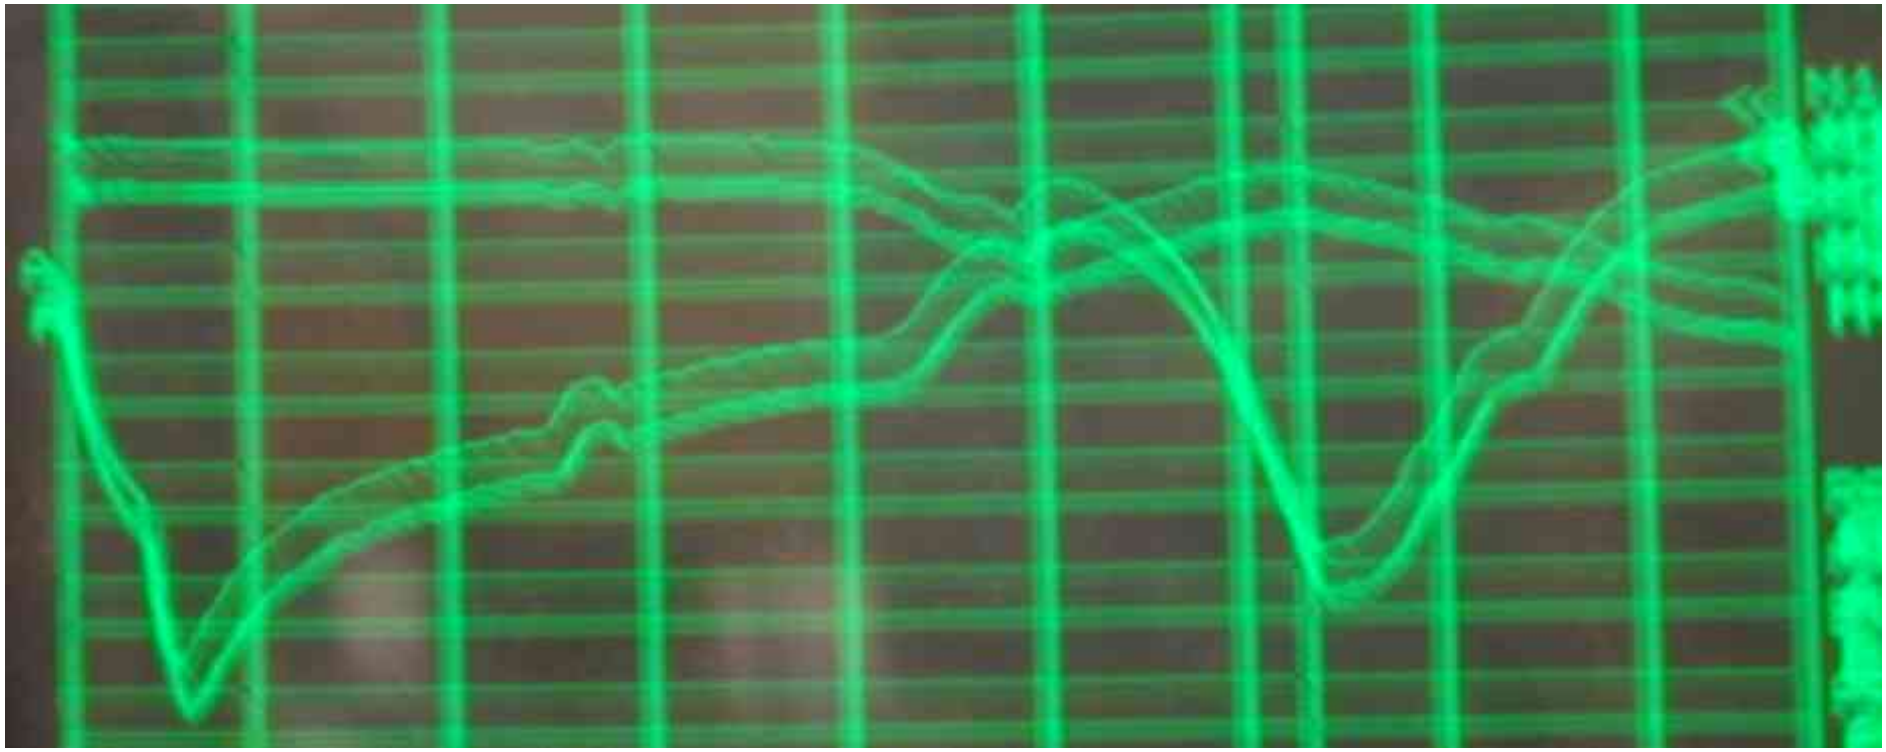


This sweep shows the following suppression using split winding method:

15.71 MHz	37.1MHz	134.8MHz	157 MHz	
-33dB	-46dB (peak performance)	-19dB	-3dB (minimum rejection)	

The same core was rewound using a normal parallel winding:

The sweep looked like this:



Common mode rejection, compared to the more complex winding, was:

Frequency	15.71 MHz	37.1MHz	134.8MHz	157 MHz
Split winding	-33dB	-46dB (peak performance)	-19dB	-3dB (minimum performance)
Normal winding	-47dB (peak performance)	-41dB	-4.6dB (minimum rejection)	-11dB

Conclusion

The ONLY change by using the more-difficult split winding is peak performance points moved higher in frequency. Performance in the HF range and lower actually decreased, so the extra effort resulting in a poorer HF balun.

This follows what many of us have been saying, and what anyone familiar with resonant circuits already understands intuitively. Common mode impedance increases with a slight amount of parallel capacitance is adding. The capacitance does NOT, as some claim, reduce performance by "leaking" RF around the choke.

The rule is simple. With any parallel L and C (neglecting losses), impedance always increases unless the parallel capacitive reactance (in ohms) is less than half the value of the inductance (in ohms).

With a choke winding impedance of 300j with an added parallel -150j capacitive reactance, the combined impedance would be -300j. The isolation would be the same! Any value of capacitance reactance higher than that (less capacitance value) would actually increase choke isolation!

There are many "improvements" we just blindly accept from reading articles, because on the surface they seem to make sense. This dispels one of the myths about baluns.

Another common myth is the widely accepted claim moving a choke balun to a lower common-mode impedance point of a circuit, such as the input of a tuner, improves balance or balun performance in the system. If you think baluns at the input of tuners are a good idea, go to this W7EL link and read the section on current baluns. You might be surprised!

If you arrived here from a link from K3BU, I want to apologize for the personal nature of that page and this response. Why is this response necessary? None of us like to see false or out of context claims or personal attack articles. Many of the comments from below were removed from context and quoted to mean something else in another internet article. It is important to read everything ***IN CONTEXT****.*

How Does an Inductor or Loading Coil Work?

The most basic answers are:

What does the coil do? A loading coil does not replace a missing fraction of a wavelength. The coil simply inserts a series inductive reactance that cancels capacitive antenna reactance. When a 150 ohm reactance inductor is inserted in series with a 150 ohm capacitive load (like an antenna), only the resistive parts remain.

What determines current distribution in a loading coil? The capacitance to the outside world and the impedance above the loading coil. The current in any inductor would be equal at each end except for displacement currents, which are "imaginary currents" that flow through capacitance.

How much difference is there in loading coil current entering the coil and loading coil current exiting the far end? If the antenna beyond the coil has a low self-impedance compared to the impedance of the shunting capacitance from the coil to "ground", the currents at each end of the coil will be essentially equal. It has NOTHING to do with electrical degrees the coil compensates for. In other words if the portion of antenna above or beyond the loading coil is long or has a large area compared to the physical size of the coil, current is essentially equal throughout the coil.

What does significant current taper in the loading coil indicate? It generally indicates a poor antenna design, where the loading coil (or any other application using an inductor) has high stray capacitance to other areas of the antenna system (like the groundplane) compared to the capacitive reactance of the antenna beyond the inductor. Significant current taper indicates a poor loading coil or poor antenna design.

click to view typical installation measurements

The Difference Between a Loading Coil and a Normal Inductor

There really isn't any difference, except the location where the coil is used. Mobile loading coils or loading coils for short antennas often have very high reactance. They have small amounts of capacitance at the end, and so stray capacitances are more of a concern. Stray capacitance from turn-to-

turn increases circulating currents and has the effect of increasing inductance and effective resistance at the expense of reducing bandwidth and Q. Stray capacitance to the outside world causes the coil to behave like an L-network, and transform impedances instead of providing a series reactance. This is why the optimum form factor of a coil becomes longer compared to the diameter with any inductor having very high reactance.

Inductors with low reactance are less critical of stray capacitances. Optimum form-factor in a low reactance inductor leans towards a short coil with the diameter nearly equaling length. In tank circuits or loading coils used with longer antennas or with capacitance hats, an optimum inductor is shorter and larger in diameter.

Most optimized inductors fall between 1:1 and 4:1 length to diameter ratios, the exact value depending on the terminating reactances. A coil is a coil, they behave the same way regardless if used as a loading coil or a tank inductor.

Common myths about inductor behavior:

One common myth is loading coil current is reduced as it passes through the coil. There are two reasons cited for this. One idea is the current is reduced because the loading coil replaces a certain amount of "electrical degrees" of antenna area, like the current taper in an antenna. The other idea is that series loss resistance causes a current reduction.

We often find inexperienced builders of 5/8th wl antennas think the "loading coil" needs to contain 1/8th wavelength of wire in order to make a "3/4wl antenna" and thus cause a low feed impedance. In other cases, some claim a half-wave of wire wound on a form causes a 180-degree delay, and is useful for phasing in a collinear array.

The basic flaw is the above ideas do not account for what happens in a coil with mutual coupling between turns. The flawed viewpoint is that current goes in one end, winds its way around through the physical length of wire in the coil, and after a time delay comes out the other end. There is a physical mechanism that prevents this, as we might intuitively think, from actually happening . The mechanism is the magnetic field in the coil!

What Really Happens

When current flows in the transmitter-end of the coil, a magnetic field is created. This magnetic field causes charges in the other turns to instantly move. This effect ripples through the coil at light-speed, just over 186,000 miles per second. As long as the magnetic flux coupling is high, the delay through the coil is the speed of light over the physical length of the coil. The electrical delay is the physical length of expressed the coil expressed in degrees at the operating frequency.

(Another interesting effect occurs. The increasing magnetic field sets up an "opposing voltage" as it cuts across conductors. This opposing voltage, created as the field expands, is what causes the current to rise slower than the applied voltage. If the exciting voltage is decreased the field collapses, and now the voltage changes polarity and aids current flow! If we don't allow the current to flow, the voltage will rise until it does. This is what causes the kick in a relay coil when we open the relay coil path, or the spark in an ignition when the points abruptly open.)

In an RF system, the physical size of the coil actually does add some "antenna effect". For example, on 160 meters the wavelength is about 550 feet. 1.5 feet is about one electrical degree. A skinny one foot tall coil, with negligible stray capacitance, would have about 0.67 electrical degrees phase delay. This delay occurs because to coil occupies a physical length of .67 degrees. Current at each end would be almost perfectly equal, the taper would be about what we would expect for a fractional-degree-long coil.

(*In the real world, all components have some stray capacitance and flux leakage, so they have a different amount of electrical length and current taper than the "negligible capacitance" case. In good coil designs, the capacitance and leakage is small and can be ignored. I'll show you measurements later to prove this.)*

Now let's look at an extreme case. If the entire antenna is "coil", like a helically wound antenna with no top hat or stinger, current would be reduced to nearly zero at the open end. This is because distributed capacitance over the length of the antenna is fairly high, the shunting capacitance has a low impedance compared to impedance at the end of the antenna, and current is diverted to ground in the form of displacement currents.

Compact loading coils are another matter. In many cases phase delay is negligible or immeasurable by normal methods...flux coupling is nearly perfect. A good example would be a relatively compact toroid or a compact nearly-square L/D ratio loading inductor. I've found it impossible to measure the current taper in a toroid and very difficult to measure in a compact air-core loading coil. (The opposite extreme would be be a perfectly straight wire with no folds or bends or the helical antenna described above.)

In the case of the toroid or compact coil, the behavior would be such that doubling the turns nearly perfectly quadruples inductance. If we doubled turns and inductance simply doubled or increased at a much faster rate, we should know the coil is in a mode other than a pure inductor mode. This is a ***strong*** indicator inductor operating Q is less than optimum, and the inductor might behave less than ideally in critical applications.

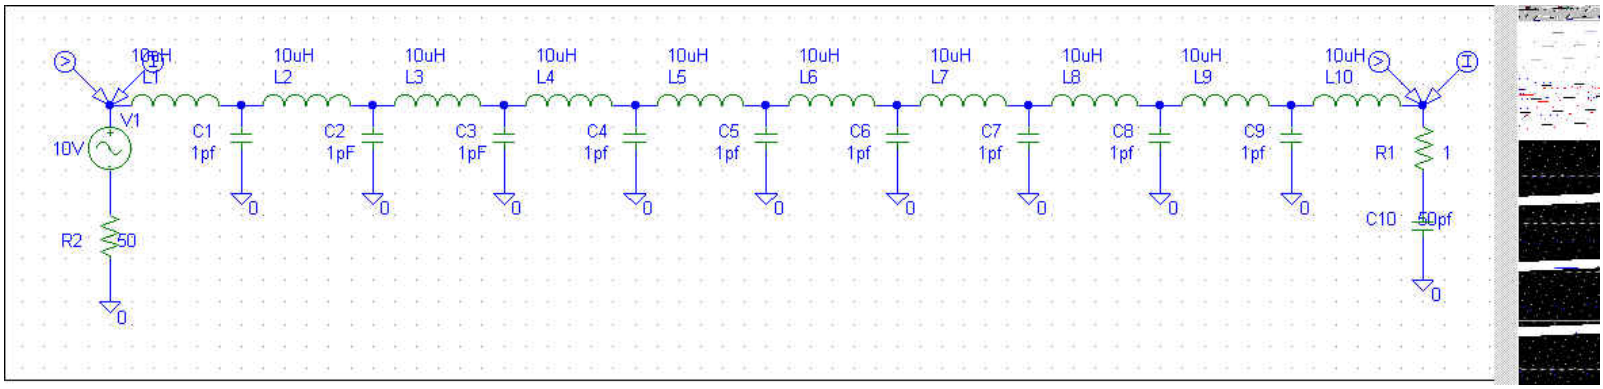
As a matter of fact, observing inductance change while adding turns can be an excellent test for flaws or shortfalls in system design. A linear increase in inductance when adding conductor length indicates design problems.

A perfect impedance squaring effect indicates minimal electrical phase-delay, or "antenna length" of an inductor. Impedance squaring as turns are doubled indicates the undesired inductor stray capacitance has a high reactance compared to the antenna system beyond the loading coil. Of course there can be exceptions, but it is a good general rule that large current taper indicates the loading system is much less efficient than necessary.

Making a Delay Line

It's certainly possible to make a delay line from a coil without opposing flux, but doing so requires stray capacitive reactance to be significant compared to the value of distributed inductance in the coil. This would occur in a very long helice, a very large diameter helice or loop, or an inductor near a large metal counterpoise or ground plane.

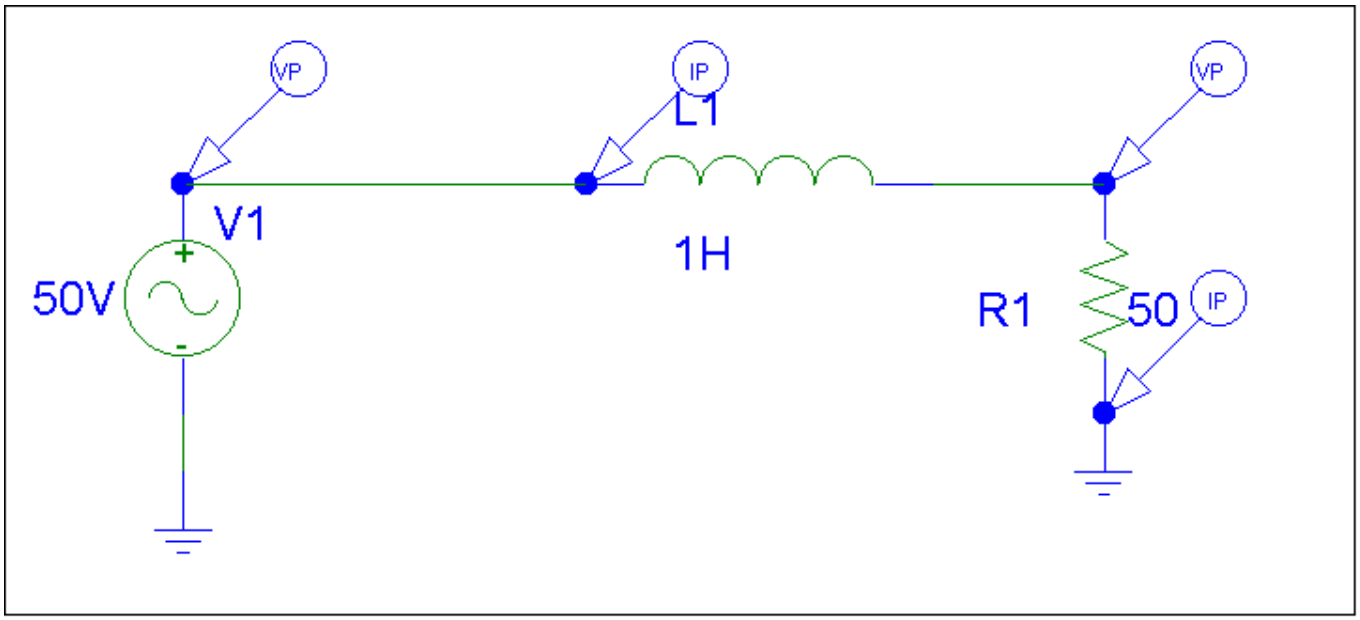
It's important to remember unless a coil is "stretched out" or "expanded" a great deal, the phase delay will not even be close to the physical conductor length. (The exception could be if you had so much capacitance the inductor acted like a series connected string of L/C/L networks as shown below).



In any case while this effect might be good in a collinear antenna or plate choke (assuming you do it right) it is a BAD effect in a short loaded antenna!

Inductor E/I Phase shift

An inductor delays the flow of current in relationship to applied voltages as the magnetic field inside the coil expands. Voltage increases before current starts to flow. This phase relationship between voltage and current is often confused with time-delay phase in the inductor. Say we have this simple circuit:



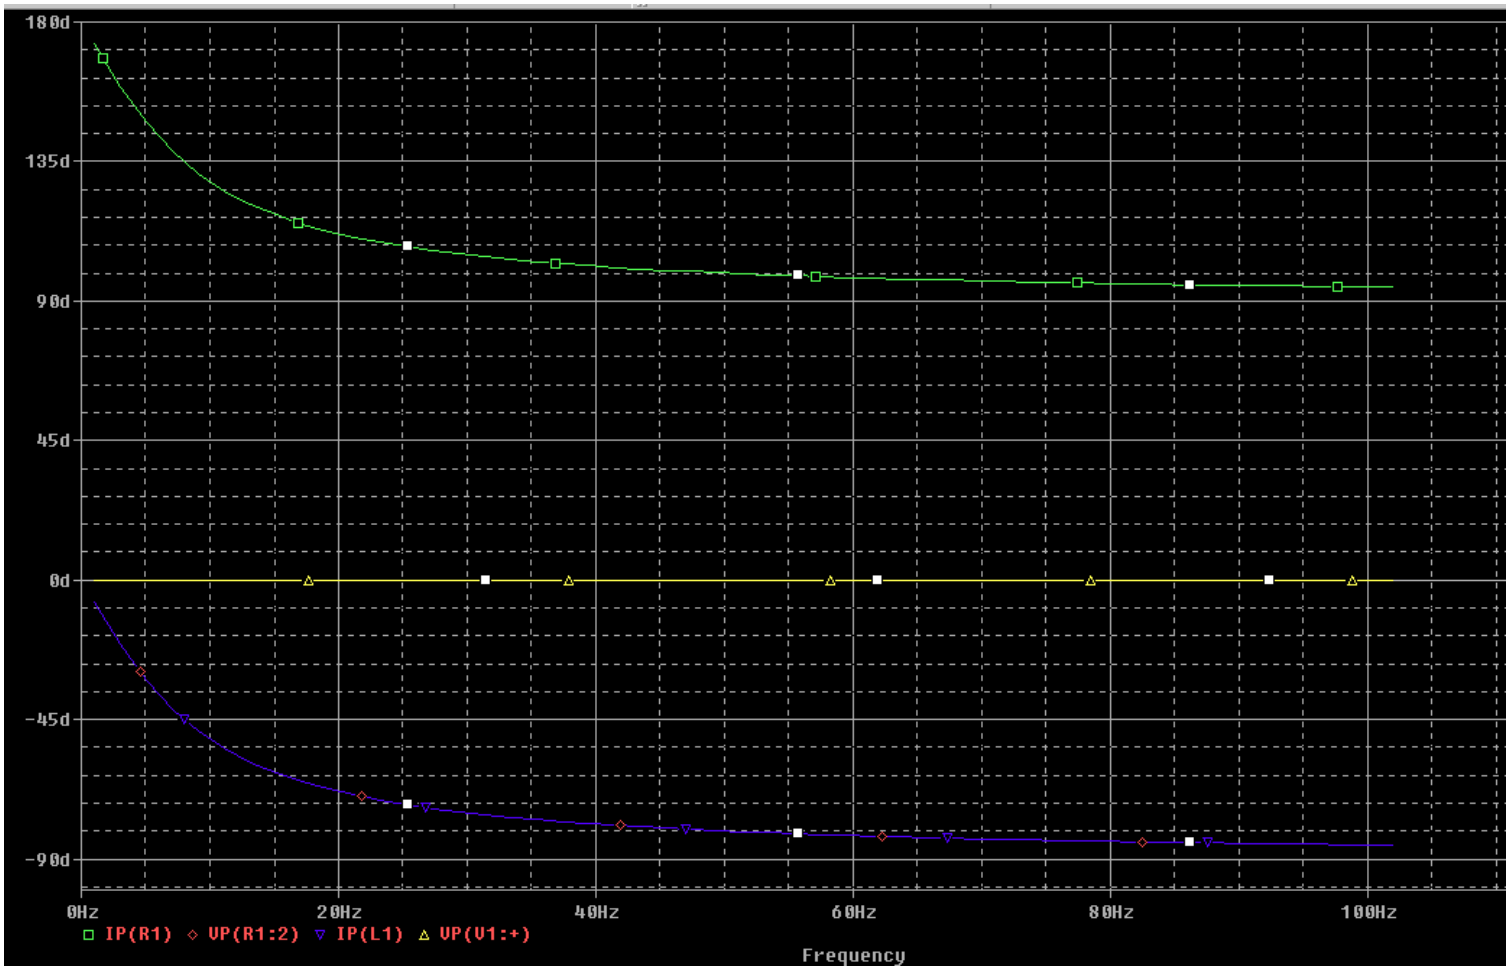
Current and voltage at V1 will be out-of-phase by the effect of L1 "charging" with magnetic flux. Current appears AFTER voltage rises, and falls after voltage falls. Current in R1, however, is exactly in phase with voltage across R1. That's because the voltage across R1 is always E=I*R.

Every component must follow the Laws or electrical rules established for that component.

The current in R1 is delayed from VOLTAGE rise in V1 by the voltage to current phase delay of L1. This does result in a time delay in relationship to voltage rise at V1, but there is NO current time delay through L1! V1, L1, and R1 all have the same peak current at the same time!!!

The notion that antenna loading coil delay current by the same time as they delay response to increased voltage is obviously nonsense.

Here is a graph of phase delays in the above system:



Current in the load, generator, and inductor all exactly track in the same relationship from dc up. There is no "phase delay". The generator voltage is a straight line different than current, and this indicates the generator sees a "reactive load".

The Misplaced Notion

Proponents of the idea that coils replace "antenna length" so far have been unable to define a set of rules or logical reasons why a current reduction and electrical-degree phase delay related to antenna area "replaced" would occur in a two-terminal component. While a long inductor with poor flux linkage from end-to-end or an inductor with low values of stray capacitive reactance to a groundplane compared to series impedance can cause SOME current inequalities or phase delays, the amount is normally immeasurable with normal thermal current meters with a reasonable coil form factor and termination above the coil. The amount of current taper actually rivals the disturbance of the system by adding the measurement device, unless we are very careful in how we construct the measurement device.

Both W7EL and myself made independent measurements that show the fact the coil or inductor is in an antenna has nothing to do with current distribution in the coil. Some people have actually incorrectly reported W7EL's data! Here's what he had to post on rec.radio.amateur.antenna to correct misrepresented claims.

The Need for a Measurement

An article on E-ham claimed measurements proved a new concept about loading coil current. The E-ham article put forth an idea that current disappears as it moves through a loading inductor without a mechanism like displacement currents providing a path. This claim conflicts with established component behavior, so it would indeed be fascinating if it were true! One of the claims supporting the idea that coils in antenna work differently than coils in circuits was that a non-radiating toroid loading inductor showed a current taper when used in an antenna.

I recently constructed a calibrated current meter that slips over whip antennas and masts, and is for all practical purposes totally immune to variations in voltage in the system. It also is mostly plastic, and has minimal effect on stray capacitance of the antenna. The resonant frequency and currents are not significantly perturbed by measurements with this meter. When I added a similar meter used in the other tests, resonant frequency shifted significantly! This is a sure sign the meter's capacitance or inductance is affecting the system.

In late December 2003 and early January 2004, I made additional measurements of loading inductor currents. The results clearly agree with the analysis that had been presented on this page since early 2003. Without displacement currents, currents into and out of a loading inductor *are equal.* That is a hard rule, it agrees with theories defined by people much smarter than me, and I believe it is unbendable unless the works of Faraday, Maxwell, Ohm, and Kirchoff were incorrect.

A sample of measurements above and below the loading coil with various antenna above the coil (current as percent of reference) follow:

	Toroid with hat	Small 2x2" coil with 24" hat up 24"	Long 12x3" coil with 24" hat up 24"	Long 12x3"coil with 6' whip
Current below	100%	100	100	100
Current above	100	94.4	73	76%

	Toroid with whip	long 12x1.5" coil with 6' whip	long 12x1.5" coil with 24" hat	Small 2x2" coil with 6' whip
Current below	100%	100	100	100
Current above coil	100%	79%	75%	96%
Current in whip 1ft above top of coil		73%		

The most revealing thing was how noticeably small changes in stray capacitance near the middle and top of the loading coil affect current distribution. It was quite evident hanging a large meter on each end of the coil would greatly perturb the system.

Clearly we do NOT want:

- **A large hat just above a large coil**
- **A long large coil and a short whip**
- **A coil near large sheetmetal**

More data along with photographs will appear on a new page over the next month or so. Until then, I can assure everyone the conventional theories presented below are accurate, and the theory that "electrical length" the coil "replaces" is incorrect. Loading coils indeed behave like any other inductor in the world.

Independent measurements by a reliable engineer have agreed with my measurements above. Anyone doubting my data need only read the following e-mail from W7EL.

On to the old text in this page:

The Incorrect Assumption

Another commonly misconception is, since voltage increases at the far end of the loading coil, current must logically decrease. After all, we have a fixed amount of power and voltage has increased. The assumption is:

1.) We multiply voltage times current to get power.

2.) If voltage increases current must decrease.

Unfortunately, this is ***not*** correct in reactive systems! Simple P (power) = I (current) times E (voltage) only works when the system is non-reactive. This condition only occurs at resonance, and only ***below*** the loading coil at the antenna feedpoint!

In a reactive system, like in a mobile whip above a loading coil, voltage and current are no longer in phase. As a matter of fact, voltage and current can closely approach being 90 degrees out-of-phase when the whip is electrically very short. Since the antenna area above the loading coil is highly reactive (voltage is not in phase with current), we can not multiply voltage times current without considering phase differences.

You may have heard the term "reactive power" or VAR (volt-amperes-reactive). Reactive power is voltage times current without consideration of phase angle. We can have kilowatts of VAR power with only a low power transmitter, and that is what we actually have in the reactive part of the small antenna.

Coil Q and Changes in Efficiency

Current taper or reduction has been cited as a reason coil "Q" has little effect on signal level in mobile systems. Speculation is only the first few turns of the loading coil carry significant current because the coil "leaks" magnetic fields and radiates, and this is why the coil Q has little effect.

Another idea proposes the loading coil "makes up" a certain missing part of the antenna. It goes on to conclude the loading coil can be accounted for in "electrical degrees", making up the "missing difference" in antenna degrees. This isn't true either. The inductor doesn't know where it is and suddenly change from "x" ohms reactance to electrical degrees! It responds to AC currents and voltages as any inductor in any circuit does. It doesn't suddenly change measurement units.

As an example of this, try to define a 45-degree electrical length inductor at 1.8 MHz. That would mean it is a capacitor at 3.61MHz, where it is over 90-degrees long! How many turns at what length and diameter is a 45-degree inductor?? Where is a formula that allows converting a given size inductor to electrical degrees? This shows how useless and meaningless that definition is!

The inductor adds a certain amount of series reactance, that's all. A 300uH inductor is not 20-degrees long, nor is it 80-degrees long, so far as radiation goes unless it is really that long ***physically***. It is a certain number of ohms reactance at a certain frequency, or a certain number of units called Henries. It is not "electrical degrees" that it adds, it is a non-dissipative reactance (in combination with a loss resistance because of finite quality) at a certain frequency!

A loading inductor can "insert" a large amount of phase shift, but the phase shift is between voltage and current. The only exception to this would be if the inductor had considerable distributed shunt capacitance to the outside world, and acted like a string of series inductors (with the antenna) and shunt capacitors (shunting to the ground system). In that case we could expect coil Q to be extremely low, since it would be the electrical equivalent of a lossy transmission line. That's either an awful loading coil, or it is a less-efficient helical loaded antenna!

The Correct View

Another group of people don't argue against established and proven circuit theory. They understand charges flowing into one end of the loading coil must have someplace to branch off (a virtual third terminal), or they must flow out the other end. Without that additional "virtual" path, charges flowing into the coil would always equal charges flowing out. This is true regardless of radiation, losses, or induction fields.

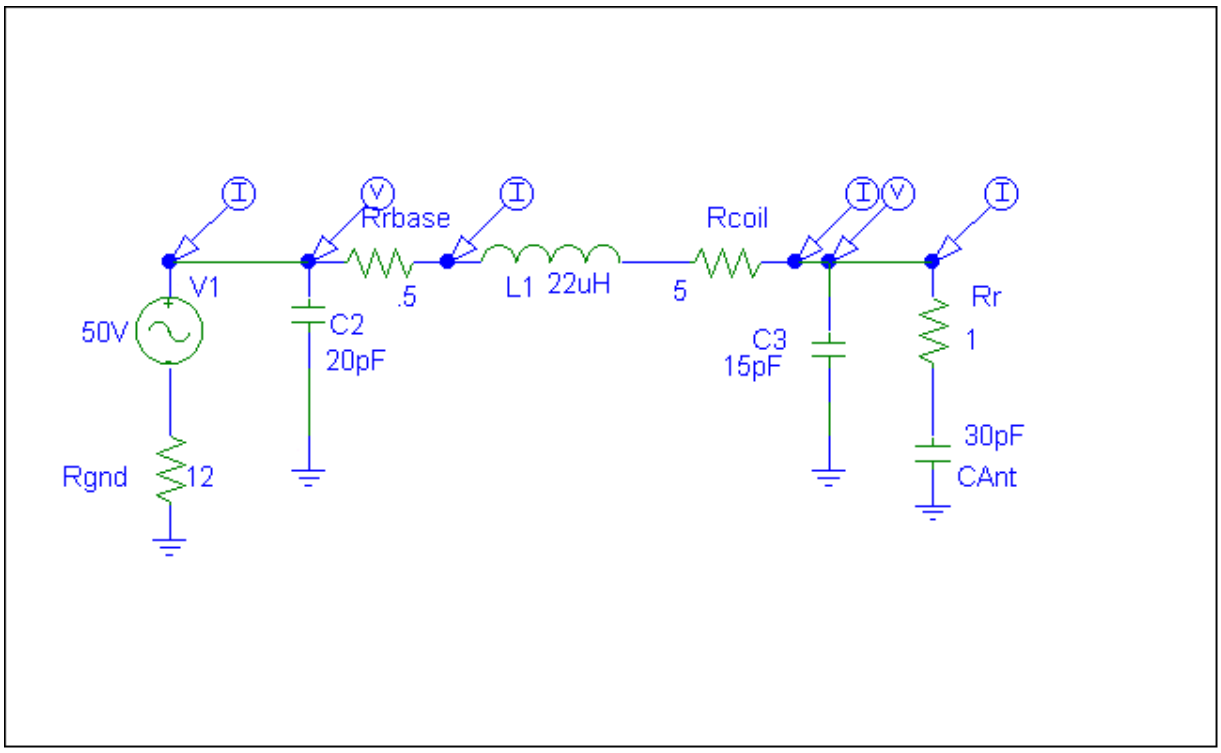
This makes perfect sense when we think of any dc circuit, antenna, or RF system. Electrical rules are satisfied, the system behaves as it does in the real world.

There is very little change in current, unless the coil is physically very long compared to the rest of the antenna above the coil or unless the coil is laid right against "grounded" conductors and the whip above the coil is very short. This fits perfectly with helical verticals, where the coil is "stretched out" over the length of the antenna.

It also agrees with base loaded antennas, which have nearly as much current into the antenna above the coil as at the feedpoint. It agrees with center loaded antennas, where current below the coil is essentially uniform and the whip above has triangular distribution.

Current ***can*** be different in various areas of an inductor, but ***only*** if shunting capacitances (impedances) to the outside world are significant compared to load capacitance (impedance). Another condition where current can vary substantially is with operation near the condition of self-resonance in what is normally considered or defined as a "series-resonant" mode. This would be a very poor and inefficient loading inductor, such as when a 160-meter antenna is used at a secondary resonant frequency in upper HF.

Circuit Model of a Mobile Antenna



The above model shows what might be a typical mobile antenna installation.

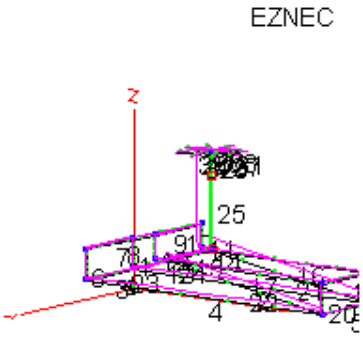
1. Rgnd ground resistance of vehicle normalized to feedpoint
2. V1 coaxial feedline
3. C2 base capacitance
4. Rrbase Radiation resistance of the base area of the antenna
5. L1 loading coil
6. Rcoil coil equivalent series loss resistance
7. C3 coil shunt C to ground
8. Rr top area radiation resistance
9. Cant equivalent antenna capacitance above coil area

My 160 Mobile Antenna

I've worked all continents except Africa while 160-meter mobile. I have CW contacts at over 10,000 miles, and SSB as far as Europe (4000 miles). My mobile antenna consists of an eight- foot antenna with a six-foot hat (made from surplus Ford or Chrysler car antennas) at the top. The loading coil is at 5 feet.

This antenna has been on the truck for thousands of miles, without mechanical failure. It is mounted at the upper left corner of the truck bed, about one foot back from the cab.

The following is a model of the current antenna system on my Ford F-250 HD long bed super cab truck:



The base impedance in the model is:

Frequency = 1.854 MHz.
Source 1 Voltage = 24 V. at 2.35 deg.
Current = 1 A. at 0.0 deg.
Impedance = 23.98 + J 0.9853 ohms
Power = 23.98 watts
SWR (50 ohm system) = 2.087

Actual measurement at my Johnstonville, GA farm in open flat pastures on August 17 at 8AM. Wet soil 25.8 ohms 0j base impedance, pretty close agreement to EZNEC model and earlier data! (I did have to adjust the model for very low ground conductivity, otherwise the resistance was far too low. It's my belief that NEC-2 underestimates ground losses in small radial or counterpoise systems that are close to earth.) Earlier text shows a base resistance of ***28 ohms***, that was dry soil with a slightly different loading coil and antenna.

The modeled current distribution for 1-ampere applied at the base (in 1-foot intervals) is:

1ft= 1.0031

2 ft= 1.0091

3ft= 1.0178

4ft= 1.0318

<Coil>

5ft= 1.0175

6ft= .97512

7ft= .92984

8ft = .89522

Measuring the current into and out of the loading coil with a small thermocouple RF meter, I detect no difference This is in close agreement with the model.

The efficiency of this antenna knowing coil Q, radiation resistance, and base resistance calculates just under 1 percent. The model indicates about 1/3 percent efficiency. This is reasonably close.

Removing the hat (in the model only) shows the following changes:

1ft = 1.0043
2ft = 1.0133
3 ft= 1.0279
4 ft= 1.0566

<coil>

5 ft= .95508
6 ft= .72232
7 ft= .27813
8 ft = open

I haven't tested the above, but with the same loading coil loss resistance the model says efficiency is now around 3dB worse. Removing the hat, with NO change in coil resistance, shows nearly loss nearly doubles. Of course the coil resistance would increase, because the loading coil nearly quadruples in size. Bandwidth is less and efficiency is less, even if I could maintain the same coil resistance.

Examples of Unequal Current

In the above models, we see that current into and out of the one-foot long coil is about the same. There is only about ***2% change in current*** even though the coil occupies 12% of antenna length in the "hat-loaded" antenna, but in fairness I couldn't resolve that change with a reasonably good RF current meter.

The model predicts ***10% change in a non-hat antenna***, but I never measured that antenna to confirm it.

Clearly there is no basis to the claim current is high only in the first few turns of an inductor, or that current tapers in relationship to "electrical degrees". The most accurate way to state the effect would be to say: "When the loading coil is short and the capacitance of the antenna beyond the coil is reasonable (in this case 3000 ohms Xc or less), there is an immeasurable reduction in current in the coil. When the required loading reactance is very high (in this case 8000 ohms), the reduction in current is about what we would expect for an equivalent length of antenna replacing the coil."

Degrees Vs Radiation Resistance

This upper four feet of this antenna resonates near 24 MHz with the hat. We can assume it is 90 degrees long at 24 MHz, which would translate to 6.9 degrees on 1.85 MHz. Following that same logic, this would mean the loading coil would be about 83 degrees long electrically. Using the incorrect logic proposed by others where the loading coil "makes up the difference in electrical degrees", there would be almost no current past the loading coil. Obviously this is not the case, the loading coil has very little "electrical length". As a matter of fact, the electrical length is about equivalent to the physical length!

This goes back to radiation theory, and my favorite saying: "Five hundred feet of wire in a one foot long tube is still one foot of antenna". Some CB manufactures sell antennas to consumers with the claim they use 5/8 or 3/4 wavelength of wire in an eight-foot fiberglass whip, so the antenna has more gain. Obviously this is not true. Let's not let such silly claims spread into amateur radio!

Related topics:

Inductors

The spice inductor model shows one example of how unequal current is created. The model demonstrates a coil having significant distributed capacitance to the point of current return in the system compared to terminating impedance of the coil. In a monopole this return path would be to the groundplane, or anything closer to the potential of the groundplane than the area above the loading coil's position in the antenna system.

Another Practical Antenna Example

Let's assume we have a lossless 15.3 foot long 0.2 inch diameter conductor over a perfect groundplane. Eznec gives the 1.821 MHz base impedance as .3004 -2169j. In other words, the antenna "looks like" .3004 ohms of load resistance in series with 40.32pF on 1821kHz. The return path for current is through the .3004 ohm resistance and 40.32pF capacitance, back to the ground of the antenna (it is a Marconi antenna).

Such a termination (load) would require a series inductance of 2169j (189.57µH) to cancel feedpoint capacitive reactance. A typical 190µH inductor

would be rather large, requiring somewhere around 53 turns when using a 4" by 4" form factor. One would expect a physically large inductor to have noticeable but very small displacement currents to the groundplane, when the small stray coil capacitance is compared to the 40.32pF termination capacitance. This raises two very important design guidelines:

- ***When installing a loading coil of substantial inductance in an electrically short antenna, sheetmetal and dielectrics should be kept away from the coil and areas of antenna above the loading coil. This would include dielectrics on or near the inductor, since the presence of dielectrics would increase undesirable capacitance.***
- ***When inductive reactance requirements are large, as when short thin "stingers" without hats are used above a coil, the coil form factor should lean more towards long and thin. Capacitances near the open end of the coil (high voltage end) should be minimized. This would be true even when the coil length increase results in a small reduction in mutual turns coupling, since the stray capacitance may result in a larger loss penalty than the slight increase in accumulated resistance from additional wire length.***

Efficiency

Efficiency in any antenna near earth is almost always dominated by ground related losses, short-height Marconi antennas are no exception. The overall effect of loading inductor Q and matching system losses are "diluted" or "swamped-out" by ground losses. Ground losses cause most systems to have greatly reduced sensitivity to inductor design.

The only consistently predictable factor in efficiency in fractional wavelength Marconi antennas with limited size ground systems is radiation resistance. Efficiency increases almost directly in proportion to radiation resistance.

Radiation Resistance and Power Radiated

Radiation resistance is probably the most poorly defined term used with antennas. The lack of clear definition creates errors and misjudgments when predicting antenna performance. If you wish more detailed information, this page contains information on radiation resistance. For the purposes of this discussion and to avoid pitfalls associated with using feedpoint impedance as radiation resistance, I'll use the same definitions Jasik, Balmain, and others have used. This definition is based on the IRE definition of radiation resistance being equal to the net or effective current causing radiation squared divided by the power radiated as EM energy, or Rr=Pr/I^2.

Using this definition, a folded dipole has a radiation resistance identical to a conventional dipole of the same physical dimensions (~70 ohms).

Radiation is caused by charge acceleration, there is no magic. The only thing affecting radiation resistance in a short vertical antenna near ground is current distribution over the linear area occupied by the radiation portion of the antenna. The general rules are:

Radiation resistance of a Marconi vertical in the maximum possible radiation resistance case for a given height (this is the case where current is uniform throughout the structure) is equal to 1580*(H/L)^2 where H equals height and L equals wavelength and both are expressed in the same units. Using degrees, we see a 10-degree tall antenna has a maximum possible radiation resistance of 1580*(10/360)^2 or 1580*.000772 = 1.22 ohms. This would apply even if the antenna is a vertical, DDRR, Fractal, or folded unipole with considerable top loading.

If current is triangular, radiation resistance would decrease by a factor of four to 0.305 ohms.

Power radiated is given by I^2*Rr

With 100-watts applied to a 10-degree tall antenna, net current in a lossless antenna with uniform current distribution would be 9.05 amperes. With triangular distribution, such as appears in a small diameter short base loaded whip, current would be approximately 18.1 amperes. We are in serious problems if the inductor reduces current along its length, since the only possible way to radiate 100 watts would be to have somewhere around 9 amperes of effective current integrated over the 10-degree vertical area of space for the radiator!

Ground Losses

All current flowing (or displaced) vertically into the antenna must equal current flowing out of the ground or counterpoise system. Even though ground losses are distributed losses, we must normalize all losses to the feedpoint in order to compare systems. There are cases where this will not always occur, causing us to falsely assume we have lower losses than really exist.

In this tutorial and comparison, I have normalized ground losses to the same point where radiation resistance is considered.

System Losses

(Measured data below of actual antenna given below was from 1995 data taken at a different location near Atlanta with a slightly different loading coil and antenna. There is a slight disagreement with current data. I left this all in so you can see the departure from measurements and models using 8 year old data.)

Base Loaded (Triangular Antenna Current Distribution) with no ground loss

Assuming we have a base-loaded antenna, and the operating frequency has a wavelength of 550 feet (around the 160-meter band), a 15.3 foot vertical would fit the above 10-degree value. Interestingly enough when we compare Eznec to formulas available in older (1950 vintage) engineering textbooks, we find radiation resistance predicted by Eznec is .3003 ohms while the triangular current estimate for the same height radiator is .305 ohms! This is an amazing degree of agreement, illustrating what we could do before modeling programs became available. (With perfect top loading, both Eznec and longhand calculations show approximately 1.2 ohms of radiation resistance.)

Assuming our 15.3 foot tall (10-degree) base-loaded antenna uses a coil Q of 200, the coil has 10.845 ohms of ESR. Total resistance with a perfect ground would be 10.85+.3= 11.15 ohms. Current into this system with 100 watts applied would be around 3 amperes, resulting in ~2.7 watts radiated and ~97.3 watts lost as heat in the inductor.

Doubling coil Q (400) would provide 5.73 ohms of base resistance with 4.18 amperes. Power radiated would be 5.2 watts, power lost as heat would be 94.8 watts. Efficiency does not quite double, changing from 2.7 to 5.2%. This results in a 2.8dB change in signal level.

Top Loaded (with no ground loss)

If we added a four-wire hat with 15-foot wires, current would no longer be triangular. While we wouldn't quite reach the optimum uniform distribution, current at the top would be about 78% of current at the antenna base. Feedpoint impedance would become 0.97 -551j, and the antenna would look like 0.97 ohms in series with 159pF.

Using a coil Q of 200, we would now have 2.76 ohms of inductor loss. Current becomes 5.18 amperes. Radiated power is 26 watts, while power lost as heat becomes 74 watts. Even in the perfect ground case, the change in efficiency caused by top loading is large. Top loading (with only the hat) results in 9.8 dB change in signal level when compared to the base loaded case when coil Q remains 200. Efficiency is 26%. The coil remains at ground level for easy matching and frequency change.

In this case current at each terminal of the loading coil would be essentially the same regardless of poor coil mounting techniques. In order to have significant current taper in the coil or in the bottom of the mast, shunt capacitance would have to be a significant compared to 160pF. The antenna's high input capacitance relaxes inductor and antenna mounting electrical requirements.

Base Loaded (high ground loss)

My F-250HD Super Cab pickup truck, when parked over open medium quality pasture land, has a ground resistance of about 20 ohms (normalized to the feedpoint) on 160 meters. Applying this ground loss to the base loaded antenna, the system has a feedpoint resistance of 20+.3=20.3 ohms. (This is reasonably close to actual feedpoint resistances measured with a similar operating antenna.) Adding coil losses, the system has 20.3+10.85=31.15 ohms. (**NOTE: Current coil is ~8 ohms ESR, 10.85 ohms is from ~8 year old data**) Current is sqrt (100/31.15) or 1.79 amperes.

This results in .96 watts radiated, and 99.04 watts lost as heat. Efficiency is now around .96%.

Substitution of a coil with a Q of 400 results in 25.7 ohms feed resistance, or 1.97 amperes antenna current at 100 watts. In this case efficiency is now 1.16% for 1.16 watts radiated. The change caused by doubling coil Q with high system ground losses is about 0.8dB, compared to almost 3dB in the perfect ground case! With a poor ground (in this case typical of a very large vehicle), a large change in coil Q produces little change in system efficiency.

Another Top Loaded (high ground loss) System Example (made prior to the EZNEC model above)

Using a large hat isn't practical in a moving mobile, although it could apply to fixed stations suffering with poor ground systems. When the hat is smaller, such as a mobile requires, the loading inductor can be moved higher in the system. Such a move would produce uniform current below the loading coil, with a current shape above the coil dictated by the construction of the upper portion of the antenna. My own mobile uses a six-foot diameter hat manufactured from stainless steel automobile antennas arranged in a spoke. I have no problems with wind or occasional obstructions. While unsightly, a modest hat is workable.

In order to keep the systems comparable I'll use the same radiation resistance provided by a large hat, but intentionally add high ground loss as a lumped resistance. This model ignores field losses near the antenna.

In this case we have 0.97 -551j as the inductor termination presented by the antenna. With ground losses normalized at 20 ohms and an inductor Q of

200, we have 20+2.76+.97 = 23.73 ohms of feedpoint resistance. Current is 2.05 amperes, and power radiated is 4.1 watts. Power lost is 95.9 watts.

Efficiency is 4.1%, a 6.3dB increase over a base-loaded triangular current system with the same lossy ground. This system is 8dB down from the same "top-loaded" distribution using a perfect ground.

When the system has significant fixed losses, increasing radiation resistance four times by top loading provides a similar dividend in system efficiency. At the same time a substantial increase in coil Q provides only minimal change in field strength.

Current Through Coil

Inductor spice model

There has been some speculation that current is high only in the first few turns of a loading inductor. Radiation comes solely from charge acceleration or current over spatial (in line) distance.

If any loading inductor shows substantial decrease in current over the length of the inductor, it is an absolute certainty that the inductor is poorly designed and that the system above the loading inductor is not contributing to system efficiency. The reason for this is very simple and straight forward. Any two-terminal component (even considering wire as a "component" applies) MUST have equal charges flowing into and out of each terminal. Voltages to other reference points can be different, but for every charge moving into one terminal a like number of charges MUST move out of the other terminal. Radiation, induction fields, and loss resistances have no influence on this rule.

In order to have any change in current, there must be an additional path or paths for charges. This path can be through leakage resistances, or through fictitious currents called displacement currents. Whatever the path, the total charge movements must be reconcilable. We simply can not have current "disappear".

The normal path upsetting "unbalancing" current into and out of each terminal in an inductor is provided by displacement currents through electric fields. As with any system, the amount of current flow is proportional to potential difference and impedance of the path. In order to shunt a substantial current out of an inductor, the potential difference between the ends of the path has to be high compared to the impedance of the path. The impedance of the stray path must also be reasonably low compared to the normal desired path.

Current diversion is problematic in very large inductors operated at (or very near) internal self resonance, when the self resonance is what we typically refer to as a "series-resonant" condition. This condition is common in plate chokes used in vacuum tube power amplifiers, where the system operates over many octaves of frequency range.

"Series resonances" inside components occur when distributed inductance forms a pair (or multiples of pairs) of "L" networks. The large series inductance from each end of a winding reacts with the small stray capacitance at the center, and forms a very high impedance transformation L network. The electrical potential at the center of the system becomes extremely high, and even the smallest amount of capacitance to surrounding objects will carry a substantial displacement current. The large displacement currents cause the terminal impedances to drop, and allow considerable current to concentrate in small areas of the component. At the same time, considerable voltage can be present. The normal result is arcing or destruction of the component, or failure of the system depending on the choke to operate.

Series resonance always occurs at a frequency higher than the self ***parallel*** resonant frequency of the component. A loading coil operating under such conditions would be required to have serious design errors to fall into this category, since the end termination capacitances should always be substantially higher than stray capacitance throughout the component. Failure to follow this rule would result in needless loss and reduced SWR bandwidth in an antenna.

The speculation or supposition that the first few turns of a loading coil carry most of the current is clearly untrue. In order to shunt current off, high series impedances would have to exist along with high stray shunting capacitance to areas removed from the radiator. Additionally, the remaining coil area connected to the top area of the antenna above the loading coil would have to present a high impedance to the area where current reduction occurs. This would never be the case, unless the top area of the antenna and loading coil are not resonant near the operating frequency.

A reasonable test for proper inductor and system design would be to remove the antenna above the loading coil, measuring system resonance. If resonance does not change substantially, the area above the coil is not correctly terminating the system. First-order self resonance of the inductor (parallel resonance), when removed from the system, should also be far above the operating frequency of the system. If self-resonance comes within three or four times the operating frequency range, the loading coil almost certainly will have needless performance shortfalls.

Conclusion

A normally functioning inductor has essentially equal currents throughout the inductor, loading coils are no exception. Any current difference requires a substantial current flow through undesired stray capacitances or leakage currents. Neither radiation or induction could change this, it is a basic rule of circuitry.

In a reasonably well-designed system, current into and out of the loading inductor should be substantially equal. Differences in current would indicate excessive and problematic undesired stray capacitance in the loading system design, or measurement errors.

Reduced sensitivity to coil Q is primarily a function of additional losses in the system, not reduction of current through the coil.

Independent Measurements

Tom,

Thanks very much for sending the copy of the posting. I'd appreciate it very much if you'd post the following on the same reflector for me:

It was brought to my attention that the following statement was recently posted on this reflector by Yuri:

"I will leave it here, as the rest of it. W7EL, author of EZNEC measured toroid coil and found that it HAS different current at its ends, roughly proportional to the part of antenna that it replaces."

This is not true. I assume the statement was made due to careless reading of the postings I made on rec.radio.amateur.antenna, rather than a deliberate distortion, so I'll very briefly describe the results again here. I made measurements of the current into and out of two different toroids in series with an antenna at its base. The first measurement was made using a 33 foot vertical with seven ground radials, whose feedpoint impedance measured 35 - j185 ohms at 3.8 MHz, and a toroidal inductor with reactance of 193 ohms and Q a bit over 300. I found that the difference in current between input and output of the inductor was 3.1% in magnitude and with no measurable phase shift, despite the short antenna. The 3.1% current difference between input and output can be explained simply by 6.8 pF of stray capacitance between the coil output and ground and/or current probe, or a bit greater value distributed over the coil. I repeated the measurement on the bench, with a series resistor and capacitor in place of the antenna, and measured 2.3% difference between input and output current. This is within measurement error of being the same as when connected to the antenna. (One would expect the stray C to be a bit different, also.) So in the one case I did the measurement with the inductor "replacing" a very significant

part of an antenna and in the other with the inductor replacing no antenna at all (or an entire antenna, if you choose), and got essentially the same result. How this can be interpreted as my having drawn the conclusion stated by Yuri is beyond me.

Unfortunately, the fact that the antenna is spaced only about 1/4" from a 4 foot mounting pipe (which altered its input impedance), in addition to the abbreviated ground system, left a great deal of wiggle room for people proposing alternate theories, so I did a second test with a more idealized antenna. For this test I constructed a vertical antenna that was 33 feet high, made of #16 insulated wire, and strung 23 radials out on the surface of the wet ground. The feedpoint impedance of this antenna at 3.8 MHz was measured as 15.8 - j437 ohms. This is close to the theoretical impedance, assuming about 8 ohms of ground loss resistance. The inductor had a reactance of 387 ohms. As described in my posting on rraa of November 11, the inductor "replaces" about 33 electrical degrees of the antenna.

The result from the second test was a current difference of 5.4%, again with no measurable phase shift. And again, this small difference can be explained by about the same amount of stray capacitance. It's nowhere near the 16+% that the "cosine rule" (that the output current equals the cosine of the "replaced" antenna) proposed by Yuri and others would predict. In no way did my measurement validate his theory -- 5.4% isn't even "roughly" more than 16%.

Frankly, I'm a bit embarrassed to have bothered to make these measurements at all -- it's a lot like making careful measurements to validate Ohm's law in order to refute someone's measurements that "prove" it wrong. As it is, it's turned out to be even worse than just a waste of time, since the results are now being distorted to support the very theory they clearly refute. I hope this will clarify just what measurements I made and what they showed.

For anyone who can stomach the waffling, backpedaling, and insults which characterized the original discussion, look up the thread "Re: Current in antenna loading coils controversy" and its variants in the google archives of rec.radio.amateur.antenna. Postings describing my measurements were made between November 8 and 11, 2003. If you read the thread, particularly the reaction to my posting of the measurements, you'll see why I've given up on that newsgroup as a forum for rational communication.

Many thanks to Tom, W8JI for bringing the misleading quote to my

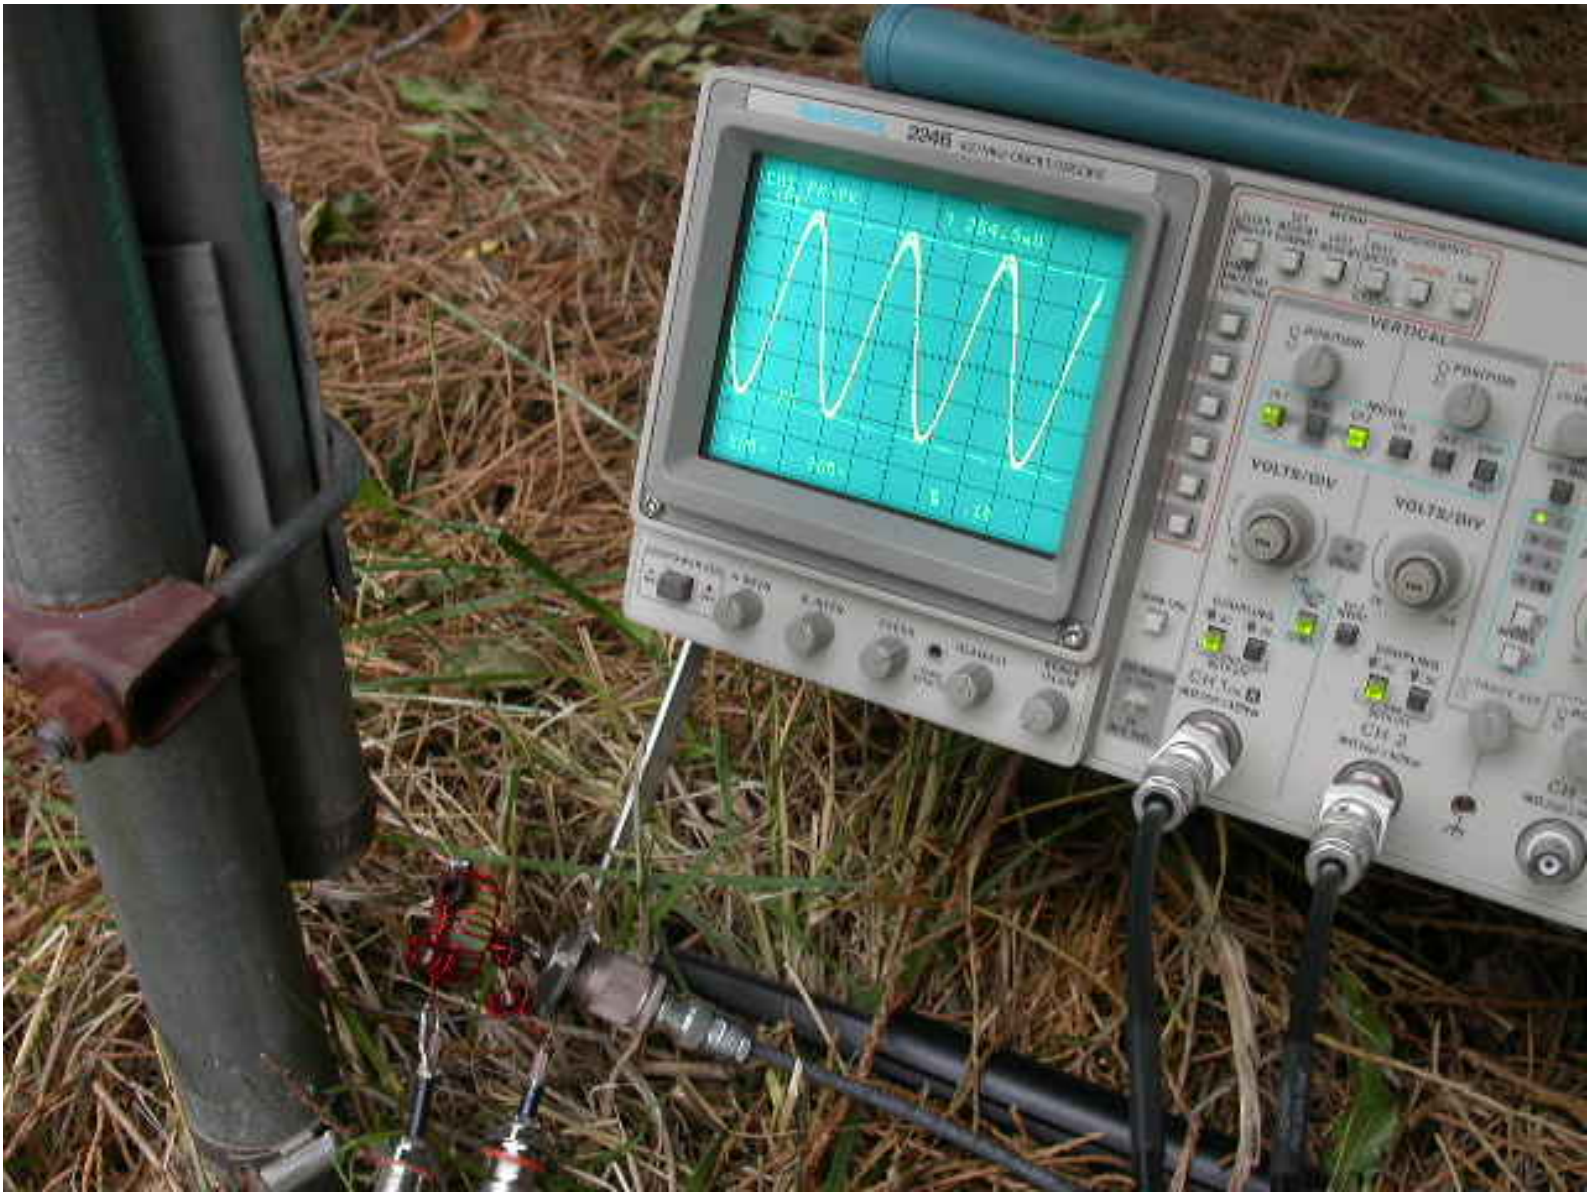
attention and for posting this for me.

Roy Lewallen, W7EL

Roy's Measurements

[Home] [Up]

W7EL's Antenna current measurements:



This is the overall measurement setup described in the rec.radio.amateur.antenna newsgroup on and about November 9, 2003, showing both traces on the oscilloscope. Signal input is from an HP 8640B signal generator.

This is a closeup of the inductor and current probes. The upper pipe is the vertical antenna. The one to its left is the mounting, which extends about four feet above ground. The two are spaced 1/4" apart. The yellow toroid is the inductor being measured. The smaller black cores are the current probes. One core of each probe is a transformer, with the wire carrying the current to be measured passed through the core's hole. The second core is a common mode choke or "current balun", which serves two functions. One is to insure that no significant current flows on the outside of the coax cables connecting the probes to the oscilloscope. The second is to isolate the probes and reduce any possible capacitive coupling that might disturb the measurement. The probe outputs are terminated with 50 ohms at the scope.

Inductor operation

The following is a copy of RRAA postings by Roy Lewallen W7EL about inductors. I think the technical portion of these posts are useful for understanding current in loading coils, and how we need to cross check theories properly. I've included all of the text, even though much text is not technical. This really is educational, so read it if you have time!!!

I think the goal should be education, not conversation, so I enlarged important text size and changed color to blue in what I think are important areas.

Comments of mine are in RED.

W8JI Tom

The following are verbatim copies of postings made on rec.radio.amateur.antenna, in the thread "Re: Current in antenna loading coils controversy" (first posting), "Re: Current in antenna loading coils controversy - new measurement" (last posting), and "Re: Current in antenna loading coils controversy (long)" (remainder of postings). I and others made many additional postings on the topic, which should be available at http://www.groups.google.com.

Roy Lewallen

January 11, 2004
Posted on 11-4-03:
No, I will make one more comment. After a bit of reflection, I think this might be at the core of some people's problem in envisioning a lumped inductor.
When a current flows into an inductor, it doesn't go round and round and round the turns, taking its time to get to the other end. An inductor wound with 100 feet of wire behaves nothing like a 100 foot wire. Why? It's because when the current begins flowing, it creates a magnetic field. This field couples to, or links with, the other turns. The portion of the field from one turn that links with the others is the measurable quantity called the coefficient of coupling. For a good HF toroid, it's commonly 99% or better; solenoids are lower, and vary with aspect ratio. The field from the input turn creates a voltage all along the wire in the other turns which, in turn, produce an output current (presuming there's a load to sustain current flow). Consequently, the current at the input appears nearly instantaneously at the output. Those who are physics oriented can have lots of fun, I'm sure, debating just how long it takes. The field travels at near the speed of light, but the ability of the current to change rapidly is limited by other factors.

So please flush your minds of the image of current whirling around the coil, turn by turn, wending its way from one end to the other. It doesn't work at all like that. The coupling of fields from turn to turn or region to region is what brings about the property of inductance in the first place.

That was a great explanation of how an inductor works. I often learn new or better ways to view things when reading what Roy writes!

Radiation is another issue, and provides a path for current, via displacement current, to free space. (I can see it now in Weekly World News: WORLD FILLING WITH COULOMBS! DISASTER LOOMS!) For a component to fit the lumped element model, radiation has to be negligible. And, for the same reason, it can't be allowed to interact with external fields as a receiver, either.

This is very fundamental stuff. You can find a lot more about the topic in any elementary circuit analysis or physics text. If you don't believe what you read there, just killfile my postings -- you won't believe me, either, and reading what I post will be a waste of time for both of us.

Real inductors, of course, are neither zero length nor do they have a perfect coefficient of coupling. And they do radiate. The essence of engineering is to understand the principles well enough to

realize which imperfections are important enough to affect the outcome in a particular situation. We simplify the problem by putting aside the inconsequential effects, but don't oversimplify by ignoring factors that are important for the job at hand. Those who insist on using only the simplest model for all applications will often get invalid results. And those who use only the most complex model for all applications (as is often done in computer circuit modeling), often lose track of what's really going on -- they become good analysts but poor designers. I've seen people capable of only those approaches struggle, and fail, to become competent design engineers.

And with that, I'm outta here. Hope my postings have been helpful.

Posted 11-8-03:
Here are some preliminary details about the inductor current measurement I made.

My antenna isn't nearly as ideal as the one Yuri described. (But if my results are different from the ones reported at the web site Yuri referenced, I'll be eager to hear why.) It's about 33 feet high, and has only 7 buried radials. The feedpoint impedance indicates a loss of about 25 ohms at 7 MHz, so I'd expect it to be a bit more at 3.8. It's bolted to a galvanized fence line post which protrudes nearly four feet from the ground, with spacing between the antenna and the post of about 1/4". This mounting has only a minor effect on the feedpoint impedance at 7 MHz, which is the antenna's intended frequency of use. It's quite profound at 3.8 MHz, though. The expected 370 or so ohms of capacitive reactance is transformed to 185, while the feedpoint R is 35 ohms, not far from the expected value. So the overall feedpoint Z is 35 - j185 ohms at 3.8 MHz, measured with a GR 1606A impedance meter. (I found that my MFJ 269 was about right with the X, but measured R as zero -- apparently the combination of low frequency and large X is a problem for it in resolving the R.) So I built an inductor with measured impedance of 0.6 + j193 ohms. It's 26 turns on a T-106-6 toroid core. Q is a bit over 300. This was placed in series at the antenna feedpoint.

For current measurements, I made two identical current probes. Each one consists of 10 turns wound on an FT-37-73B ferrite core. The two leads from the winding are twisted and wound in bifilar fashion on another FT-37-73B core, 10 turns. This is then connected to an oscilloscope input via a two-foot (approx.) piece of RG-58. A 50 ohm termination is also at the scope input. This gives the probe a theoretical insertion impedance of 0.5 ohm. While making the measurements, I moved, grabbed, and re-oriented the coax cables, with no noticeable effect. This gave me confidence that the outsides of the coax weren't carrying any significant current.

One probe went to each channel of the scope. I left the two scope inputs in the cal position, put both probes on the wire at the input end of the inductor, and recorded the p-p values with the scope's digital measurement feature. Then I reversed the order of the probes and remeasured. I found a slight prejudice toward the probe closest to the source -- 1.2% in one ordering, and 2.1% in the other. Averaging the two channels, though, showed them to be the same within less than 1%. (Each probe was always connected to the same scope channel, so this is a test of the probe-scope channel combinations.)

Then I moved one probe to the output side of the inductor, and measured input and output current.

And I reversed the probe positions on inductor input and output. The ratio of output to input current in the two tests differed by only 1.4%.

When I encounter an astrologist, they invariably ask what "sign" I "am", then proceed to tell me how my personality meets their expectations. So what I do instead is to have them tell *me* what "sign" I "am" *first* -- which they should easily be able to do, based on my personality. Well, they don't find that to be fair, for some reason (although I certainly find it amusing). And so, I doubt if the following challenge will be regarded to be fair, for much the same reason. Those with alternative rules for solving circuit problems are challenged to predict what the ratio of output current to input current will be. I'm particularly targeting Cecil, and others who have bandied about a lot of pseudo-analysis about electrical length, reflections, and the like. And, Richard (Harrison), who said something like "an inductor without phase shift is like". . . I don't recall. . .hot dog without ketchup or something. Pull out your theories, and calculate it, like any competent engineer should be able to do. For cryin' out loud, it's a simple series circuit (except for Cecil, where it's some kind of distributed thing).

First post your answers, then I'll post the result of my measurements.
Roy Lewallen, W7EL

Posted on 11-11-03:
It sounds like the predictions are in. Among the several people who believe that the current out of a small inductor doesn't equal the current in, only Yuri was able to calculate a predicted value for the test, of 2.5 - 5% reduction in current at the output compared to the input, with a phase shift of about 18 degrees.

You see above Yuri "predicted" a current value based on a cosign formula that relates to antenna area. One way to test a theory is to change the conditions or parameters of the test, and see if the predictions apply in multiple cases or if it was just a "guess" or dumb-luck. This is ALWAYS a good idea. Watch what happened when Roy changed the antenna length and used the same formula!

What I measured was a 3.1% reduction in magnitude from input to output, with no discernible phase shift. The 3.1% is an average of two readings, with the input and output probes exchanged. The output was smaller than the input in both measurements, about 2% and 4%. So I believe there's a real difference between output and input current, although with the accuracy of my measurements, I only have reasonable confidence it's somewhere between 1 and 5%. I can resolve about 2-3 degrees of phase shift, though, and I couldn't discern any at all. (Yes, the scope trigger was from one channel, not

alternating.) So I have very high confidence that Yuri's prediction of 18 degrees is **incorrect.**

I don't subscribe to the notion that the current out of a very small inductor should be different than the current in due to some magical property it acquires when connected to an antenna. My working hypothesis is that the currrent difference I did see was due to stray capacitance, either from the probes or simply to the Earth and other objects. It would take an equivalent of 6.8 pF at the output of the coil (that is, between the coil output and the current probe) to get 3% reduction, and only about 1/3 that amount to see the minimum value of reduction of 1% I estimate was actually present.

Here is where Roy changed the test. Now the coil isn't in an antenna, and the "sine rule formula" should not apply. If the sine rule was correct, the current differential should have changed significantly.

I repeated the test on the bench, with a 36 ohm resistor in series with a 220 pF capacitor substituting for the antenna. The result was a 2.3% output:input reduction, again with no discernible phase shift. This is within the measurement error of being the same result. This is what should be expected -- except for unintentional coupling to the antenna's field, the inductor's environment is the same on the bench as at the antenna base, in these single frequency, steady state tests. (That also contradicts what some newsgroup participants have been claiming.)

So, although the small output:input current reduction was within Yuri's prediction, the phase shift certainly wasn't. If time permits, I'll make a more idealized antenna and repeat the measurements with a larger inductor at the base of a more reactive antenna. I'll predict in advance that if I double the amount of loading L, I'll approximately double the amount of current magnitude attenuation -- that is, to somewhere around 6%. That's what should be expected if the cause of the attenuation is stray C or a similar phenomenon.

I've added a picture to the http://eznec.com/rraa/Inductor_Current_Measurement.html page, showing the overall setup including the scope. It gives a little better perspective on the relative sizes of various objects.

Roy Lewallen, W7EL

Posted on 11-11-03:
Today's project was to construct and measure a more idealized antenna.

The antenna is 33 feet high, made of #16 insulated wire. I put out 23 radials on the surface of the

wet ground. Radials were of various lengths, most about 30 feet long. The feedpoint impedance of the antenna, measured with a GR bridge, was 15.8 - j437 ohms at 3.8 MHz. Allowing 3% lengthening effect for insulation, EZNEC says a lossless vertical of that height and diameter should have an input Z of 7.5 - j478. 8.3 ohms loss resistance is reasonable for that number of radials, and the somewhat lower than predicted reactance is likely due to the fact that the radial wires were grouped together as they came up a few inches to the antenna base, and not immediately coming in contact with the ground. That would add a bit of inductive reactance.

I wound an inductor on a T-106-6 core as before, but with more turns, for a measured Z of 1.3 + j387 ohms. After putting it in series with the antenna at the base, the base impedance measured 17.1 - j54 ohms. This is only 4 ohms from the expected reactance, and spot on the expected resistance, so measurements are consistent.

Analyzing verticals with EZNEC, made from #16 wire at 3.8 MHz, shows that:

-- An antenna 63.2' high is resonant.
-- An antenna 35.9' high has a feedpoint reactance of -j437 ohms.
-- An antenna 59.35' high has a feepoint reactance of -j54 ohms.

With a resonant height of 63.2', you could say that 63.2' is "90 electrical degrees" as far as the antenna is concerned. So you might say that my inductor has "replaced 33.4 electrical degrees" of the antenna.

Here again the test is modified to test Yuri's prediction.

Using Yuri's cosine rule, we should then expect the inductor output current to be cos(33.4 deg) times the input current, or 16.5% less. Also, we should expect to see those 33 degrees of "replaced antenna" as phase shift from the input to the output of the inductor. That is, the current change from the input to output of the inductor is the same as it would be for the portion of the antenna it "replaces". (I think Jim Kelley subscribes to this theory also, but I'm not sure.)

In contrast, conventional electrical circuit theory predicts no current difference between the input and output for a physically very small inductor with no radiation or stray coupling. I saw about 3% in the previous measurement, which I believe can be attributed to stray capacitance. So I predicted that we should see about twice that amount with the higher valued inductor used for this experiment (387 vs 192 ohms reactance). I didn't see

any measurable phase shift between input and output before, so I didn't expect to see it this time.
So for this test, there's quite a difference in predictions for output:input current --
**Yuri's method predicts a reduction of output current magnitude of 16.5% and a phase shift of 33 degrees.

**I predict around 6% magnitude reduction (due to stray C) and no measurable phase shift (less than 2 or 3 degrees).

I have very high confidence that my measurements are good enough to resolve the difference between these two possibilities.
Would anyone care to comment before I post the measurement results? And, Yuri, please correct me if I've misinterpreted your theory.
Roy Lewallen, W7EL

Here are the test results, still using the same formula. If the results of the Cos theory and formula are correct, the results would be 16.5% current reduction and 33 degrees phase shift. This shows why it is important to test new formulas in a variety of applications.

Posted on 11-11-03:
Ok,
For anyone who cares, the magnitude of the current out of the inductor in the later test measured 5.4% less than the current in. No phase shift was discernible. An analytical person could build on this information to investigate the properties of longer inductors placed elsewhere in the antenna.

Thank you for the comments, Cecil, Yuri, Richards, Art, and others. I've learned a good lesson from this -- that this isn't an appropriate forum or appropriate audience for the sort of quantitative analysis and reasoning I'm familiar and comfortable with. And that the considerable time and effort required to make careful measurements is really of very little benefit -- certainly not anywhere near enough to justify it.
With a great sigh of relief from everyone, I'm sure, I'll now turn this thread back over to Yuri, Cecil, et al.
My apologies to everyone for taking up so much bandwidth.
73,
Roy Lewallen, W7EL

So there we have it. The Cosine theory that states an inductor replaces part of

the antenna and has the same or similar phase shift and current taper as that part of the antenna proved false once the system was perturbed. It is quite typical for a formula that is incorrect to work at one point just by sheer luck.

When we have a theory, the test is to apply that theory to various systems and see if it works in all cases. If it does not work in all cases, the theory is incorrect.

While I agree it should not be necessary to prove conventional circuit theory, I think Roy's test (and my test) might shed some useful insight into how short and heavily loaded antennas actually work. A secondary benefit is we see how an incorrect idea or concept can actually work once in a while just by sheer luck, and why we need peer review.

Many people have the misplaced notion a wire in an inductor replaces a certain "electrical length" of the antenna. That isn't true. A loading inductor simply cancels reactance (corrects power factor). Current change across the inductor actually indicates a problem with the inductor, unless it is intentional.

Mobile Antenna Current Measurements at W8JI

[Home] [Up]

A sample of measurements above and below the loading coil with various antenna above the coil (current as percent of reference) follow:

	Toroid with hat	Small 2x2" coil with 24" hat up 24"	Long 12x3" coil with 24" hat up 24"	Long 12x3"coil with 6' whip
Current below	100%	100	100	100
Current above	100	94.4	73	76%

	Toroid with whip	long 12x1.5" coil with 6' whip	long 12x1.5" coil with 24" hat	Small 2x2" coil with 6' whip
Current below	100%	100	100	100
Current above coil	100%	79%	75%	96%
Current in whip 1ft above top of coil		73%		

The most revealing thing was how noticeably small changes in stray capacitance near the middle and top of the loading coil affect current distribution. It was quite evident hanging a large meter on each end of the coil would greatly perturb the system.

Mobile Antenna FS Comparisons

[Home] [Up]

The hat used in these tests was the DX Engineering Hot Rodz system.

Type	Height Base	Top Length	Hat dia	Field Strength	Frequency	Relative FS	
Reference				-18.5			best tested antenna
Large air	36"	84"	0	-18.50	7.2	0.00	3"dia #12
Large Air	36'	27"	47"	-18.70	7.2	-0.20	3" dia #12 47" hat
Small air	36"	27"	47"	-19.90	7.2	-1.40	1.5"dia #16 47" hat
TarHeel	42"	27"	47"	-21.00	7.2	-2.50	Tar with 47" dia
TarHeel	43"	84"	0	-21.10	7.2	-2.60	Tar with 7' whip
RM-20	36"	27"	52"	-21.20	7.2	-2.70	Hustler RM-20 on 40m
TarHeel	43"	27"	23"	-22.00	7.2	-3.50	Tar with 23" dia
TarHeel	61"	84"	0	-19.80	3.5		
TarHeel	59"	27"	47"	-19.70	3.5		47" DXE

The most striking things are:

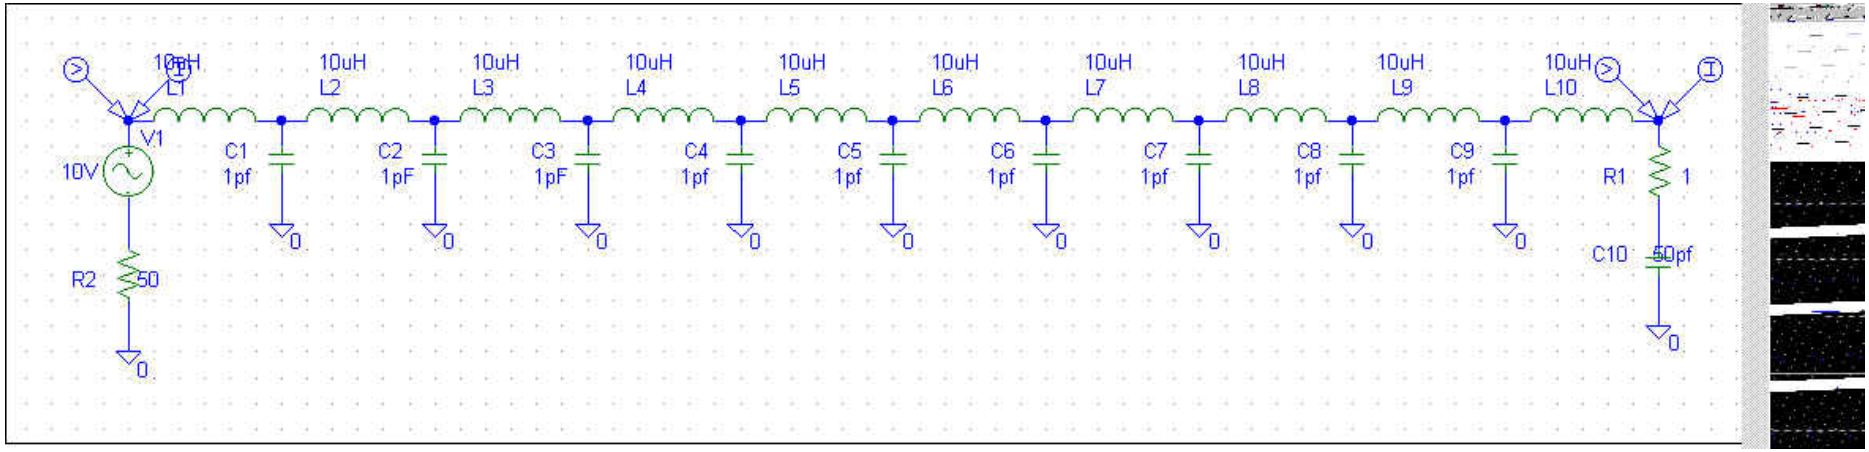
- **The range between the best and worse system was only 3.5dB**
- **A large hat at the TOP of the antenna allows considerable shortening with no loss in efficiency**
- **For a given height antenna, efficiency is increased with a hat at the top**

Mobile and Loaded Antenna

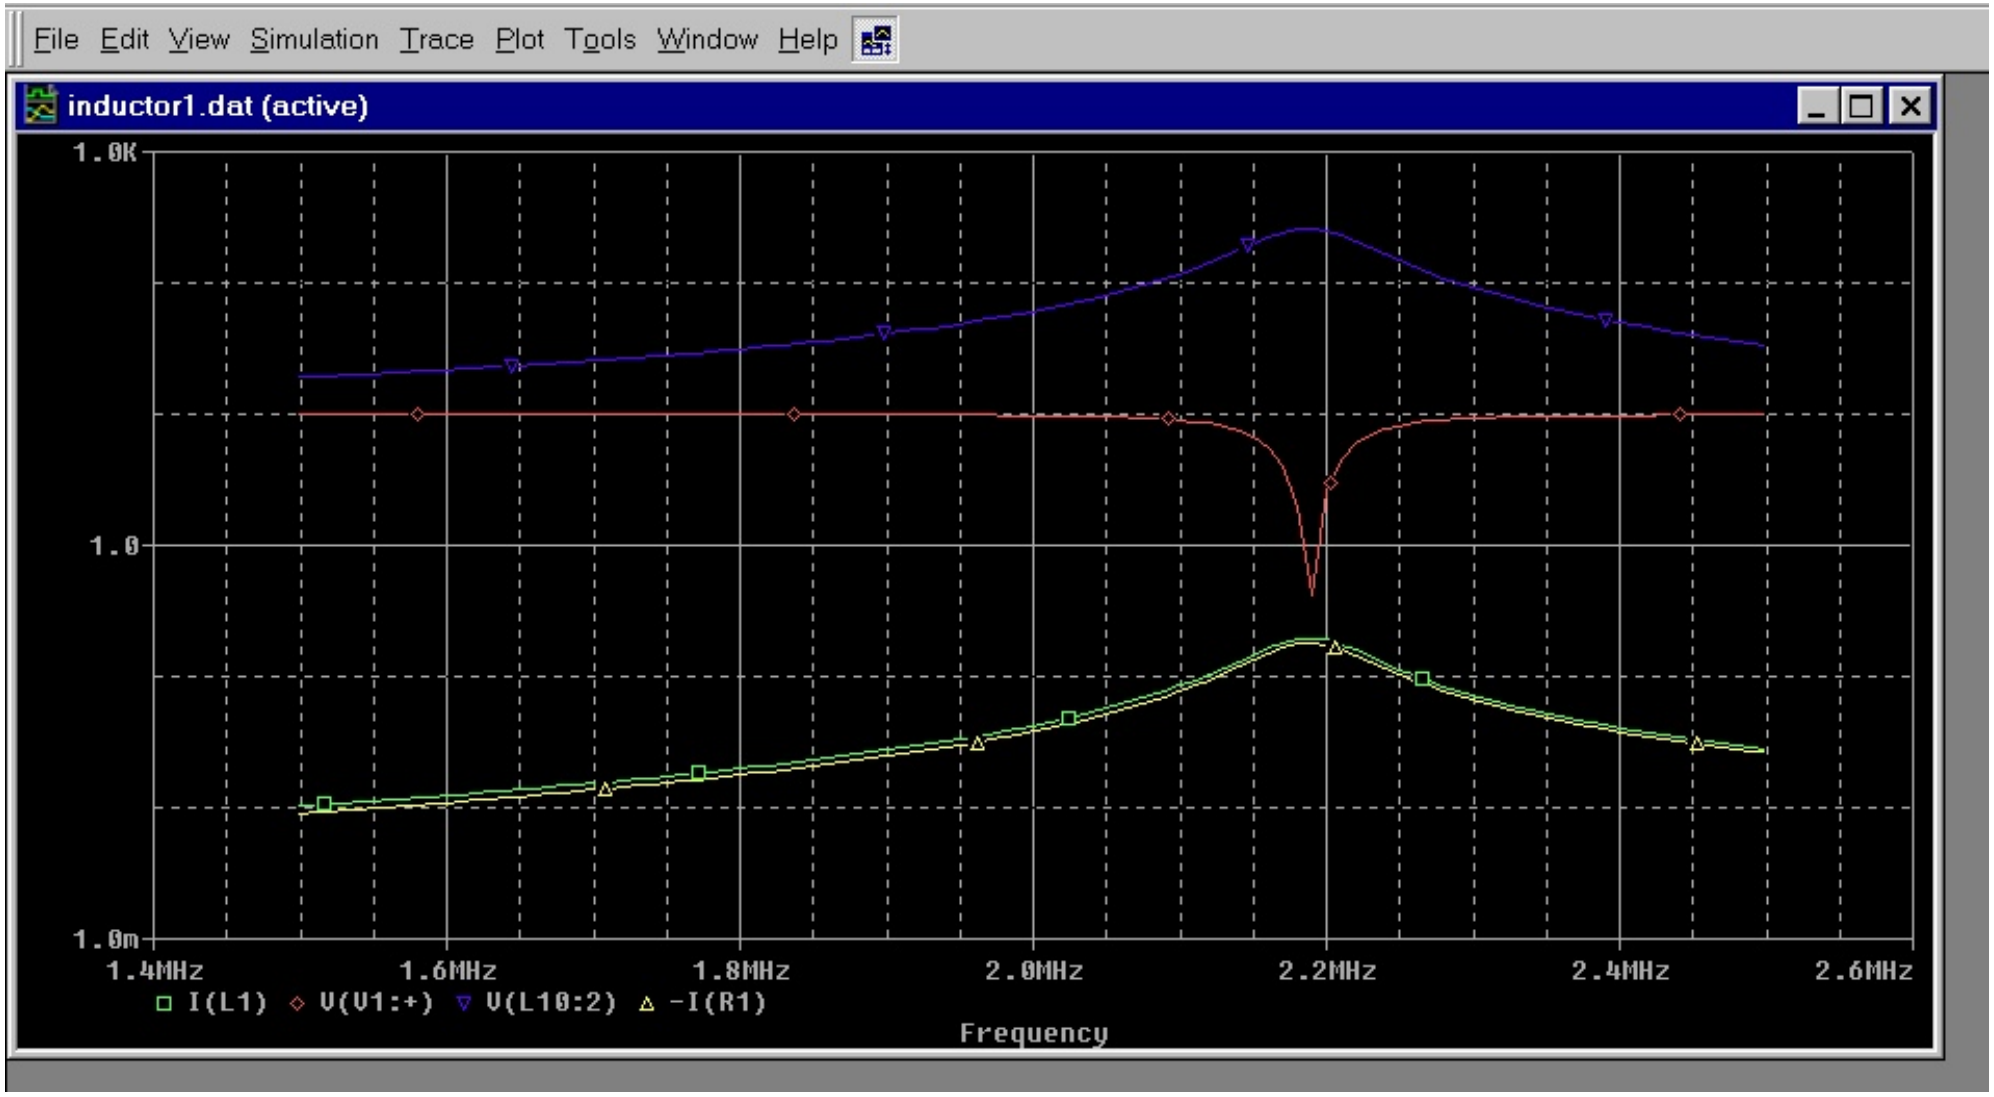
Inductor Spice Model

[Home] [Up]

Spice model of inductor including stray capacitances:



Simulation.



Red=input voltage

Green=input current

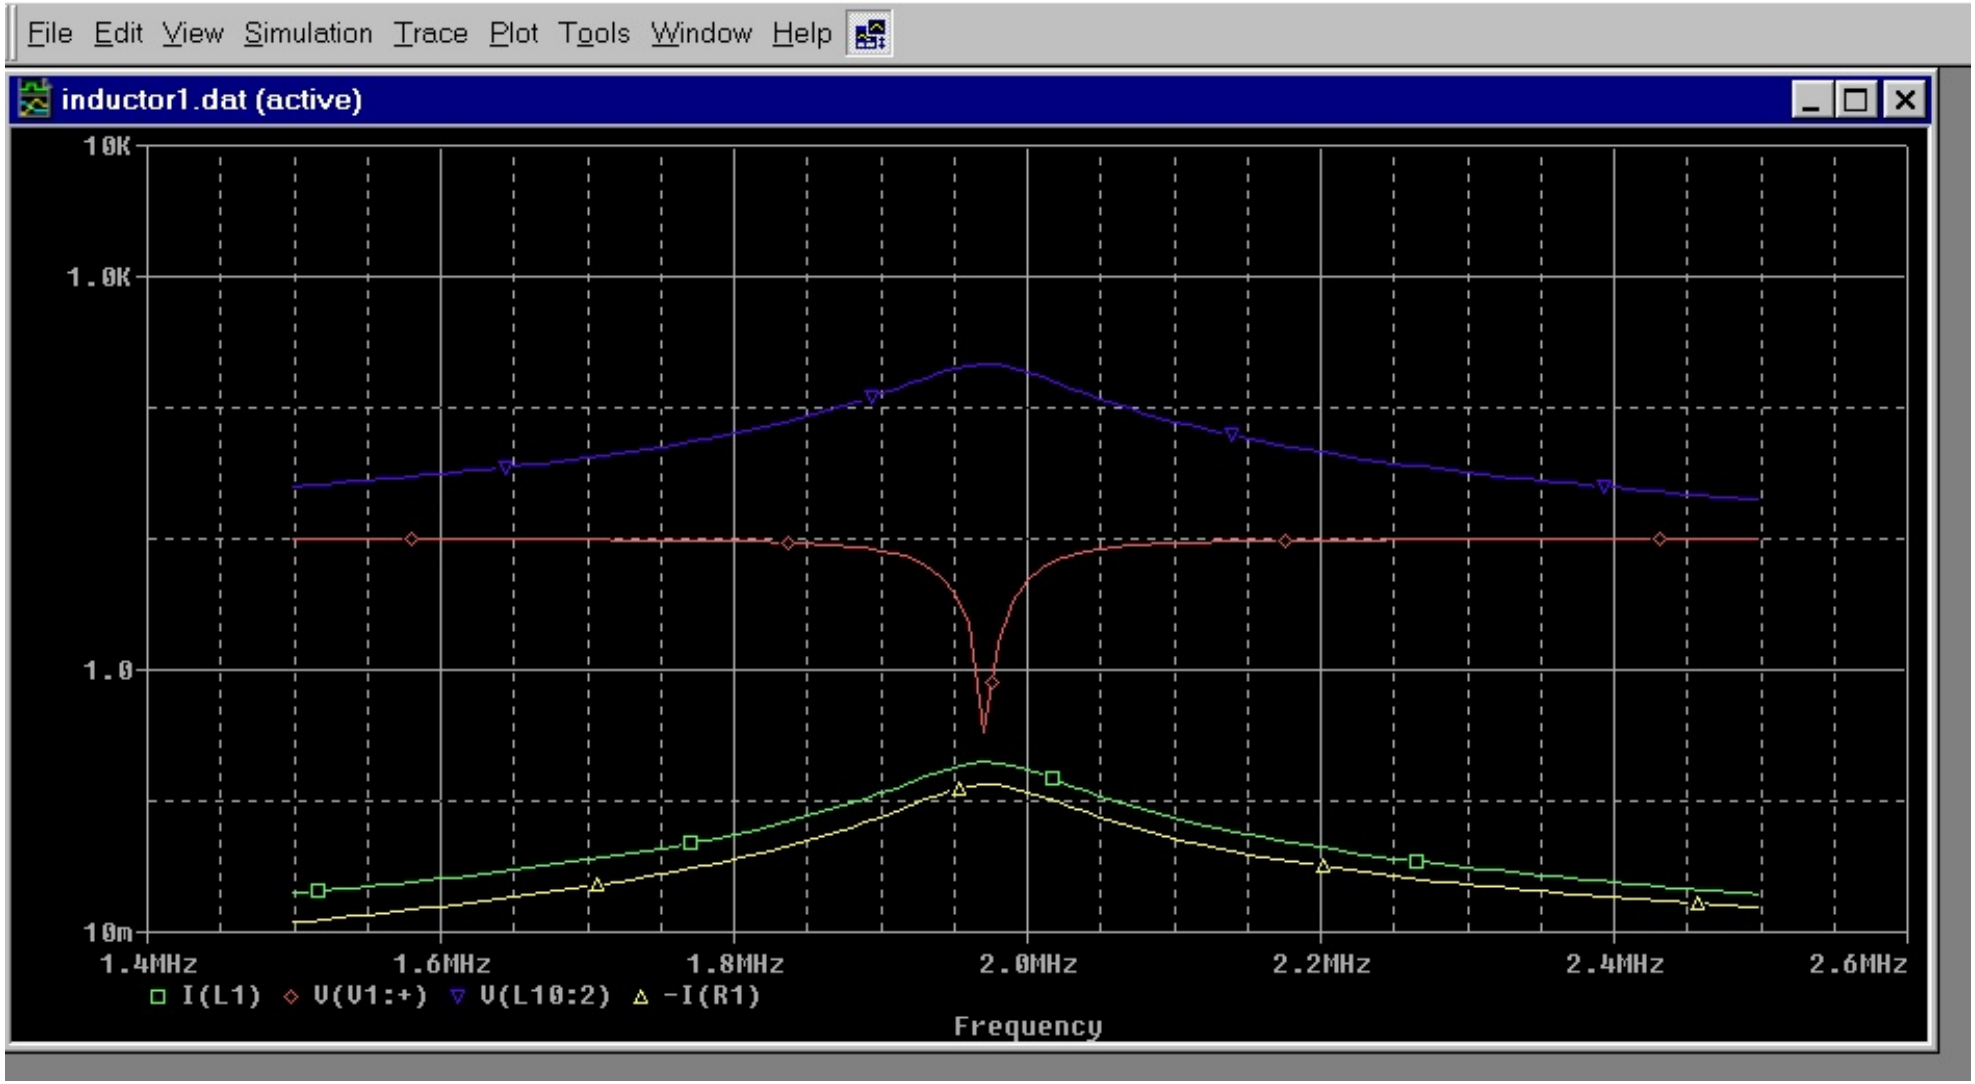
Blue=load voltage

Yellow=load current

This system (including reasonable leakage capacitance) representing a 50 ohm source driving a 100uH inductor with stray capacitance of 9pF and a 50pF load (small

whip), shows input and output currents are essentially equal, while output voltage greatly increases at resonance.

In the following SPICE plot, increasing stray capacitance shows expected departure from equal input and output currents. Distributed capacitance to ground is now at 45pF, nearly equal to the 50pF antenna capacitance:



Again despite stray capacitance nearly equaling load capacitance, current levels at input and output are reasonably similar:

Green=source current

Yellow=load current

Red=source voltage

Blue=load voltage

If we multiply output voltage times current, the apparent power is many dozens of times the input power. The reason is simple, phase relationship between voltage and current along the inductor changes even while current remains essentially uniform.

Although casual experimenters often assume a loading coil "replaces" the missing length in an antenna and has sinking voltage with rising current, this is not the case unless stray capacitance is extreme or the inductor is incorrectly and inefficiently operated at or near self-(series) resonance. The loading inductor really just corrects power factor, and bringing voltage and current into phase at resonance. It does replace missing length by simulating an antenna.

Linear loading is no different, it simply behaves like a very lossy low-Q coil and does not add radiation to the system. Unless of course we are talking about heat radiation.

Loading Inductors

[Home] [Up] [Inductor Spice Model]

Optimizing Inductors

While intended mainly for antenna loading coils, the text below also applies to other resonant systems, such as amplifier tank circuits.

Related pages:

Inductor spice model

Mobile and loaded verticals

Optimum form factor of any inductor depends heavily on the actual end use of the component. Current through and voltage across an inductor as well as the required reactance influences both materials and form factor of an inductor. In high impedance systems, optimum form factor becomes longer with a smaller diameter. Even the best insulation materials will have a deleterious effect on component Q when impedances are high, and dielectric constant often becomes more important than dissipation factor in insulating materials. With low impedances, optimum form factors become more square and insulation has a much less noticeable effect.

Weight, size, and cost often require use of less-than-ideal materials and construction, but careful design generally results in a compromise that doesn't noticeably compromise system performance.

As a further complication, very simple systems might work quite differently than we intuitively believe. Many experimenters fail to consider what the inductor does in the system, and how the inductor behaves internally. For example many people assume, with a fixed amount of applied power, as voltage increases current must proportionally decrease. This isn't true in reactive systems, where voltage and current are not exactly in-phase or 180-degrees out-of-phase.

It is relatively common for programs and formulas to greatly overestimate maximum obtainable inductor Q. Confirming measurements are often flawed, either being made far from the operating frequency or with inadequate methods or equipment. This is especially true in high impedance high frequency systems.

Worse of all, antenna manufacturers and builders tend to seriously understate or estimate loss in other forms of loading, specifically linear-loading.

There are five common errors we should avoid:

- Building for excessive Q, when the reduced ESR will not noticeably improve system efficiency
- In antennas, considering inductor ESR directly as a portion of loss resistance at the point where radiation resistance is taken, rather than normalizing ESR to the point where radiation resistance is taken
- Believing programs or articles predicting Q's in the range of 1000 or more for inductors
- Thinking one optimum form factor (L to D ratio) always provides optimum performance
- Misapplying radiation or loss resistance formulas
- Believing claims that loading reactance obtained from stub or linear-loading provides lower loss than well-designed lumped loading

Before doing anything with information in this article or any other article related to loss and efficiency in antennas, please read the radiation resistance article on this site!

Range of Inductor Form Factor

There are two critical form factor dimensions, diameter and length. The ratio of diameter to length has two limits. The first limit occurs when the inductor occupies only one wire diameter as the length. The other limit occurs when the inductor is one wire diameter in diameter. The first condition would be met by a single layer pancake coil, the second by a linear conductor such as the inductance of a single wire transmission line. Optimum form factor occurs between these two extremes, and varies with the exact application.

Length-to-diameter ratio is important for two reasons:

- Shorter lengths and larger diameters increase capacitance across the inductor. Capacitance across any inductor carrying time-varying current increases circulating currents in the inductor, increasing loss while simultaneously reducing system bandwidth.
- Longer lengths and smaller coil diameters reduce mutual coupling between turns and increase leakage flux. This results in use of increased conductor length for a given inductance, increasing wire resistance.

These two situations are obviously in direct conflict, a balance must be achieved. Optimum balance between conflicting L/D effects listed above depend heavily on external circuit capacitance and operating frequency.

There is actually only one nearly constant parameter in design of high-Q RF solenoid inductors,

turn-to-turn spacing. Optimum turn-to-turn spacing occurs when the spacing or gap between turns is about the same diameter as the wire. If the turn-to-turn gap is filled (even partially) with insulation, optimum ***conductor spacing*** increases.

For the purposes of this article, the following terms are used:

- D=diameter
- d=turn diameter
- L=coil length

As a general rule, Q in a RF inductor peaks with a form factor (L/D) between 1 and 4.

The size and shape of the conductor used in the coil sets the optimum diameter, larger conductors require larger diameters.

Lower optimum L/D ratios (near unity) appear in systems where higher amounts of external capacitance load the system. Two examples would be amplifier tank circuits or large antennas with considerable loading capacitance beyond the coil. Another way to view this is by resonant frequencies. Form factor moves closer to 1:1 when an inductor is operated far below its natural self-resonant frequency.

Higher optimum L/D ratios (up to 4:1) occur when capacitance values external to the coil are reduced. Small mobile antennas without hats, especially top-loaded antennas, require longer form factors. Such systems operate the inductor closer to its self (parallel) resonant frequency.

The Reason Optimum Form Factors Vary

The underlying reason for change in optimum form factor with external circuit impedance rests almost entirely on inductor stray capacitance and mutual coupling between turns.

With high external capacitance, any reasonable amount of internal stray capacitance shunting the inductor causes a very small change in circulating current in the inductor. The external circuit, in effect, determines circulating currents. In this case, inductor Q is set mostly by flux leakage and conductor resistance in the inductor.

In such a system designers can place turns closer together, increasing mutual coupling or flux linkage from turn-to-turn. Since external capacitance causes most of the circulating currents, any increase in inductor distributed capacitance has little effect on the system. It becomes most important to reduce wire resistance by minimizing wire length. Dielectrics around the conductors have little effect on Q, because increases in capacitance caused by replacing air with a dielectric has little effect on the overall circulating currents.

As the system's external capacitance is reduced, circulating currents inside an inductor become increasingly influenced by stray capacitance. This includes capacitance within the inductor, as well as capacitance between the inductor and objects surrounding the inductor.

If inductor design or location is poor, and if system impedances are high, current can actually vary significantly along the length of an inductor. In properly designed systems, this will not occur.

When external capacitance is reduced, the coil ends must be increasingly separated from each other. The form factor chosen must reduce coil diameter while increasing length. In high impedance (reactance) systems, reducing capacitance improves component Q in spite of the resistance penalty resulting from increased conductor length required in long form factors.

We also must avoid using dielectrics near or in the inductor, especially any dielectric coating or between turns. Dielectrics other than air or vacuum, even low dissipation factor dielectrics, increase stray capacitance. Anything that increases capacitance will reduce component Q, and ALL dielectrics (other than air or vacuum) increase capacitance. The most noticeable effects in high reactance systems often come from dielectrics increasing capacitance, rather than actual dielectric losses!

The increase in loss can be directly proportional to the increase in capacitance, even when required turns are reduced. Low-loss Teflon or Polyethylene dielectrics can be nearly as detrimental as higher dissipation factor materials like fiberglass or Delrin.

Inductor Modeling Programs

Many inductor modeling programs fail to consider two important effects:

- They ignore capacitance across the inductor
- They ignore "current pushing" or bunching caused by strong magnetic fields

The first effect causes Q to peak well below the self-resonant frequency of the inductor. The second effect causes a decrease in Q as frequency is increased or as turns are brought closer together. The second effect occurs because current flows in a smaller and smaller cross section of conductor with increasing frequency.

If a model, prediction, or estimate does not show Q dropping drastically as first order (parallel) self-resonance is approached, the results almost certainly contain significant Q errors.

I've corresponded with some program writers who claim to have verifying measurements, and found their test equipment doesn't reliably operate (or operate at all) at the operating frequency of the inductors! Verifying inductor Q at frequencies far below the operating frequency in the model

does NOT provide any assurance the model or predictions are correct.

Optimum Q

There is a strong tendency to overkill the size of inductors, in an effort to reach unrealistic Q factors. Examples are commonly found in high-performance mobile antenna systems, where ground loss and other system resistances dominate the system. We often find high performance inductors with Q's in the several hundreds (at the upper practical limit of Q) and very low ESR's used in systems where overall loss resistances normalized to the feedpoint are very high.

Even though electrical problems are ***NOT*** created when using the highest possible Q, there is a point where the end improvement in signal level does not justify the physical size and cost to obtain "excessive" Q.

One example can be found in my Trap Measurements article, where differences in trap Rp (parallel resistance) when #10 AWG and copper tubing are compared, with unnoticeable changes in performance.

Another example appears in my mobile and loaded antennas article.

Inductor Placement in Antennas

The optimum location of an inductor varies with ground resistance and overall length of the antenna. Fortunately efficiency changes are smooth and gradual changes. Minor errors in placement generally do not result in noticeable efficiency changes.

Radiation Resistance and Mobile and Loaded Antennas articles on this site give some perspective of how load placement affects radiation resistance.

Q Ranges

The highest Q HF inductors I have measured, at least when operated away from self-resonance, are copper tubing coils and edge-wound inductors, such as those commonly used in high power tank coils. The highest Q I have measured in very large inductors of optimum form factor in the HF range has been near 1000.

Miniductor-type coils have a surprising amount of Q for the wire size, and maintain Q better as self-resonance is approached than larger coils.

These are the typical ranges of peak Q I have measured:

	HF Q Peak	Q at 80% of self-resonant freq
Copper Tubing Coils	600-1100	400-600
Edge-wound inductors	600-900	400-600
#8 miniductors	500-700	300-500
#12 miniductors	300-500	200-400
#16 miniductors	250-350	200-300
Large #2 mix iron on 1.8MHz	500-600	
enameled wire close-wound	200	100

As I measure inductors in the future, I'll include pictures and impedance data here.

Final Comments

We should keep the following in mind:

- Optimum form factor varies with application.
- Q peaks at some frequency significantly lower than self-resonant frequency, at self-resonance Q is zero (the coil appears as a pure resistance to any external circuit). Above that frequency inductor becomes the electrical equivalent of a low-Q capacitor.
- Linear Loading is really nothing other than a poor form-factor inductor. The radiation from the linear loading does NOT change the radiation resistance of the antenna except as the effective position of the load might change from the direction of fold. In all cases, a proper form-factor inductor would have less loss, and provide the same radiation resistance.
- Most inductor Q calculation programs overestimate Q.
- Any metal around an inductor decreases Q. Copper or steel, it often has nearly the same effect.
- Any dielectric (even low dissipation dielectrics) decreases Q because the dielectric increases shunt capacitance. This increases circulating currents. The effect is most pronounced as self-resonance is approached.

Radiation Resistance

[Home] [Up]

Related pages on Antennas , radiation and fields , mobile and short verticals

My 2004 Dayton Hamvention Power Point presentation on Small Verticals can be downloaded here... DAYTON 2004.

The main points when dealing with small antennas are:

There is no magic bullet or magic cure to make a small antenna act like a large one. It all comes down to current distribution over linear distance.

Small antennas require extraordinary care to obtain high efficiency.

How do we make a *small* antenna as efficient as possible?

- First, we make current as uniform as possible over the length of the antenna.
- Second, we use low loss loading such as optimum form (size, length, and diameter) loading coils.
- Third, we make the antenna as large and straight as possible in a line. We don't fold, bend, zigzag, or curve the antenna especially in the high current areas.
- We keep the high voltage points (the open ends) away form other things (like lossy earth), and the high current areas away from other large lossy conductors.
- Most important, we keep current as high as possible throughout the length of the antenna by using as much capacitance as possible at the antenna ends.

What this does is maximize radiation resistance (while at the same time minimizing loss). The text below explains how radiation resistance and loss interact.

Radiation Resistance

Radiation resistance is probably the most abused and misused term in antennas. The reason it is so often misused is the lack of clear definition. When a term has several nebulous meanings and uses, it is only natural that misuses will appear. The lack of a firm well-accepted definition allows meanings to slip from one application into another, where a totally erroneous conclusion can be drawn from what otherwise would be a good formula!

Common Uses

There are two commonly used "correct" meanings of radiation resistance and one totally incorrect use. The "correct" uses are:

- The resistive part of an antenna's feedpoint impedance that is caused by radiation from the antenna
- The total EM power radiated in all directions divided by the square of net current causing the radiation

Neither of the above definitions include loss resistances of any type! The moment loss resistance is included, we have the third commonly used (but totally useless) definition. This definition, which includes losses, must be considered incorrect because it is comprised of resistances that have nothing to do with radiation. The misused definition is:

- The real (or resistive) part of an antenna's feedpoint impedance including loss related resistances.

The correct name for the third "radiation resistance is actually the antenna ***feedpoint resistance***, not radiation resistance!

Of the above ***good*** definitions, the first definition is the most commonly abused through mistake. The second definition is an IRE definition (albeit a good one that never caught on). In every case I've seen, it is the second good definition that always provides the most direct and useful answer.

Examples of Misuse

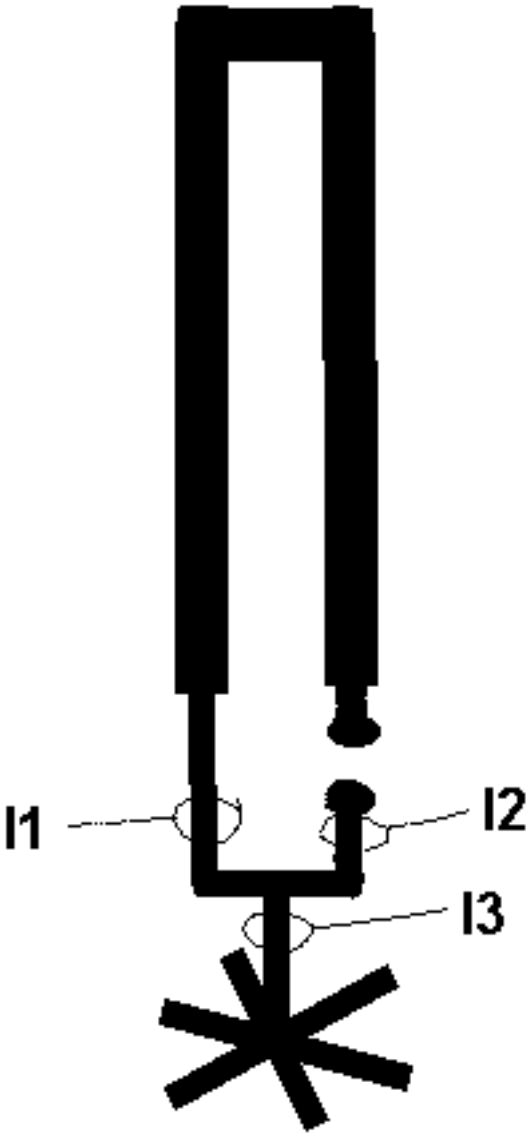
Folded Monopoles

Folded monopoles probably provide the best examples of misuse of the term radiation resistance. Quite often, in discussions of folded monopoles, claims are made that multiple drops increase the radiation resistance and lower losses. The justification for this incorrect claim is the folding raises

radiation resistance, and % eff = 100 * Rrad/(Rrad + Rloss) .

What folded monopole fanatics forget is that all losses must be normalized to the point where radiation resistance is taken, otherwise the efficiency formula won't mean a thing!

Let's look at what actually happens in a folded element, and use it to understand how the poor definition of radiation resistance causes the misunderstanding.



Consider the unipole above. Lets assume we short the open terminals, and feed it as a normal Marconi vertical with a feedpoint at the point where we measure I3. I3 is ALWAYS the vector sum or in-phase combination of currents I1 and I2. With continuity through each leg, I1 and I2 share all of the ground current. This happens regardless of where the feedpoint is located in the lower portions of the antenna.

With 1/4wl height and a reasonable element diameter, the radiation resistance (fed as a traditional monopole) would be about 36-ohms.

Assume ground loss, normalized to the point where we measure I3, could be represented by 14 ohms. Applying 500 watts would make current I3 equal 3.16 amperes. **Power loss in ground resistance would be I^2R, or 3.16^2 times 14, about 140 watts.** Feedpoint resistance would be 50 ohms. Feedpoint power, as a check, would be 3.16^2 times 50 ohms or 500 watts. With equal diameter legs, that current would divide and 1.58 amperes would flow in each upper leg.

Let's use the formula %eff = 100*Rrad/(Rrad+Rloss). We have 36/36+14 = .72 so the result is 72% efficiency, 28% loss. **28% loss times 500 watts is 140 watts in ground losses.** This matches the other method just above.

Opening the terminals and feeding as a folded unipole, half of the radiator current is in I1 while the other half is in I2. Current is halved to 1.58 amperes at the feedpoint and power remains the same. The feedpoint resistance now becomes 200 ohms. We can confirm this with I squared R, or 1.58^2 *200=500 watts. It all works out great so far!

Now let's MIS-use the same efficiency formula, like Orr does in his Handbook and others do in various places. We would have 200/200+14 = .9346 or 93.46 % efficiency.

We know we still have 3.16 amperes flowing as I3, and we know ground resistance is still 14 ohms (normalized to the point where I3 is measured). I-squared-R losses are 3.16^2 * 14 = 140 watts! We have exactly the same power loss.

Let's transform the ground loss value that was normalized at 14-ohms where I3 is measured to the feedpoint by the same impedance multiplication as the feed resistance, or 1:4. We'd now think ground resistance would be 4*14 = 56 ohms. 56 ohms of the feedpoint resistance is loss. Trying that same efficiency formula, we get:

144/144+56 = .72, or 72% efficiency!!! Now everything checks out fine.

The Common Mistake

Orr and others have used the first definition of radiation resistance, the portion of the terminal

resistance of the feedpoint responsible for radiation. Unfortunately ***they failed to normalize ground losses to the same point where the radiation resistance was taken!***

We can not use a formula that is based on everything being normalized to one point, unless we actually do that for every term in the formula!

There is no change in efficiency when the NET radiator current remains the same, and when ground current remains the same. It is pathological engineering to think otherwise.

Using The Second Definition

If we use the second IRE definition of radiation resistance, where the effective current causing radiation is compared to power radiated, we find nothing changes. A folded dipole or monopole has the same radiation resistance as a regular dipole or monopole the same size, and a small loop has the same radiation resistance regardless of turns.

The magic vanishes along with the incorrect definitions and perceptions.

You can read about this in textbooks. The "Antenna Engineering Handbook" by Jasik in 3-13, 19-3, and in other sections uses correct definitions and descriptions.

Quad's and other Loops

We find the same efficiency misconceptions in articles about small loops and large quads. Authors sometimes assume, incorrectly, radiation resistance changes in a favorable proportion to loss resistance as we make the feed impedance increase. What we really are doing is placing the feedpoint in series with a smaller portion of NET current causing radiation.

With a large full-size quad element the pattern under some conditions will slightly change, but efficiency remains basically the same. With a small loop antenna, losses can actually increase with more turns!

Terminated Folded Elements

Another abuse of radiation resistance is found in terminated antennas. Some manufacturers and authors claim a resistance can be inserted in series with one leg of a folded monopole or folded dipole, and the other leg fed. The usual arm-waving claim is the antenna isn't really resistor loaded, and that efficiency is very good because radiation resistance is high.

That claim is absolute nonsense!

A large terminated Rhombic is well-known to have poor efficiency. Rhombic gain is actually low compared to other antennas having the same sin/sin x antenna pattern, because Rhombic efficiency is generally less than 50%. At least half of the power is consumed in termination and ground losses below the antenna. The actual gain may be reasonably high compared to a dipole, but not to other efficient antennas with the same half-power beam width.

The typical manufacturing buzz-word is that terminated monopole and dipole antennas are "traveling wave antennas" and by some magic (that even large terminated Rhombic antennas can't achieve) have broad bandwidth and high efficiency.

A Rhombic focuses energy (that is not transformed into heat) into a narrow beam that has considerable gain, but if it sprayed the radiation around in a non-focused pattern, a regular dipole would win hands down. Throw a resistor on that dipole to smooth SWR variations, or on a vertical, and efficiency suffers.

I listened to a station on 75 meters 600 miles away testing a Sommer T-25 vertical. He was 30 over nine using a dipole, and dropped to S6 with the vertical. The European he was working reported a similar change. By removing the termination resistor and base-loading the same vertical, a local Ham gained almost 25dB on 80 meters!

When we abuse or misuse radiation resistance, we can invent all kinds of magical antennas. We can have CFA's, E-H antennas, terminated dipoles, small magnetic loops, and verticals with all sorts of magical claims. Few, if any, of the claims are ever correct. Any time we see a claim that efficiency changes a ***large amount*** because of feed method change, it should be a red flag.

Increasing Radiation Resistance

Radiation resistance, at least under the useful IRE definition, can be defined by the following formula:

$$Rrad := 160 \cdot \pi^2 \cdot \left(\frac{He}{\lambda}\right)^2$$

which would translate to:

$$Rrad := 1580 \cdot \left(\frac{He}{\lambda}\right)^2$$

Where *He* is the effective height center of accelerating charges that cause radiation. In other words,

He is the effective height, expressed in fractions of a wavelength, of the distributed common-mode current in the structure.

(Common-mode current is the vector sum of all currents, or the effective in-phase current at any point, or the current we would measure if we placed a giant clamp-on current probe around ALL of the conductors at that any given height.)

He and λ must both be in the same units, either given as degrees or decimal fractions of a wavelength.

As an example, a uniform current single conductor antenna has an actual physical height of 15.19 feet on 1.8 MHz, where one wavelength is 546.67 feet, the effective height is:

15.19/546.67= 0.0278 wl

Since charges are distributed evenly throughout the structure the full height is used. The effective height is .027 wl, the same as the physical height. The height in electrical degrees is .0278 * 360 = 10 degrees

We have a radiation resistance of:

$He := .0278 \qquad \lambda := 1$

$$Rrad := 160 \cdot \pi^2 \cdot \left(\frac{He}{\lambda}\right)^2$$

$$Rrad = 1.22$$

We can express this graphically in a chart, such as one found in the Antenna Engineering Handbook by Jasik:

Finding 10-degree height on the graph above, and following that line until we reach the crossing for

unity current ratio, we see the ~1.27 ohm radiation resistance is in agreement.

Notice that the number of vertical conductors does NOT enter into the equation! This is the absolute maximum possible radiation resistance we can obtain for a given radiator height.

Non-uniform Current

Radiation resistance is purely a function of the effective current distribution and height of the radiator, and is limited by height (spatial length)! Current throughout the antenna will not remain uniform if we reduce the size of the flat-top or hat.

Current will become zero at the very top with no hat, and 100% base loading. In this case, with no change in height, radiation resistance will be approximately 1/4th the value of the uniform current example. The result is exactly like a 50% reduction in effective element height.

If we follow the 10-degree line to the intersection point with 0 top current, we find radiation resistance to be around .32 ohms. 1.27 ohms, the radiation resistance for uniform current, becomes 1.27/4 or .3175 ohms.

If we stay on the uniform current line, we find that .3175 ohms would be the radiation resistance of a 5-degree monopole with uniform current.

Efficiency

It often helps to look at the extremes, so we can get a feel for the effect of changes.

Let's look at the poor ground extreme and assume we have system losses, normalized to the current maximum, that are many times the radiation resistance. This would be the case for a short 160 or 80 meter mobile antenna.

In such a system radiation resistance would dominate any change that would affect efficiency. Current distribution would mean everything to efficiency.

Assume we have a base loading coil, either good or poor, and a thin mobile whip above the coil. Efficiency would increase by a factor of approximately four times by installing a capacitance hat with several times the distributed capacitance of antenna conductors below the hat.

Moving the coil would have little or no effect on efficiency.

A six-foot antenna with a large hat would be electrically equal to a 12-foot antenna without a hat.

This is why very poor inductors used on antennas in mobile shootouts, with large hats, equal or beat very large high-Q coils in similar height antennas that do not have large hats. One case in mind was a Hamstick lash-up in a mobile. The Hamstick, a notoriously poor efficiency antenna for 75-meters, soundly trounced Bugcatcher antennas when a large hat was added to the Hamstick.

Moving the coil up on the antenna has the effect of making current below the coil uniform, but without a hat current above the coil is a triangular taper that reaches zero at the element tip. The effective height of the area above the coil is 50% of actual height.

If we add a large hat at the bottom of the whip, current in the whip is actually reduced! At the same time, we change nothing below the coil. The effect of adding a large hat below the whip is to reduce the effective height of the antenna, when considered as a percentage of physical height. Radiation resistance and efficiency is generally reduced by adding a hat just above a coil, even if the hat allows us to use a smaller coil!

Adding a large hat at either end of a coil also reduces coil Q, since a large portion of the hat capacitance directly shunts the inductor.

Conclusion

We can reach the following conclusions:

- Radiation resistance, or at least the useful definition of radiation resistance, is limited by spatial area (or height in the case of a vertical) any antenna occupies.
- Radiation resistance is maximized by making current as large as possible over the entire spatial area of the antenna.
- Surrounding objects generally reduce radiation resistance and efficiency, even when they are NOT resonant, because they reduce effective height! This includes dielectrics that increase capacitance of the antenna to ground, since any increase in capacitance appearing well below the top of an antenna reduces effective height.
- Radiation comes from charge acceleration, nothing else. The longer the linear spatial distance we move charges in, the fewer charges we need to move at any point for the same amount of EM radiation. This is just another way of saying radiation resistance is higher in physically longer structures, especially when they carry uniform current.
- Any antenna (including Linear Loading, Helical Loading, Folded Monopoles, Fractal shapes, CFA, E-H, and so on) claiming to increase radiation resistance beyond the limits outline above is based on misunderstandings or untrue distortions of basic antenna principles.

Radiation and Fields

[Home]

Related pages Radiation Resistance

We tend to think of electric, magnetic, and radiation fields as physical "things"...much like an element would be in chemistry. This can cause problems!

One popular (but incorrect) assumption is we can combine, mix or blend fields into another field. After all.... we have electric fields...we have magnetic fields...surely we can mix them and create an electromagnetic field. This would have a distinct advantage, because we all know nearfield losses are higher than farfield losses. We know the farfield field ratio (or field impedance) is set by the media the wave propagates through. With reasonably dry air or vacuum, at normal radio frequencies, we know the impedance is 377 ohms. Why not just mix the two fields and create the third field without all that needless nearfield loss?

If, in our mind's eyes, we can mix fields the next logical step would be to conclude we can separate, filter, or sort them out whenever handy. If we have a problem with electrical interference, we can just eliminate the electric field. If we have a problem with field intensity (defined as volts-per-meter) causing problems with the neighbor's VCR, we can reduce the electric field and cure the problem. After all, it is electrical interference, isn't it?

We logically might assume, just by name, we can mix the various fields and make a new field. We logically might assume we can split the combined fields back apart if we don't like what is happening to one of them.

Unfortunately, none of the above is true! The above conceptual problems started at the very beginning, because we assumed fields were physical things like building blocks. They aren't.

Fields are really just mathematical descriptions of forces between charges. We have three simple conditions that create physical forces between charges. They are electric, magnetic, and electromagnetic (radiation) forces. They are all created by distinctly different physical actions in a system. We can't mix the various names for effects resulting from a certain physical condition and create a new cause! Fields describe effects, they don't create the causes of those effects!!!

Electric Field

Electric field describes a force created by uneven charge distribution. Nature wants charges to be evenly distributed, she can only take so much piling up of charges in one spot! The force between charges, caused by nature trying to balance or even the distribution of charges, is called an ***electric field***.

Uneven charge distribution goes hand-in-hand with a voltage difference between two physical points. We can obviously can have a difference in charge distribution in insulators as well as conductors. A comb, "charged" by running through our hair (if we have any left), can have an electric field. The force of this field can pick up tiny bits of

paper, as nature tries to equalize the charge distribution. The terminals of a battery have an electric field between them, and when we place a conductor in that field the charges try to equalize. Another example would be an antenna, where a voltage difference (uneven charge distribution) between two points creates an electric field.

Any difference in ***charge distribution***, whether the charges are "moving" or standing, causes a physical force. We name this effect an **electric field,** and describe it mathematically in volts over a given distance. This field (or force) decreases rapidly with distance.

Magnetic Field

Magnetic field describes a force created by moving charges. When charges are moving, they exert a force on all other charges around them. We call this effect the **magnetic field.**

One example of a magnetic field is a conductor carrying current. Perhaps it is a wire connected between two terminals of a battery. Another example would be a RF-current carrying conductor in an antenna.

Any movement of charges causes a magnetic field, and somewhere rooted in the creation of that magnetic field is an uneven distribution of charges causing an electric field! Once again, this field (or force) decreases rapidly with distance.

Electromagnetic Field

An **electromagnetic field** is created whenever charges are accelerated. Acceleration occurs whenever a charge changes direction or velocity. When a charge accelerates, all the other charges in the universe feel a force trying to make them move. The only thing that stops that force from going on forever is if another charge (or combination of charges) accelerate to create an equal but opposing force. We call the velocity at which this force ripples through the universe the *speed of light*.

One example of electromagnetic fields is in an AC current carrying conductor, like a power line. The time-varying voltage causes charges to move back and forth, and the change in velocity and direction causes the effect called electromagnetic radiation.

It is plain to see why our antennas have all three fields, and why we can communicate so well over large distances with low power. While the electric and magnetic induction fields drop off rapidly, the (initially) much weaker electromagnetic radiation field goes on until something cancels it. It is the radiation field that allows us to communicate, not the electric or magnetic induction fields!

Near the Antenna

Near any antenna fields are a complex mixture or " soup" of various effects from charges. Charges are almost always moving in multiple directions and over various distances, when viewed from distances close to the antenna. It isn't always easy to understand what actually is happening very near antennas (where the area of the antenna is large compared to the distance from which we observe the effects of charges). Near the antenna, pattern and field impedance is generally nothing like we might intuitively imagine!

It is the response in this area, generally within $\lambda/10$ distance from the antenna, that small "magnetic loop" and

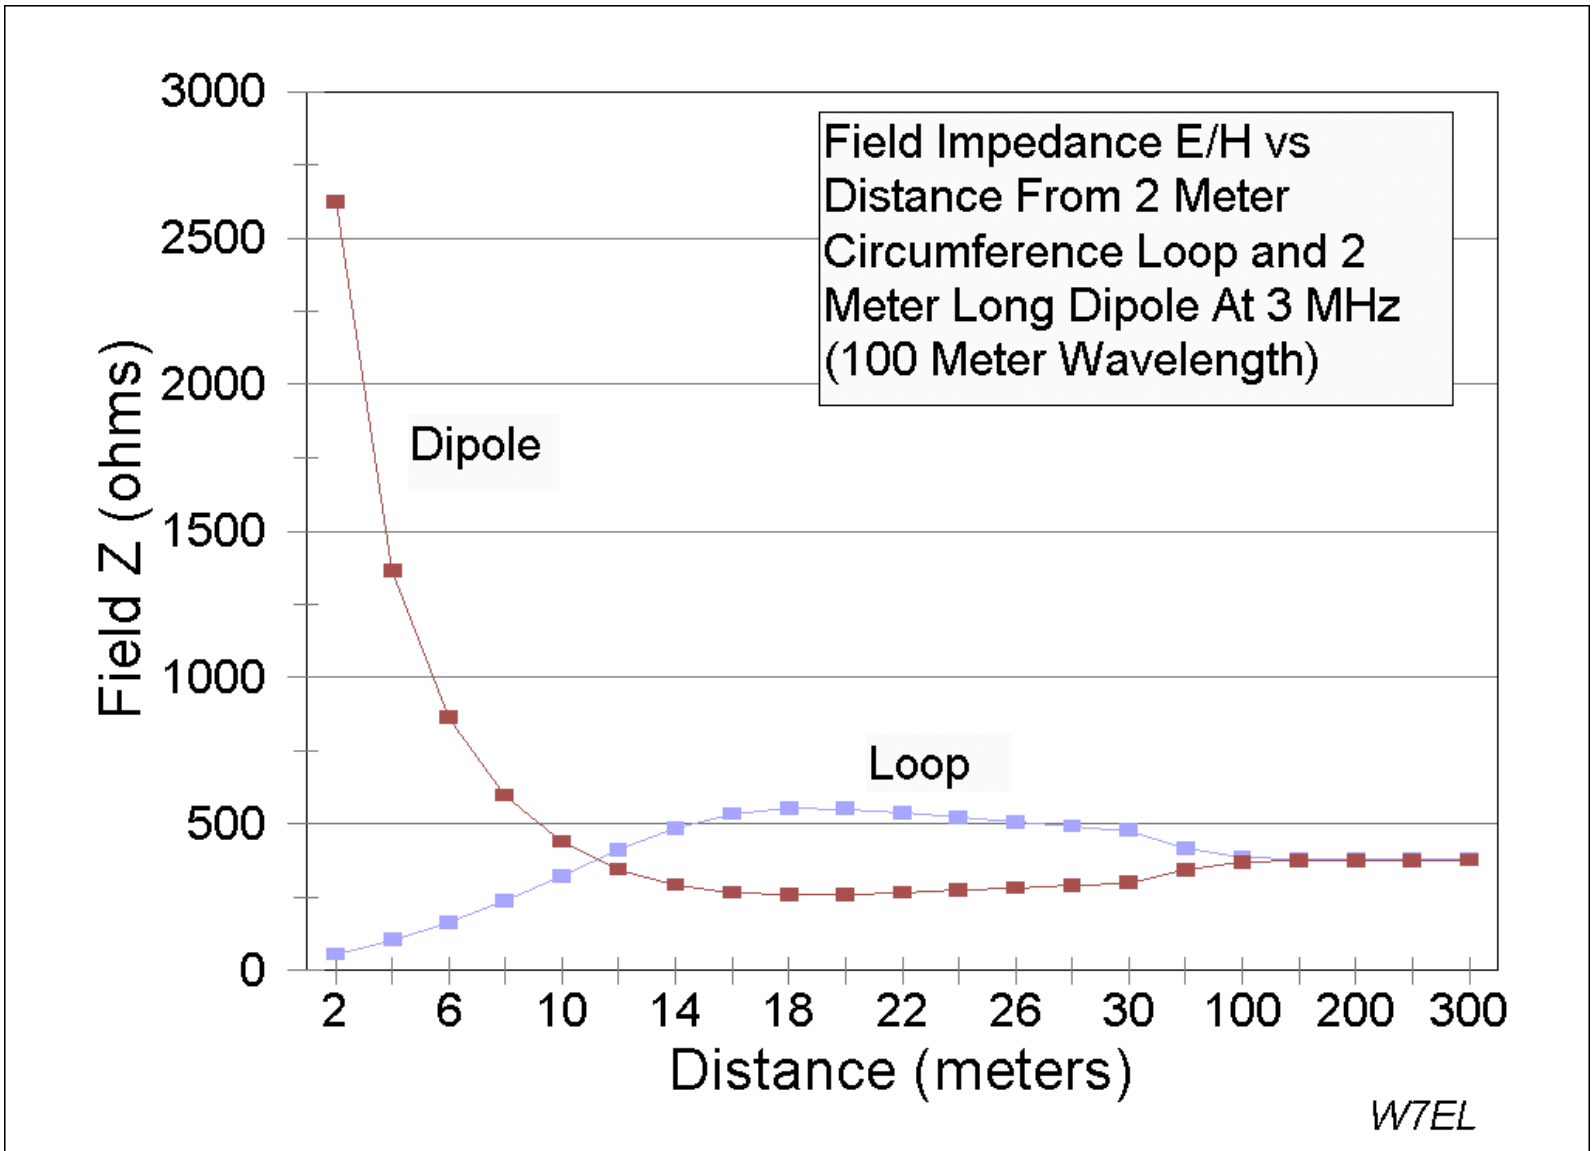
"electric dipole" antennas get their names.

Very close to the high-current area of a small loop antenna (but not near the open ends, because that is where the electric field dominates), the magnetic field dominates. Magnetic fields are mathematical descriptions of forces derived from moving charges, or current flow. This effect, when large compared to the electric field, is sometimes described by saying the "***field impedance***" is "***low***".

Conversely, near a small dipole or monopole with high voltage and little current, the electric field dominates. The largest force is from the very high open-end voltages, and very uneven charge distribution. We might say such an antenna has a " ***high field impedance***" in the area where the electric field dominates any forces cause by moving charges.

In all of these cases, if the antenna is electrically small, the dominant fields apply only within approximately λ/10 distance from the antenna!

As we move out further the weaker radiation field, because it is attenuated less with distance, starts to have a noticeable contribution to the charge forces. Because the phase of the fields (fields are a way of describing effects) is different at the antenna, the sum of the effects is different with distance. At some distance the low field impedance of a small loop becomes high, and the high field impedance of a small dipole becomes low!



W7EL

Since the distance of a wavelength in the above graph (thanks W7EL) is 100 meters, we can also considered the bottom scale as a percentage of a wavelength. We can see at about 11 percent of a wavelength (which would be about 50 feet on 160 meters), there is no difference in field impedance between a small loop and a small dipole. At distances beyond 50 on 160 meters, the loop actually has a ***higher*** field impedance than a dipole.

Losses

None of this has anything to do with losses being high or low in small antennas. Losses are directly related to the field density, and when we are close to any antenna the fields are very intense. Losses are not a field ratio problem, they are a field intensity related. In very small antennas, virtually ALL of the losses are related to reactance canceling and resistive losses in the antenna and any lossy media around the antenna!

We also must be mindful of the painful truth that we can not take either field to zero, or all radiation stops. By definition, radiation is an electromagnetic wave. We can't modify the field impedance of an antenna without changing the voltage and current distribution of the antenna.

Nearfield

The nearfield area is an area where the ultimate pattern is not fully formed, and where induction fields (from charge distribution and charge movement) have a noticeable effect.

It is possible, with large arrays of small elements, to be out of the induction field region but still find the area called the "nearfield" area or zone. Let's consider individual groups of elements as "cells", and the array a combination of small directional cells occupying a very large physical area.

Each cell has formed a radiation field. Depending on the size and type of radiator in each cell, the induction fields that charge distribution plays a role in may be attenuated so much as to be negligible, yet the radiation pattern of the entire array may not be totally formed.

This is the case with my phased Beverages and phased verticals, where the individual antennas making up the array are so distant that the effects of charge distribution (electric induction field, sometimes called the electrostatic field) or steady movement (considered at one infinitely brief instant of time, or magnetic induction field) have no effect. For example, at about 1 wavelength distance the electric and magnetic induction fields are negligible from either my circle of eight verticals or 780-foot Beverages, yet the pattern of the overall array established by the phasing of multiple cells is not fully formed. The pattern would only be fully formed several wavelengths from each array, where the distance between cells or elements is a small fraction of the viewing distance.

The total pattern of two 780-foot long Beverages spaced 350 feet apart is not fully formed even at distances of several thousand feet, yet nearfield induction effects are totally gone at much shorter distances. The field impedance is established, yet the antenna pattern is not.

The nearfield generally refers to or includes the area where "static" or induction fields still have a noticeable influence.

Fresnel Zone

The Fresnel (fre-nel, no "S" sound) zone is the area where pattern is still being formed. It may or may not include induction field areas.

Physically large arrays almost always have a physically large Fresnel zone. Even simple omni-verticals have a Fresnel zone extending out a few wavelengths. The field impedance may or may not have already been established in the Fresnel zone.

You may have heard about Fresnel zones during discussions of vertical antenna loss at low wave angles, or Fresnel lenses for lighthouses or other beacon lights.

Farfield

The farfield is the area where any changes in distance result in no noticeable change in pattern or field impedance. Losses are lower in the farfield area because field density is lower, not because we call it farfield.

Summary

There really isn't a clear distance where certain effects just abruptly stop. Transitions are smooth and gradual, because transitions are the result of distance....nothing else. These regions of effects are all distance related, and caused by the three distinct effects of charges moving, charge distribution, and charge acceleration.

Even if we could somehow make the field-impedance a certain value or electric and magnetic effects a ratio equal to farfield ratio, it would not eliminate or in the slightest amount reduce nearfield losses!

Losses are only related to the density of fields in any given media or environment, and nearfield or Fresnel zone losses decrease with distance because of the lower field intensity in any given lossy area, or wider cross-sectional area of lossy media carrying the same energy.

Larger antennas, in general, have larger boundary areas for electric and magnetic fields. With wider boundary areas, the system has less-concentrated fields and charge effects. Very small antennas of any type obviously have very concentrated fields, and the high field density or concentration of current or voltage in conductors are at the root of increased loss. The concentration of energy in a small area is the real reason losses are generally much higher in smaller antennas, and this has little or nothing to do with field impedance!

We can not mix fields and create a different field and make a small antenna become an "artificial large antenna", nor can we "filter" fields and remove the electric field to reduce electric noise.

Traps

[Home] [Up]

This article is from a talk I gave about antenna traps. It contains measurements of traps, performance of trap antennas using models of traps, and ideas on how to make trap antennas more efficient.

Try taking this Trap-Q test! Be honest.

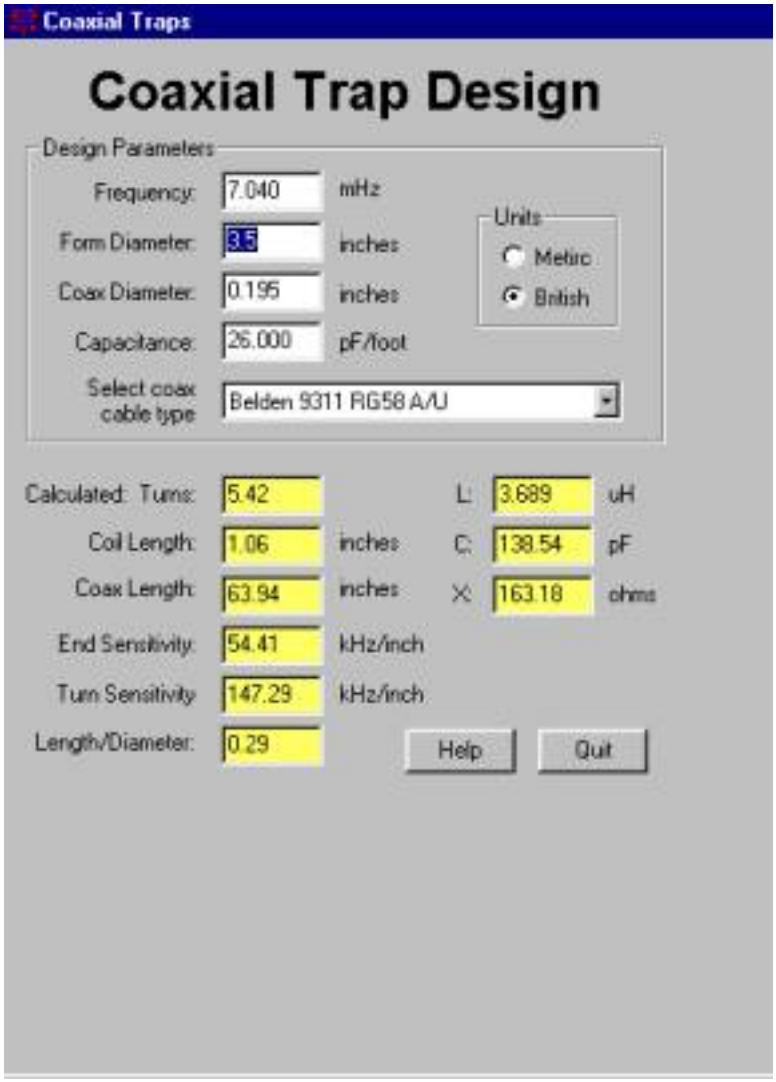
1.) Is it best to make the trap resonant close to the desired operating frequency?

2.) Does bandwidth decrease with increasing trap Q?

3.) Do traps create noticeable loss, perhaps one dB per trap typically?

4.) Does higher trap operating Q always mean lower loss?

Coaxial Trap Designer by VE6YP (Tony Fields)



This is a good program to get you in the ballpark with a trap design. It was available as freeware. (Unfortunately coaxial traps are relatively lossy on the trapped frequency compared to other types.)

The software is available at **http://members.shaw.ca./ve6yp/index.html**

7.04 MHz 3.5 inch diameter form RG58/U into the VE6YP program yields calculated values of:

Calculated	Actual Measurement
L= 3.689µH	3.116µH
C= 138.5 pF	164 pF
64 inches	59 inches

Using the program TLA by N6BV (from ARRL), we would estimate capacitance of a 59" RG-58/U cable as:

R .22 –j143.61 or about 157 pF (Q=650)

Measuring a real-world stub, capacitance was 164pF (Q=590).

While that Q seems high, remember a typical transmitting-type air-variable capacitor has a Q of several thousand!

Coaxial Trap Articles and Programs use capacitance/ft multiplied times length….

26 pF * 4.917 feet = 127.84 pF in trap program

C164 pF measured. This error, 36pF low from 164pF, occurs because the transmission line making up the "coaxial capacitor" is not actually treated as a transmission line in the modeling program.

Fortunately the error is in a useful direction, because we can shorten the cable! Coaxial capacitors are really open stubs, and should be treated that way once they are more than a few degrees long.

CONCLUSION: The difference between TLA and an actual measurement was around 4%. This is very close, but the result has significant difference from the coaxial trap program since it only considers pF per foot as the capacitance. A longer cable (in fraction of a wavelength) results in greater error by using pF per foot. The error comes because a coaxial cable capacitor is really a stub, NOT a pure capacitor!!

Trap Measurements (at resonance)

Type	F MHz	R parallel	X
Coax RG-58	7.034	17,800	0
UT-141-75 semi-rigid	7.045	45,330	0
100pF 7.5kV & #12 wire	7.040	99,850	0
60pF 15 kV & #10 wire	7.040	250,000	0
60 pF vac & Copper tubing	7.040	300,000	0
Coax RG-58	3.700	23,200	0
Coaxial with fixed mica capacitor	7.040	21,660	0

Highest R parallel equivalent is best!! Lower Rp means more loss.

Trap Measurement summary:

- **Coaxial trap poorest**
- **Once #10AWG wire is used, not much improvement**
- **Space-wound bare wire makes best inductor**
- **Transmitting-type capacitors noticeably better than capacitors made from coax**

10 Meter (Tribander) Traps

Type	Freq	R parallel	X
Coax RG-58	29.00	13,800	0
Mosley TA-33	30.64	43,100	0
Mosley Pro-57	27.46	66,080	0

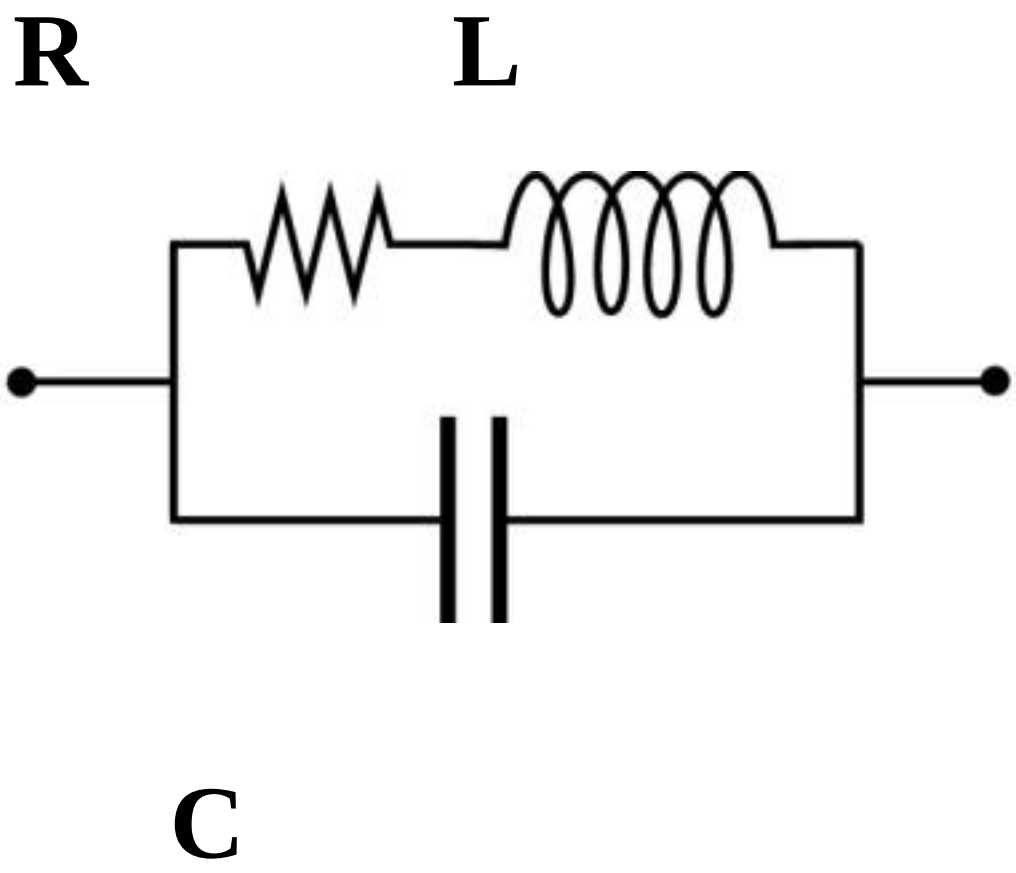
Cushcraft A3	**28.78**	**110,000**	**0**
HyGain TH-3	**29.67**	**140,200**	**0**

Traps are not all that bad when you plug them into models.

15 Meter (Tribander) Traps

Type	Freq	R parallel	X
Coax RG-58	**21.00**	**13,980**	**0**
Cushcraft A3	**21.43**	**76,270**	**0**
Mosley TA-33	**21.68**	**79,000**	**0**
HyGain TH-6	**22.23**	**142,000**	**0**

Trap Model



Measured Values Coax 7 MHz Trap

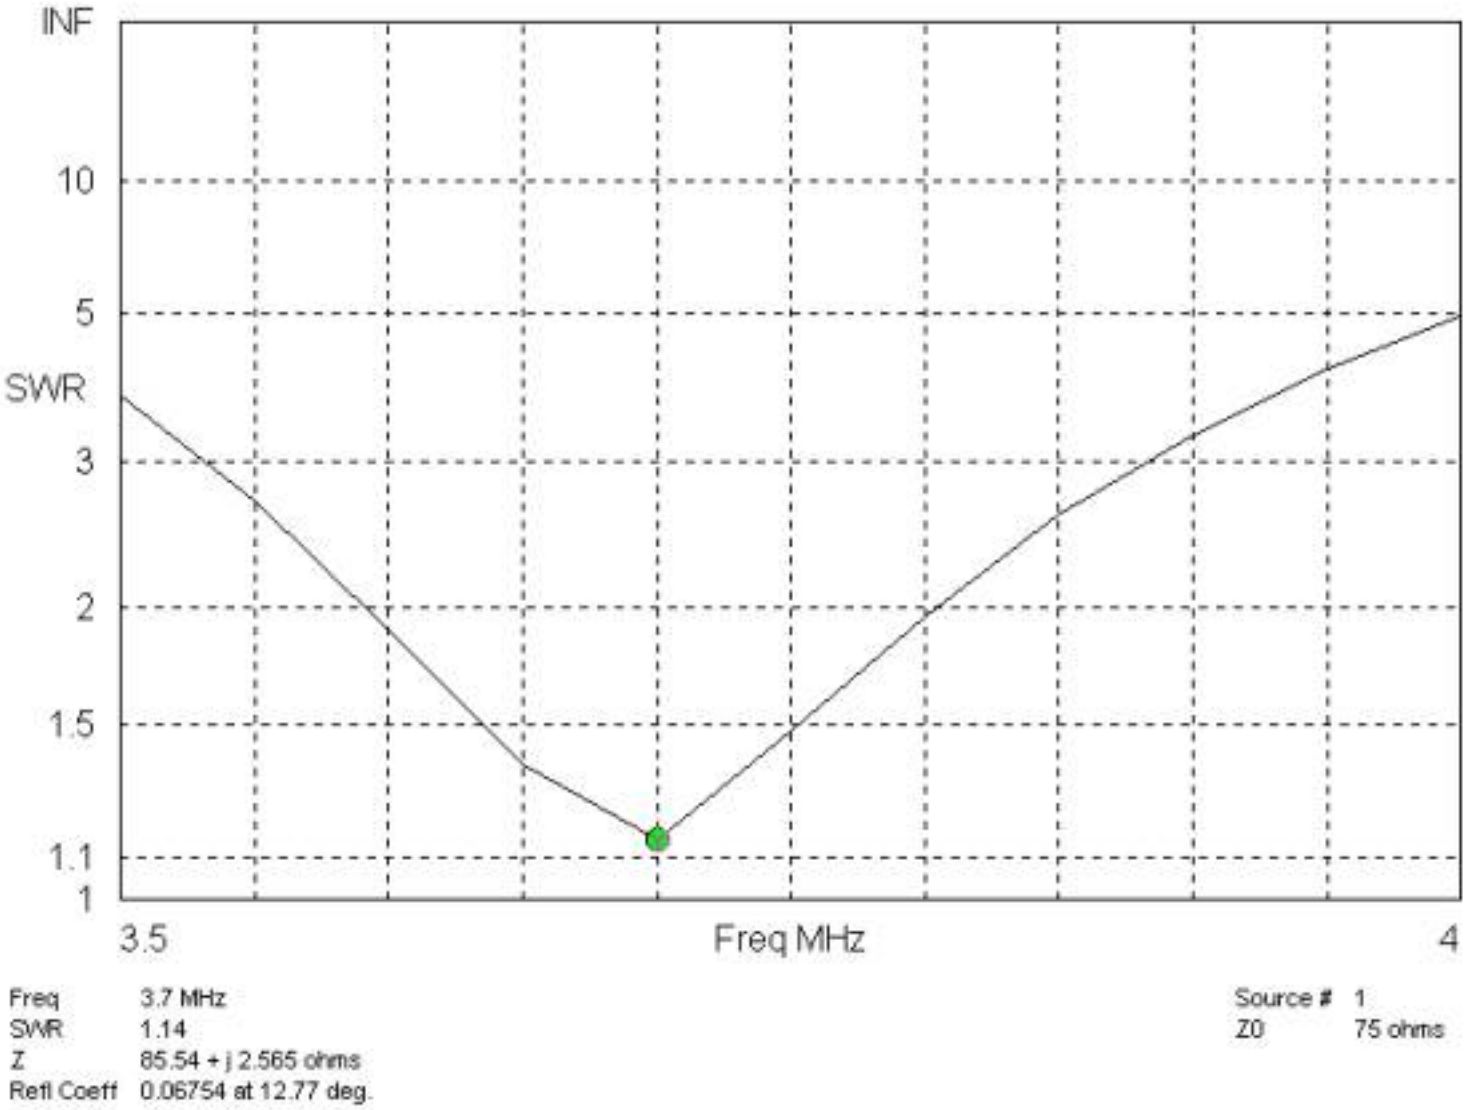
Freq	Imp	R	Xc	Q	L uH	C pF
7.04	17,800 j0	1.03	138	134	3.114	164

3.7	1.1 j 97	.6	283	88	3.114	152

Measured Values L/C 7 MHz Trap

Freq	Imp	R	Xc	Q	L uH	C pF
7.04	99,850 j0	.36	215	465	4.92	105
3.7	0.53 j 156	.25	409	294	4.92	105

SWR Bandwidth



7 MHz RG-58 TRAP

80 m 75 ohm VSWR

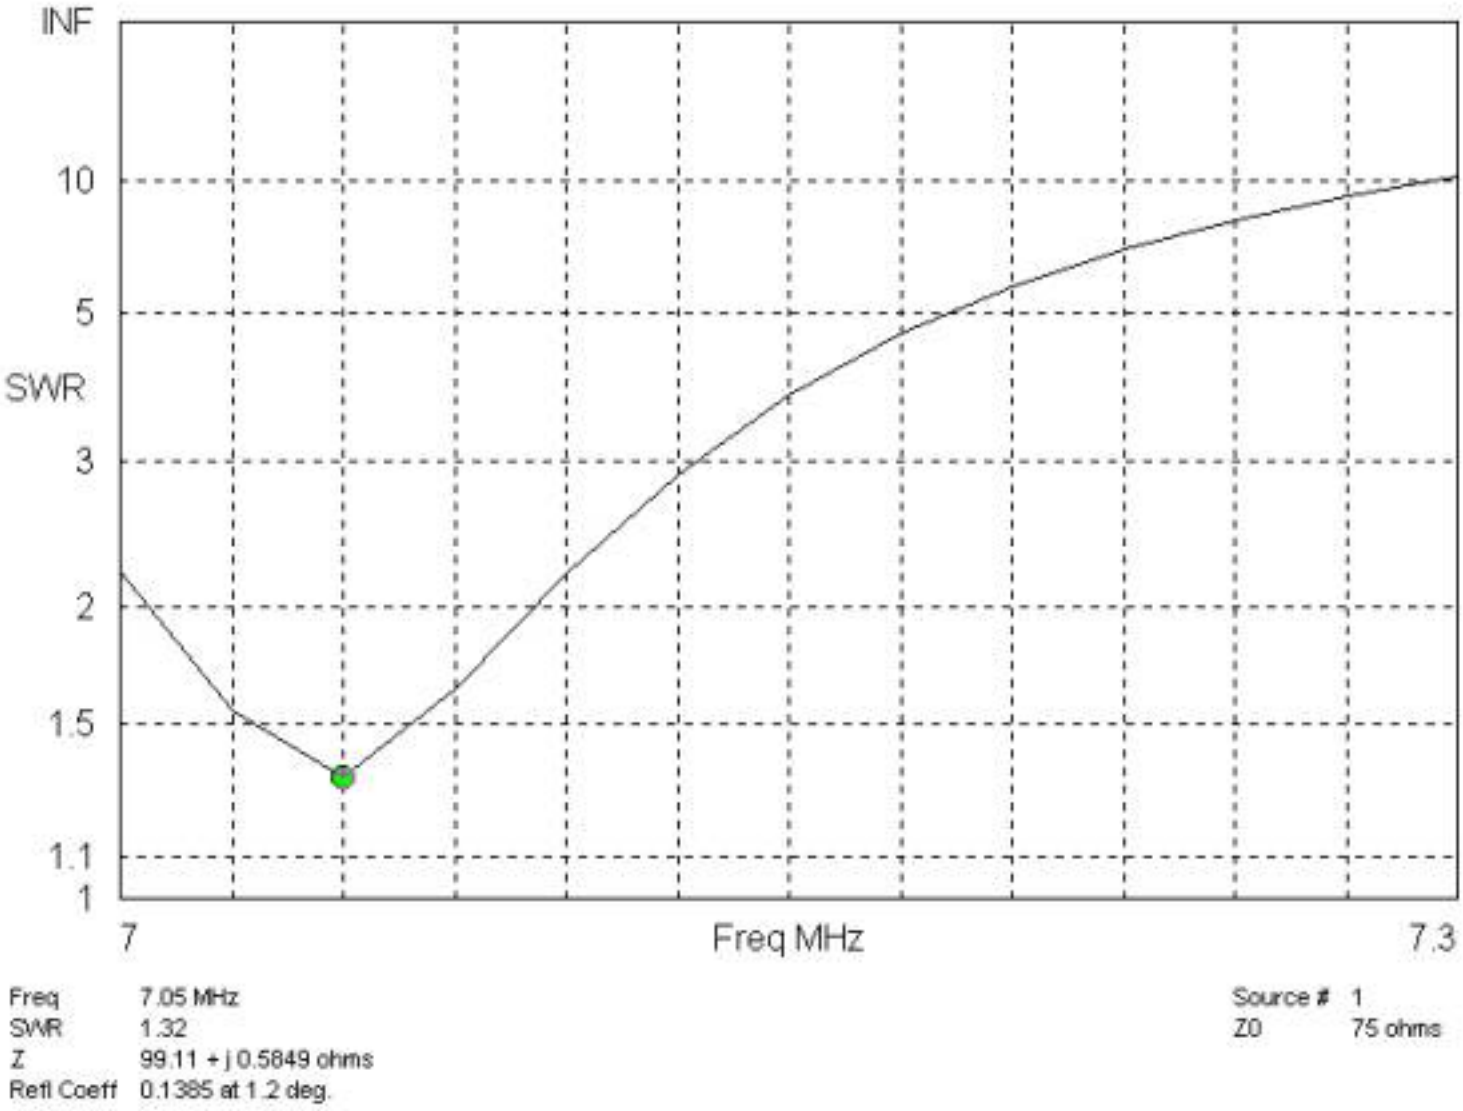
EZNEC #12AWG dipole

Coax trap 80m 2:1 VSWR ~210 kHz

Total trap loss = 0.05 dB

RG-58 TRAP, 75 ohm VSWR, 40 METERS

VSWR BW



Coax trap 40 meter 2:1 VSWR ~ 80 kHz

Total coaxial trap loss at resonance on 40m= 1.6 dB

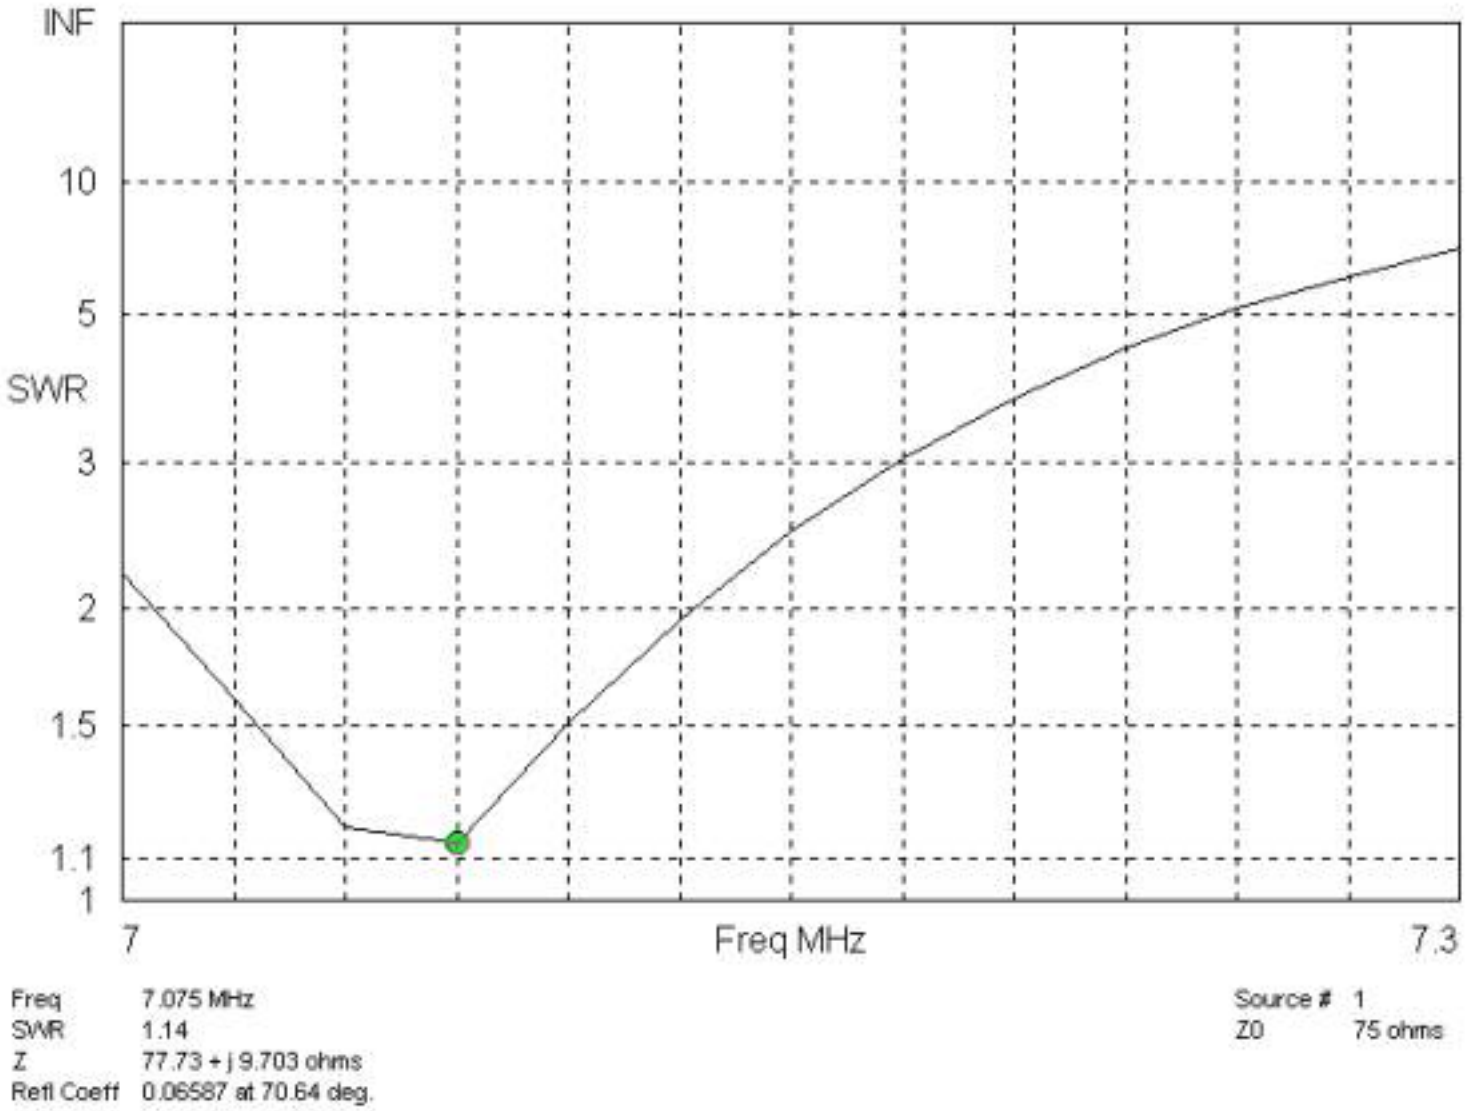
Total coaxial trap loss 100kHz off-resonance (at 7.15 MHz)= 1.06 dB

Note that loss is maximum at trap resonance!!!

Never make a trap resonant on the desired operating frequency!!

W2LH ARRL Handbook Trap Design

100pF #12awg Miniductor trap

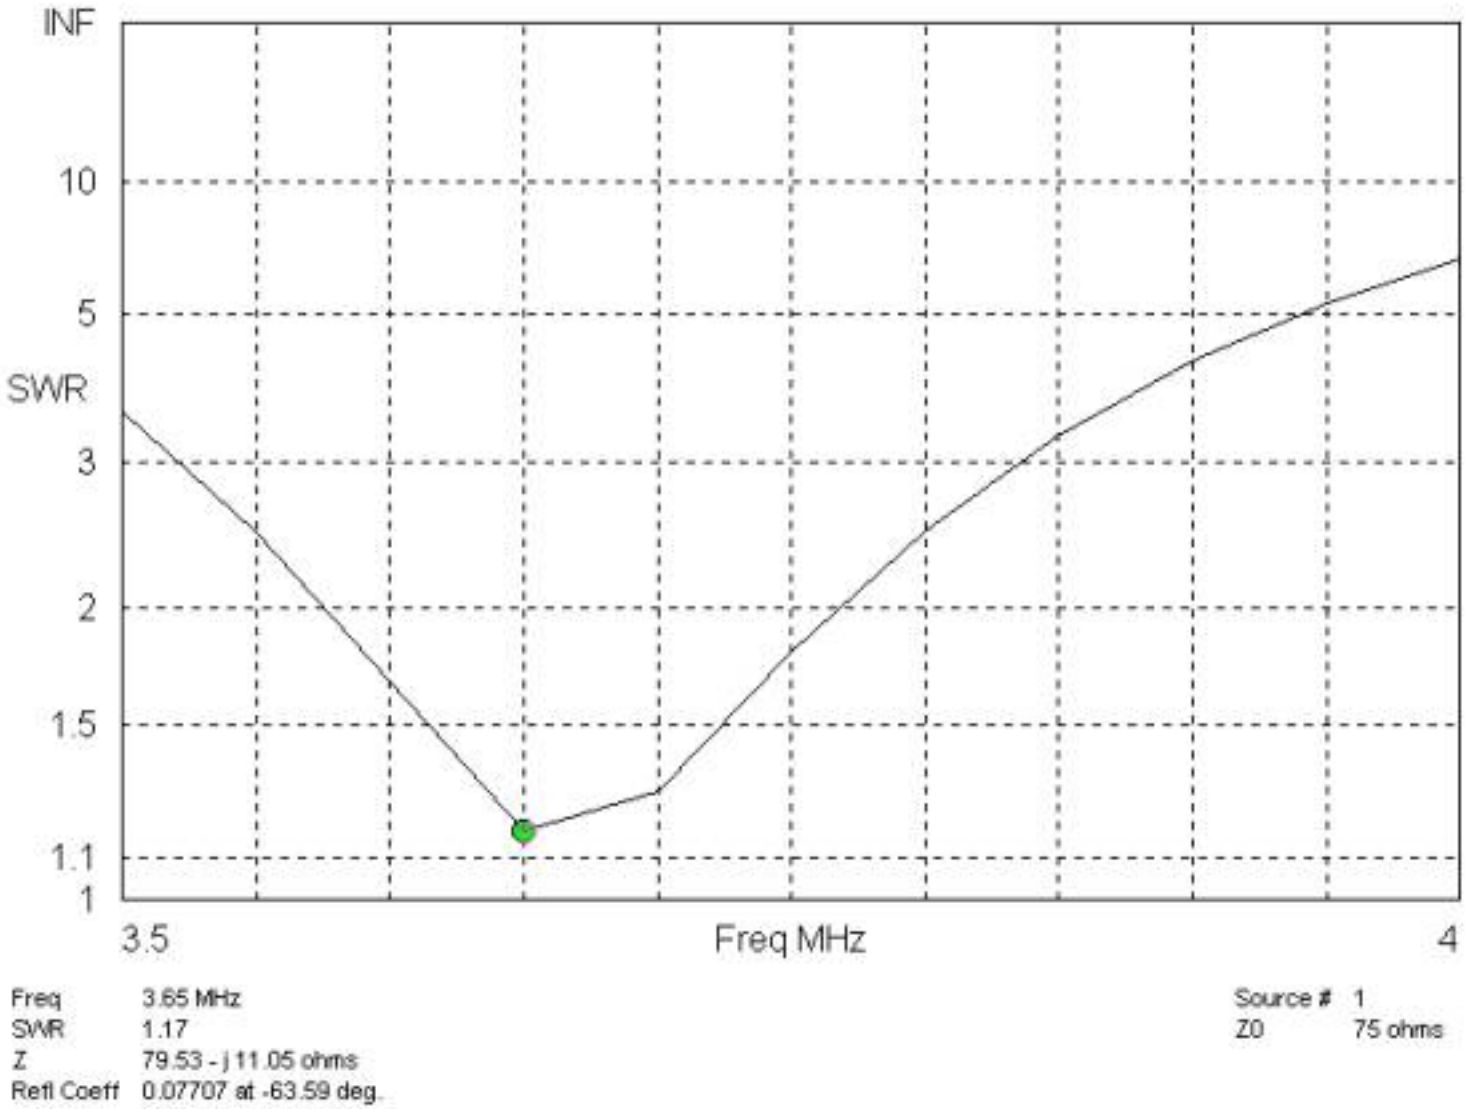


40m 2:1 VSWR ~120 kHz

Total loss = 0.24 dB

W2LH ARRL HANDBOOK TRAP 80m

VSWR

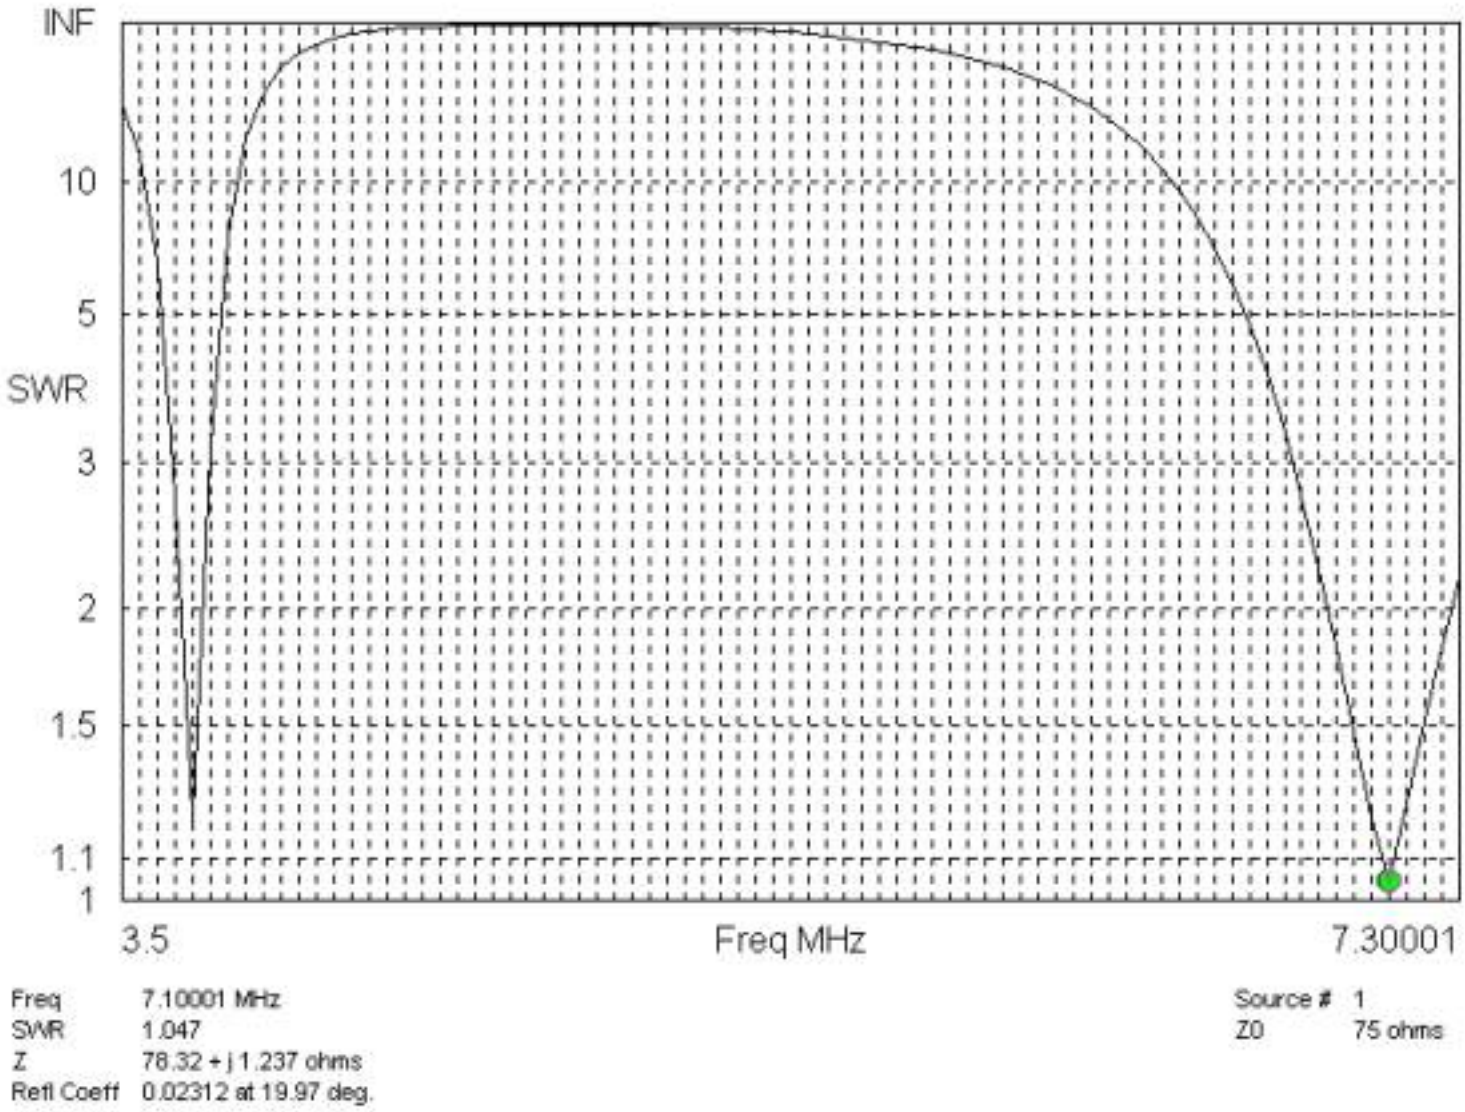


80m 2:1 VSWR BW ~ 200 kHz

Total trap loss = 0.026 dB

What happens if trap is not in band?

VSWR Bandwidth of 6.51MHz trap in 80/40 dipole



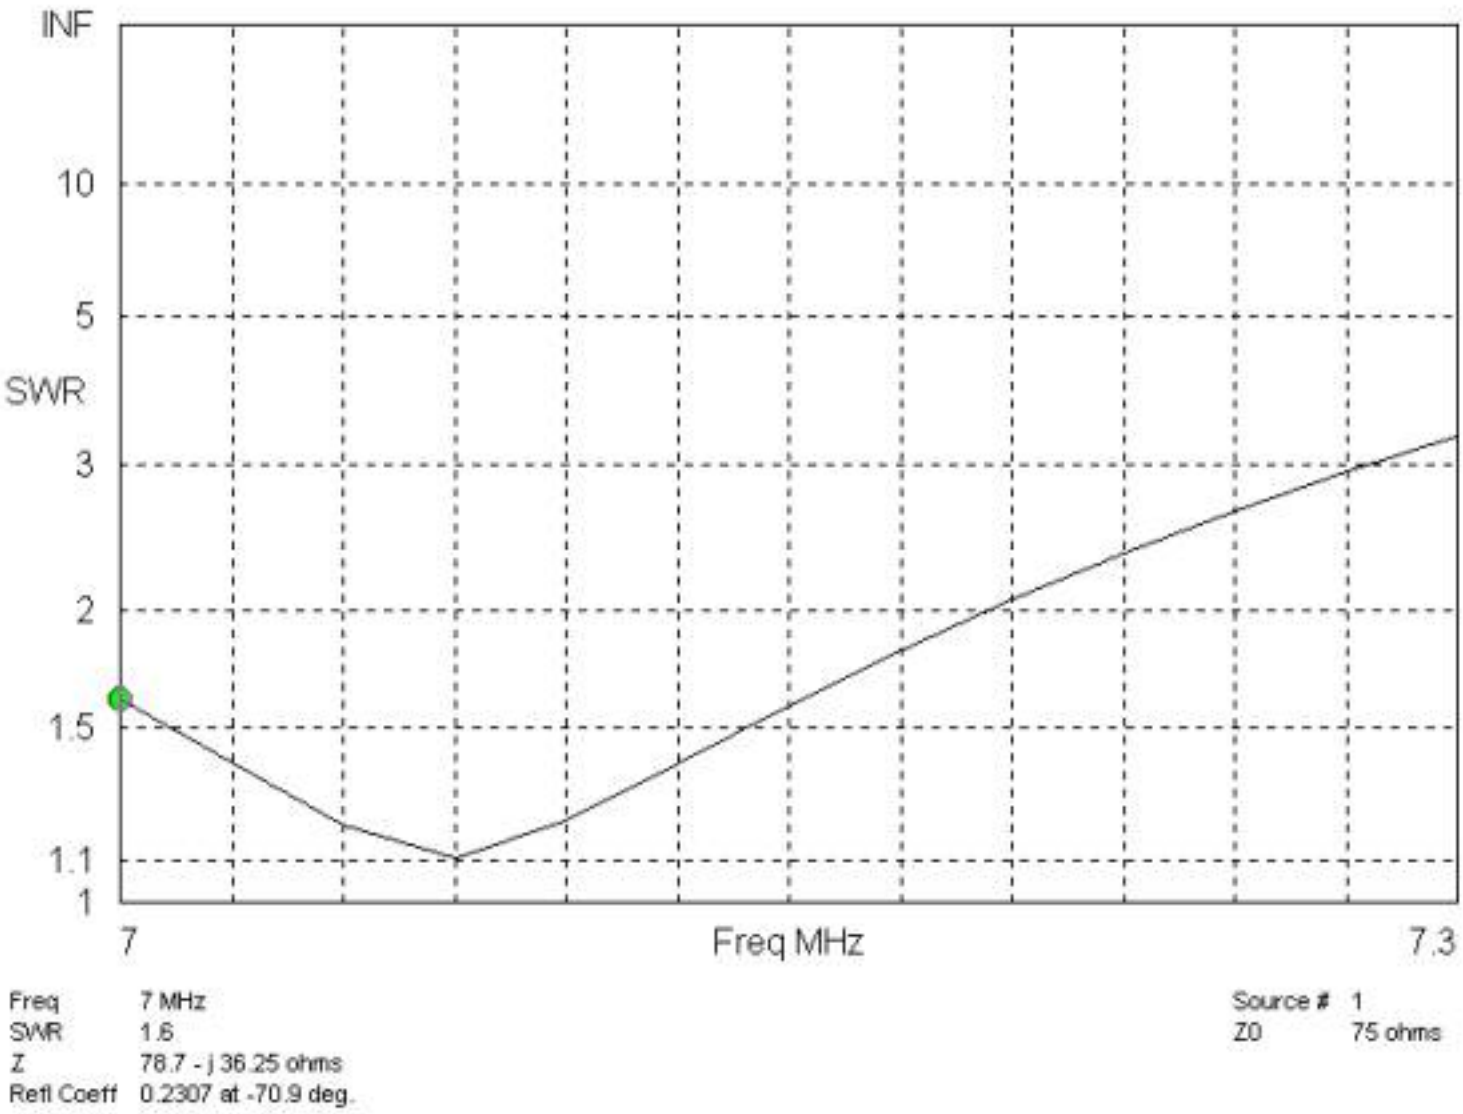
Trap at 6.51 MHz Q=130

Loss at 7.15 MHz = 0.314 dB

Loss at 3.7 MHz = 0.324 dB

This is a 104-foot long antenna, with very poor Q traps, and loss is less than .4dB! The reason loss is low is we have moved the trap slightly out-of-band.

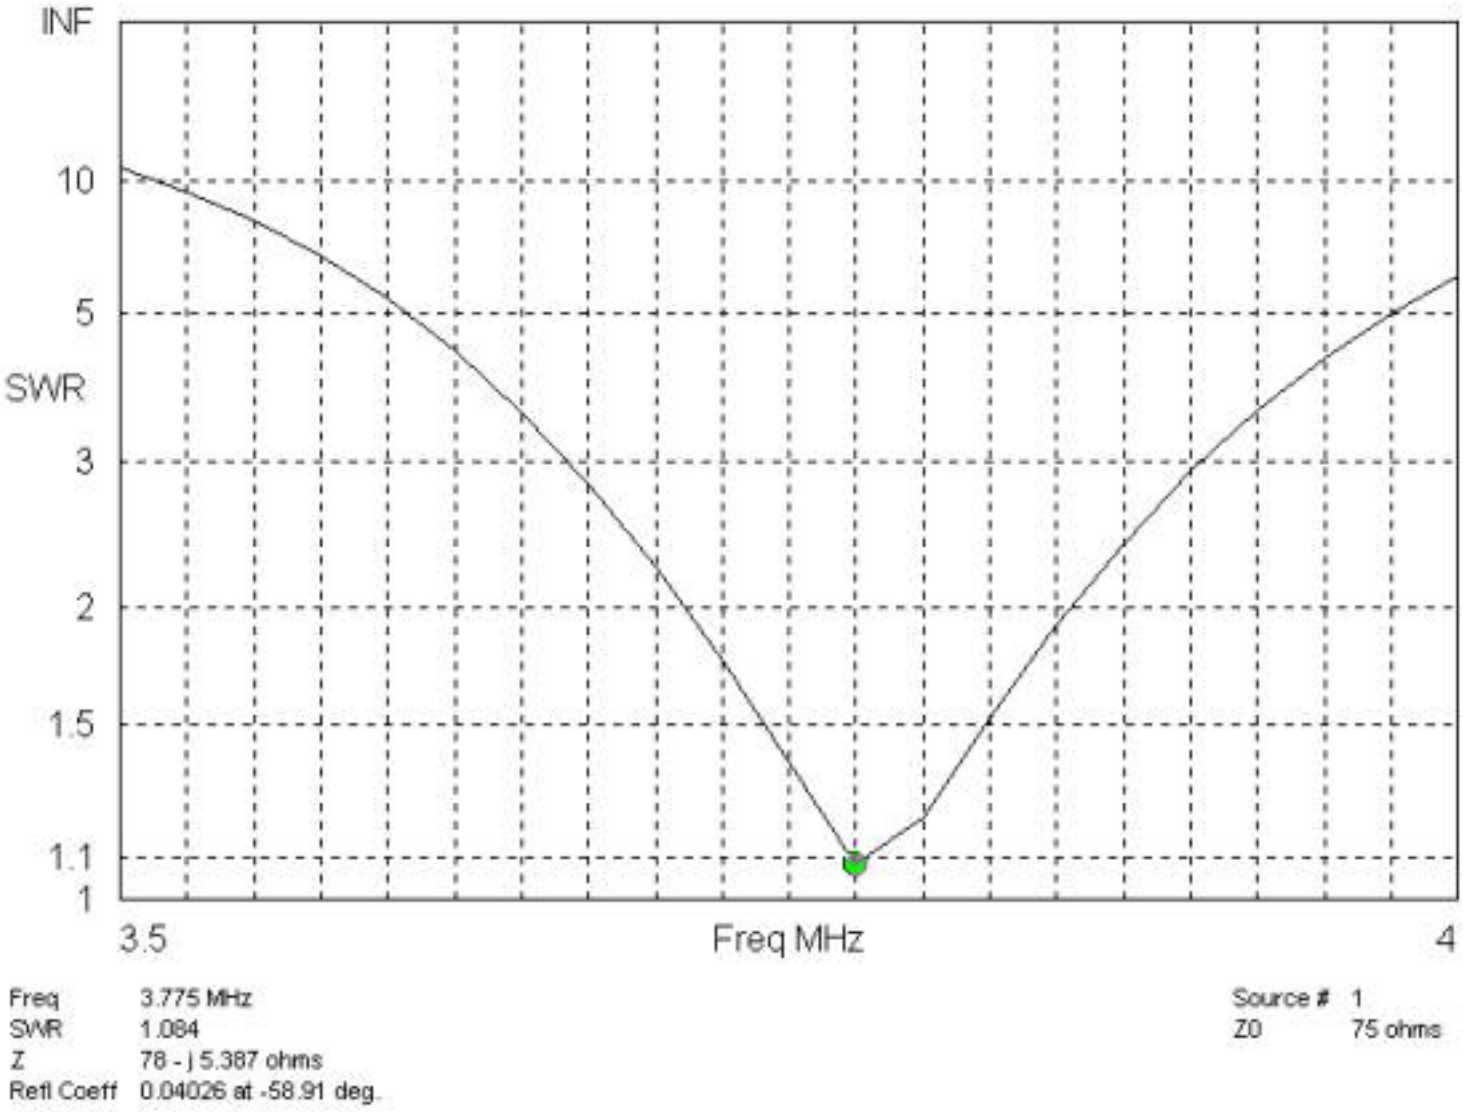
6.15 MHz Q=130 TRAP 40m VSWR



7 MHz 2:1 VSWR BANDWIDTH ~200kHz

Trap Q at resonance = 130 7 MHz loss ~ .3 dB

6.15 MHz Q=130 TRAP 80m VSWR



80M 2:1 VSWR BW ~130 kHz

Loss at 3.7 MHz = 0.324 dB

1.) Is it best to make the trap resonant close to the desired operating frequency?

NO! Loss is highest when the trap is resonant at the operating frequency!

2.) Does bandwidth decrease with increasing trap Q?

NO! Bandwidth is a function of many variables, trap Q actually has one of the smallest influences on BW.

3.) Do traps create noticeable loss, perhaps one dB per trap typically?

NO! Even the worse traps (coaxial traps) in the worse possible condition of operation are only 1.6dB loss for BOTH traps!

4.) Does higher trap operating Q always mean lower loss?

NO! Loss depends on many factors, including trap resonant frequency.

Conclusions:

- Trap loss has been greatly exaggerated by advertising hype
- Traps should not be resonant at the actual planned operating frequency
- Coaxial traps are more lossy than articles conclude
- Coaxial stubs used as capacitors can not be calculated using pF/ft unless the stub is a very small fraction of a wavelength long (less than a few electrical degrees)
- Coaxial stubs have low Q (are relatively lossy) compared to normal lumped components.

Building a Current Meter

[Home]

It takes a special meter to measure current accurately in the presence of strong electric fields, and to not disturb low-capacitance high impedance systems. The meter described below is suitable for measuring RF current accurately in high voltage applications, such as short antennas. It is also accurate in normal applications

Another current meter project link (***not*** suitable for mobile antenna measurements, however!)

http://www.ifwtech.co.uk/g3sek/clip-on/clip-on.htm

Low Capacitance, Voltage Immune, RF Current Meter

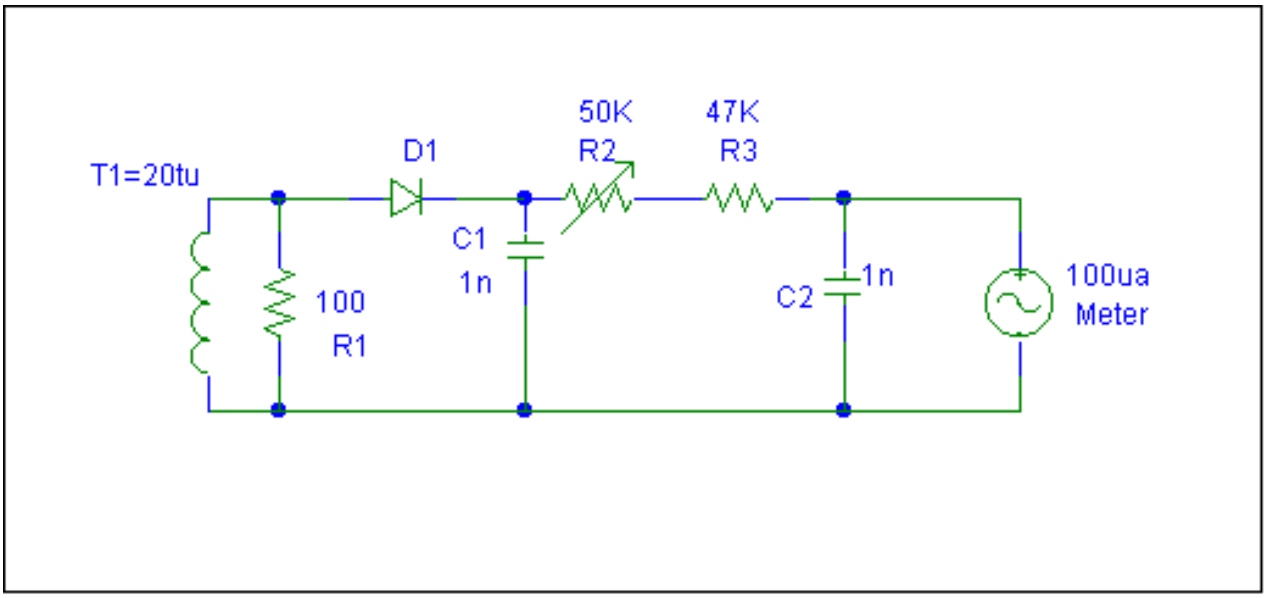
The meter is constructed with a 100uA all plastic case meter. The meter scale is plastic. The movement and all metallic areas are small. The lack of large metallic components minimizes stray capacitance added to the circuit under test by the proximity of the current meter.

Low capacitance ensures the meter has the least possible effect on the circuit being tested.

This meter has a 1.5" toroid current transformer on the rear. Just behind the meter is a calibration pot and all the circuitry. The toroid and circuitry is hot-melt glued to the meter with only the screwdriver calibration pot exposed.

I did not add a Faraday shield because the shield would increase the capacitance. Since this entire meter floats above ground, there is no need for a shield anyway, balance is not critical.

The meter has a low threshold Schottky diode detector, a series resistor for calibration, and standard .1uF bypass capacitors.



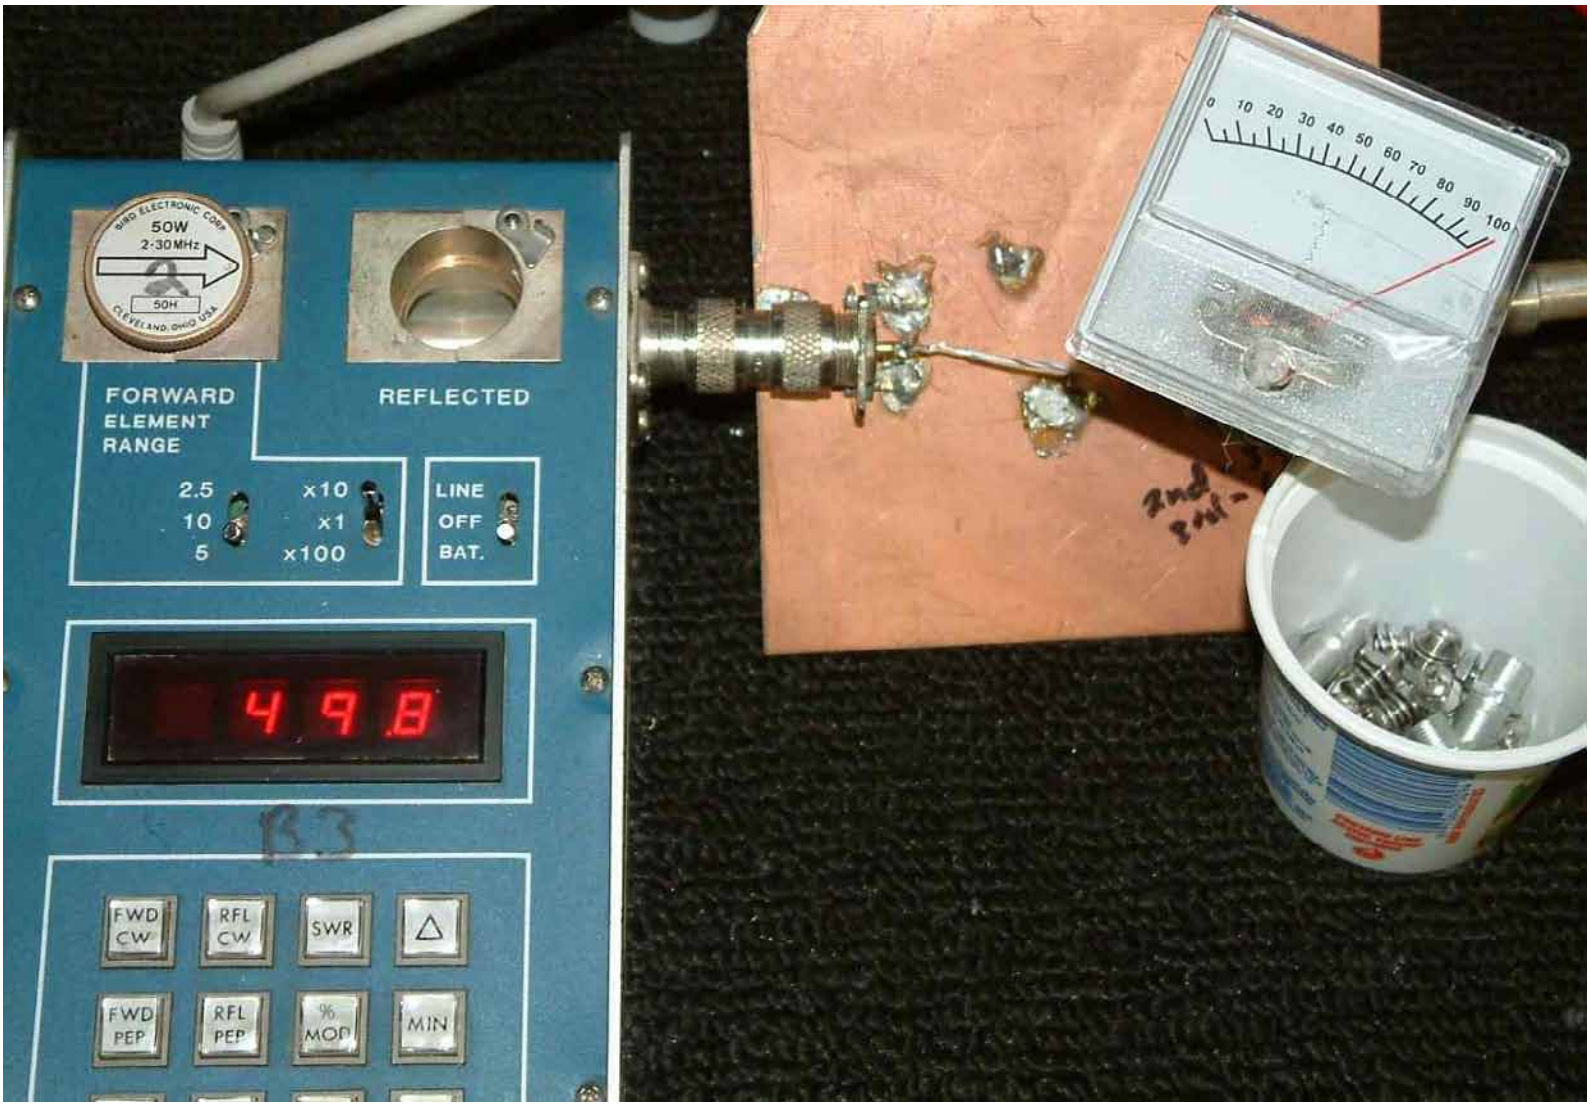
T1 is a current transformer. When the single turn primary (a whip or mast) has 1 ampere, the secondary will have

.05 amperes (inverse of the turns ratio). R1 flattens the response and limits the voltage. With 100 ohms we have .05*100=5 volts RMS. The peak dc voltage is 1.414 times 5= ~7 volts. C1 is a filter capacitor for the RF pulses, R2 and R3 set the FS range. With 100uA meter the resistance is 10,000 ohms/volt. 7 volts requires 70K ohms, which will be approximately midway on R2.

Dissipation in R1 is .25 watts from .05 amperes (T1 current) times 5-Vrms (secondary voltage of 5v with .05a flowing through 100 ohms).

Calibration

The meter is tracked in a test fixture for linearity. The actual fixture used is shown below.



The test fixture consists of two UHF female connectors soldered to a sheet of PC board. There is a single #16 Teflon wire running between the center pins.

Note the numbers "2" and "B3" on the meters. My elements and meters have calibration charts that correct for linearity errors in tracking and readings. In this case I've applied 50 watts to a precision 50 ohm load, making wire current 1-ampere.

The meter is calibrated and scale was tracked from 1 ampere down to .2 amperes.

FS accuracy is not required in comparison measurements, since the meter references against itself. Linearity within a few percent is important.

This type of meter is much more reliable and linear than thermocouple RF ammeters, and perturbs systems much less. Stray capacitance added to the system being tested is very small, because only the proximity of the meter and the compact wiring area. Contrast that to actually connecting a meter in the line with the associated lead lengths and capacitance of the meter itself, and the advantages of a transformer coupled meter become apparent.

RRAA_post

[Home]

I really begrudge the necessity of posting once more on this newsgroup, and particularly on this thread. However, I'm dismayed and disgusted by postings being made by Yuri and Cecil in other forums in which they're claiming that measurements I made agree with theories and predictions they allegedly made, and that my measurements therefore validate their theories. (A quick scan of this thread shows that they even made the false claims here, after I had quit posting.)

One of the postings is the following, made by Yuri on the eHam TowerTalk group, Nov. 21, topic "Trap Resonance":

"Why don't you mention what W5DXP came up as explanation for Tom's errors, why don't you mention what W7EL measured and that it was what I predicted based on available information and was right on - the 5% difference for the base loading coil?"

and this one, posted by Yuri on the EHam.net forum topic "Re: Current in Antenna Loading Coils" on Jan. 7:

"I will leave it here, as the rest of it. W7EL, author of EZNEC measured toroid coil and found that it HAS different current at its ends, roughly proportional to the part of antenna that it replaces."

and this one, posted by Cecil on that same group on Jan. 12:

"Roy's data clearly illustrates the phase shift through the coil. ARCCOS(Iout/Iin) gives an estimate of the phase shift (assuming forward current and reflected current are of equal magnitude). In Roy's experiment, Iout/Iin was about 0.95. ARCCOS(0.95) equals 18 degrees, an approximation for the phase shift through the coil."

As you'll see below (or by looking up the original thread), the first of my two measurements, for an antenna shortened an equivalent of about 18 degrees, resulted in 3% current attenuation across the coil (not 5%), and zero phase shift (not 18 degrees). The second test, where the

antenna was shortened more than 33 degrees, measured 5% current reduction and no phase shift. The method used in the above quote predicts more than 16% amplitude reduction and 33 degrees of phase shift for the second test. There's no way my data "clearly illustrates" Cecil's explanation. To say that it does is a pure fabrication.

I feel compelled to respond to these fabrications, and put the record straight. I'll do it here, since this is where my measurements were originally posted.

I made two sets of measurements of the current into and out of a toroidal inductor at the base of a vertical antenna. The details of the measurement method and the measurement results were posted here, on this newsgroup, on this thread. Pictures of the setup were posted on my web site, with a link posted here.

Before I posted each set of measurements, I asked for predictions of the results, so that alternate theories could be tested. (I was criticized for doing this -- it seems that the preferred method of testing a theory is to look at the results first, then adjust the theory to fit.) Yuri made a prediction (actually, two different ones) for the first set of measurements that didn't accurately predict the results. When I calculated the predicted result for the second set of measurements using the same method he had used for the first prediction, he retracted any claim that the method would be valid. (Exact quotes are below.) He didn't make any prediction at all for the second set of measurements.

Cecil made a number of vague predictions which he later contradicted or retracted. At the time the second set of measurements were posted, he had made no prediction at all.

Perhaps Yuri and Cecil have, after the measurements were posted, developed theories to explain the results. As of the time the measurements were posted, they hadn't. I highly recommend that anyone considering their alternative theories to find where they have calculated the results which agree with my measurements (particularly the second one, which was designed to produce a testable difference), and how they derived the equations used for the calculation.

Following is a summary of some of the exchanges between Yuri and me on this thread last November. The entire thread, "Re: Current in antenna loading coils controversy" and variants, is available for viewing at groups.google.com.

------ Summary ------

Here's what really happened. The following quotes are directly from the google archives of the rraa thread.

I made two sets of measurements. The first had the inductor connected at the base of a 33 foot vertical. But the vertical was mounted about 1/4" from a four foot pipe, which reduced the base reactance.

Here, I was asking for predictions for my FIRST measurement -- the one with the vertical mounted on the pipe.

Yuri posted on Nov. 9:

"In that case,
If the feedpoint current was at 0 deg of the radiator length, and coil replaces 18 deg of wire, the cos 18 deg = 0.951 which should make difference, drop in the coil current 5% (or half, 2.5 deg?)
Providing current maximum is exactly at the bottom end of the coil."

and later on Nov. 9:

">Incidentally, I take it that your prediction for the setup I did measure
>includes an 18 degree phase shift of current from input to output of the
>inductor?
>
>Roy Lewallen, W7EL
>

Yes, I used Cecil estimate/calculation and taking
cos 18 = 0.951056516 which is 4.8943483%"

So now we have his prediction, using the "cosine rule". The measurement I made showed about 3% current reduction from input to output, but with about 2% (the same amount within measurement error) also occurring when the antenna was replaced by a series resistor and capacitor -- that is, no antenna at all. So the 5% prediction was wrong. His prediction of 18 degrees phase shift, which wasn't present, was also wrong. When asked for the justification for the "cosine rule", he never offered any, so its origin remains obscure.

However, I saw that the value was too small to be convincing, which is why I devised the second test. The second test used a more ideal antenna, with more of the antenna being "replaced" by the inductor. The "cosine rule" would predict more than 16% reduction, and more than 33

degrees of phase shift.

Before I gave the results from the second measurement, I posted the predictions which had been made, as I understood them. Since Yuri had invoked the "cosine rule" for the first test, I naturally assumed it would also apply to the second. (This is simply applying the equation Yuri used in his Nov. 9 posting to the second antenna setup. It's also the equation now being used by Cecil, as shown in his quote from the eHam group.) So in my posting I said:

(Quote from my posting on Nov. 11):

"**Yuri's method predicts a reduction of output current magnitude of 16.5% and a phase shift of 33 degrees."

to which Yuri responded, also on Nov. 11:

"It is not my theory. My argument with W8JI and his followers: is the current in typical loading coil in quarter wave radiator same at both ends or does it drop with distance from the feedpoint. I have made temperature observations, W9UCW measured the difference, W5DXP provided some explanation. Based on Cecils analysis of data you provided, and on my understanding of the phenomena I guestimated drop in current in your setup. No theory, no mathematical procedure (yet) just attempt (using degrees replaced by coil in a radiator) at explanation of what is happening. I will measure things myself, try to verify previous measurements and then come up with conclusions and "theory". So far Cecils (and ON4UN book) theory seems to be closest to the truth. . . "

So now, Yuri has disclaimed the "cosine rule". /He made no other prediction of the results of the second test./

In summary, Yuri first stated that the "cosine rule" can be used to calculate the current drop. That would have predicted over 16% current reduction in the second test. Then he retracted his claim that that theory would work, before the results from the second test were posted, and never made any other prediction. He never predicted the 5% result which was measured, as he's now claiming.

And if you can find a numerical prediction anywhere in the thread which Cecil made and stayed with, my hat's off to you. $100 goes to the first person who can point to any prediction made by either Yuri or Cecil before the second measurement results were posted that predicted second measurement results of 5% magnitude and zero phase shift. (In the case

of Cecil, this would have to be a prediction that wasn't later modified or retracted before the second set of results were posted.)

My measurement results are consistent with the fact that the currents into and out of a physically small inductor are equal. The small magnitude difference I measured can be explained by stray capacitance on the order of 7 pF from the output to ground and/or the probe -- not an unreasonable amount to expect. In no way do my measurements support the odd theories being proposed by Cecil and Yuri, and any statement that they do is completely false.

Roy Lewallen, W7EL

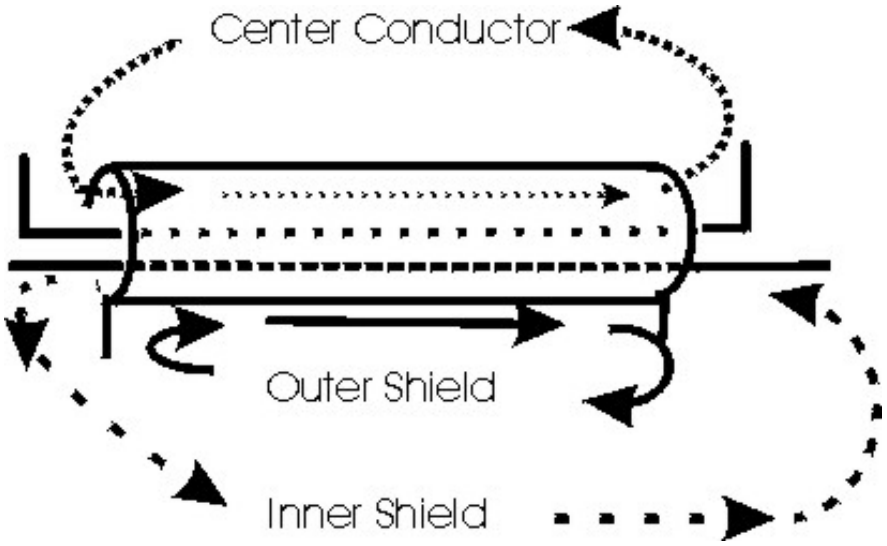
Coaxial line and shielded wires

[Home]

related pages at antennas

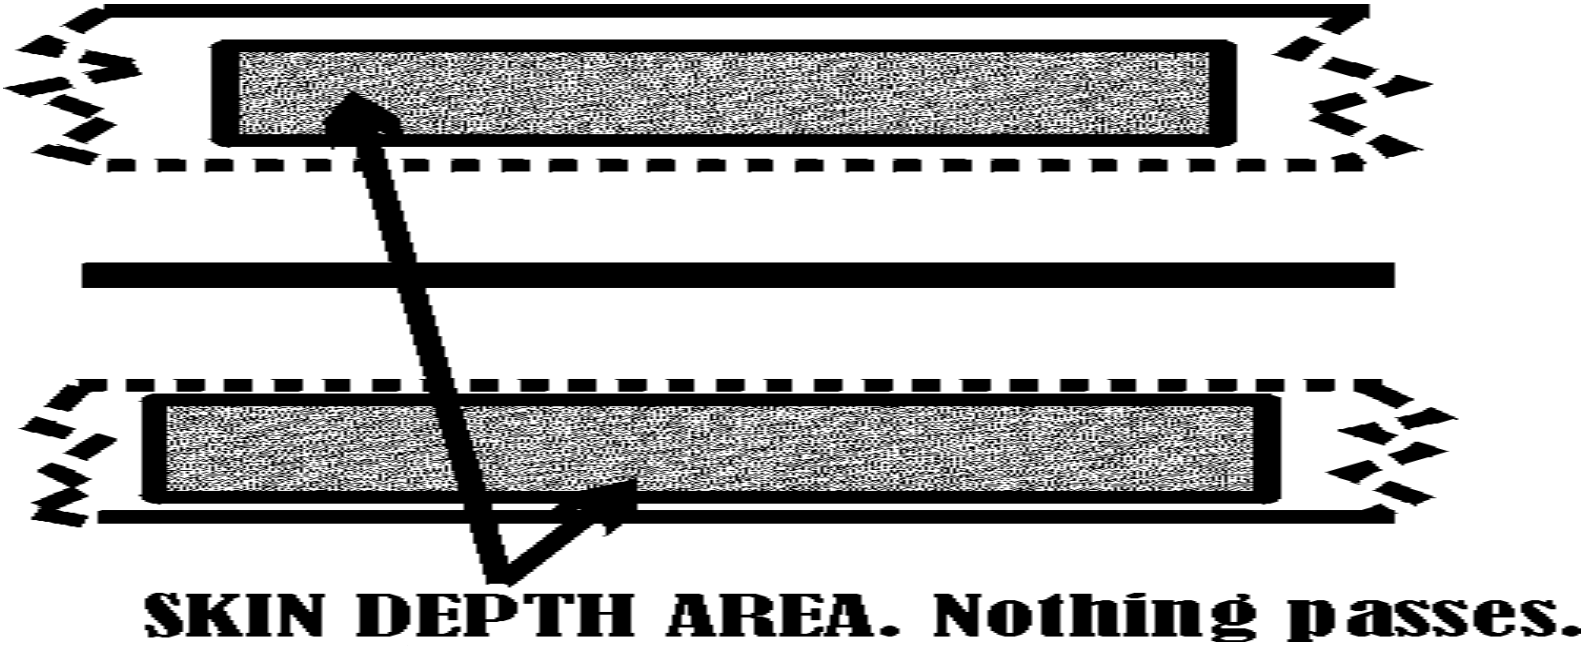
Concentric Transmission Lines (Coaxial Cable)

When the shield is more than several skin depths thick coaxial cables, single-wire shielded cables, or concentric lines become the electrical equivalent of three wire concentric transmission lines. Electrical rules require the center conductor and ***inside*** of the shield to always carry equal and opposite RF currents.



Notice in the drawing above the center and inside of the shield carry equal and opposite direction RF currents. This ALWAYS is the case when the shield is several skin depths thick. We cannot force anything else to happen!

In the drawing above and below, the outside of the shield is isolated by skin effect. It behaves like a separate transmission outer conductor. Skin effect prevents any current, voltage, or field (even magnetic) from penetrating the shield when the shield is many skin depths thick. Only the breaks at the ends connect the inner and outer shield conduction layers.



The only egress or ingress points for voltage and current are where discontinuity in the shield might occur through an intentional or accidental break in the shield.

Radiation In or Out of Shielded Lines

To operate without radiation, coaxial cables require equal and opposite currents in the shield and the center conductor. The outside of the shield must not have an RF potential difference along it's length. We cannot have voltage gradients (electrical fields) along the length, or the outer conductor layer will conduct currents. This means both ends of the cable should have zero volts to earth or the environment the cable operates in.

If we feed exactly equal and opposite current into the coax, currents have no choice but to flow ***INSIDE*** the cable shield! The outermost conductor can be treated as a single wire, since everything else is "hidden inside". There will be no "extra" current to flow over the outside of the shield. Because of this rule, we do not need to ground the shield to prevent radiation. The trick here is we need to have equal and opposite currents. When the shield has potential difference along the length we can greatly reduce outside currents by making the outside of the coax have a high impedance. We can do this by selecting a proper cable length, by adding sleeves of soft-iron magnetic materials or winding the cable in a coil with or without a core to form a choke. ***Skin depth prevents the inside of the cable from "seeing" what is done on the outside.***

Most interesting in all of this is the claim or idea the "shield" of a shielded loop allows magnetic fields to pass while filtering electric fields. The same rules apply as with coaxial lines. The shield actually becomes the antenna, and it couples to the inside only at shield gaps. If the gaps aren't exactly opposite the grounded part of the loop and inner conductors don't exit exactly at that grounded point, the shield actually UNbalances the loop!

Magnetic Loop Antennas Receiving

[Home] [Up]

(Please read the Radiation and Fields page)

Small Receiving Loops

Small loops are often referred to as "magnetic radiators". Folklore claims a small "shielded" loop antenna behaves like a sieve, sorting "good magnetic signals" from "bad electrical noise".

Nothing is further from the truth! At relatively small distances a small magnetic loop is more sensitive to electric fields than a small electric field probe.

The ratio of electric to magnetic field sensitivity is sometimes called the "field impedance". An antenna with ***high field impedance*** has a dominant electric field while an antenna with ***low field impedance*** has a dominant magnetic field when compared to free space field ratios at a large distance from the antenna.

Although fields have different ratios close to the antenna, at distances of ***about λ/2 the field impedances of all but very large antennas are virtually indistinguishable from each other***. Once we understand the basics, we might picture our antennas differently. We might find antennas don't respond to signals and noise like we thought, but at least we won't be as susceptible to the "noise" caused by rumors and folklore!

Loop Antenna Fields

It is the response in within λ/10 distance from the antenna that gives small "magnetic loop" and "electric dipole" antennas their names.

Very close to a small loop antenna (but not necessarily near the open ends of the small loop where the tuning capacitor is) the magnetic field dominates. Current is essentially uniform all around the loop circumference, while voltage has a nearly straight-line increase as we move to the tuning capacitor area. Since most of the area has uniform current and only a small concentrated area has the highest voltages, the magnetic field clearly dominates over most of the loop area.

Magnetic fields are effects derived from the actual moving of charges (current flow). The magnetic effect is related to current, and if it is proportionally large compared to voltage the field is described as having a "***low***" impedance. This is similar to the description used in circuits, where a system with high current and low voltage

is said to have "low impedance".

Small Dipole Fields

Near a small dipole or monopole the electric field dominates. A short antenna has to have very high voltages all along it's length. It normally has highest current only near the feedpoint, with current tapering down in a straight line to zero at the antennas open end. The dominant effect we deal with is from the very high voltages that appear all along the antenna. We say the antenna has a "***high field impedance"***.

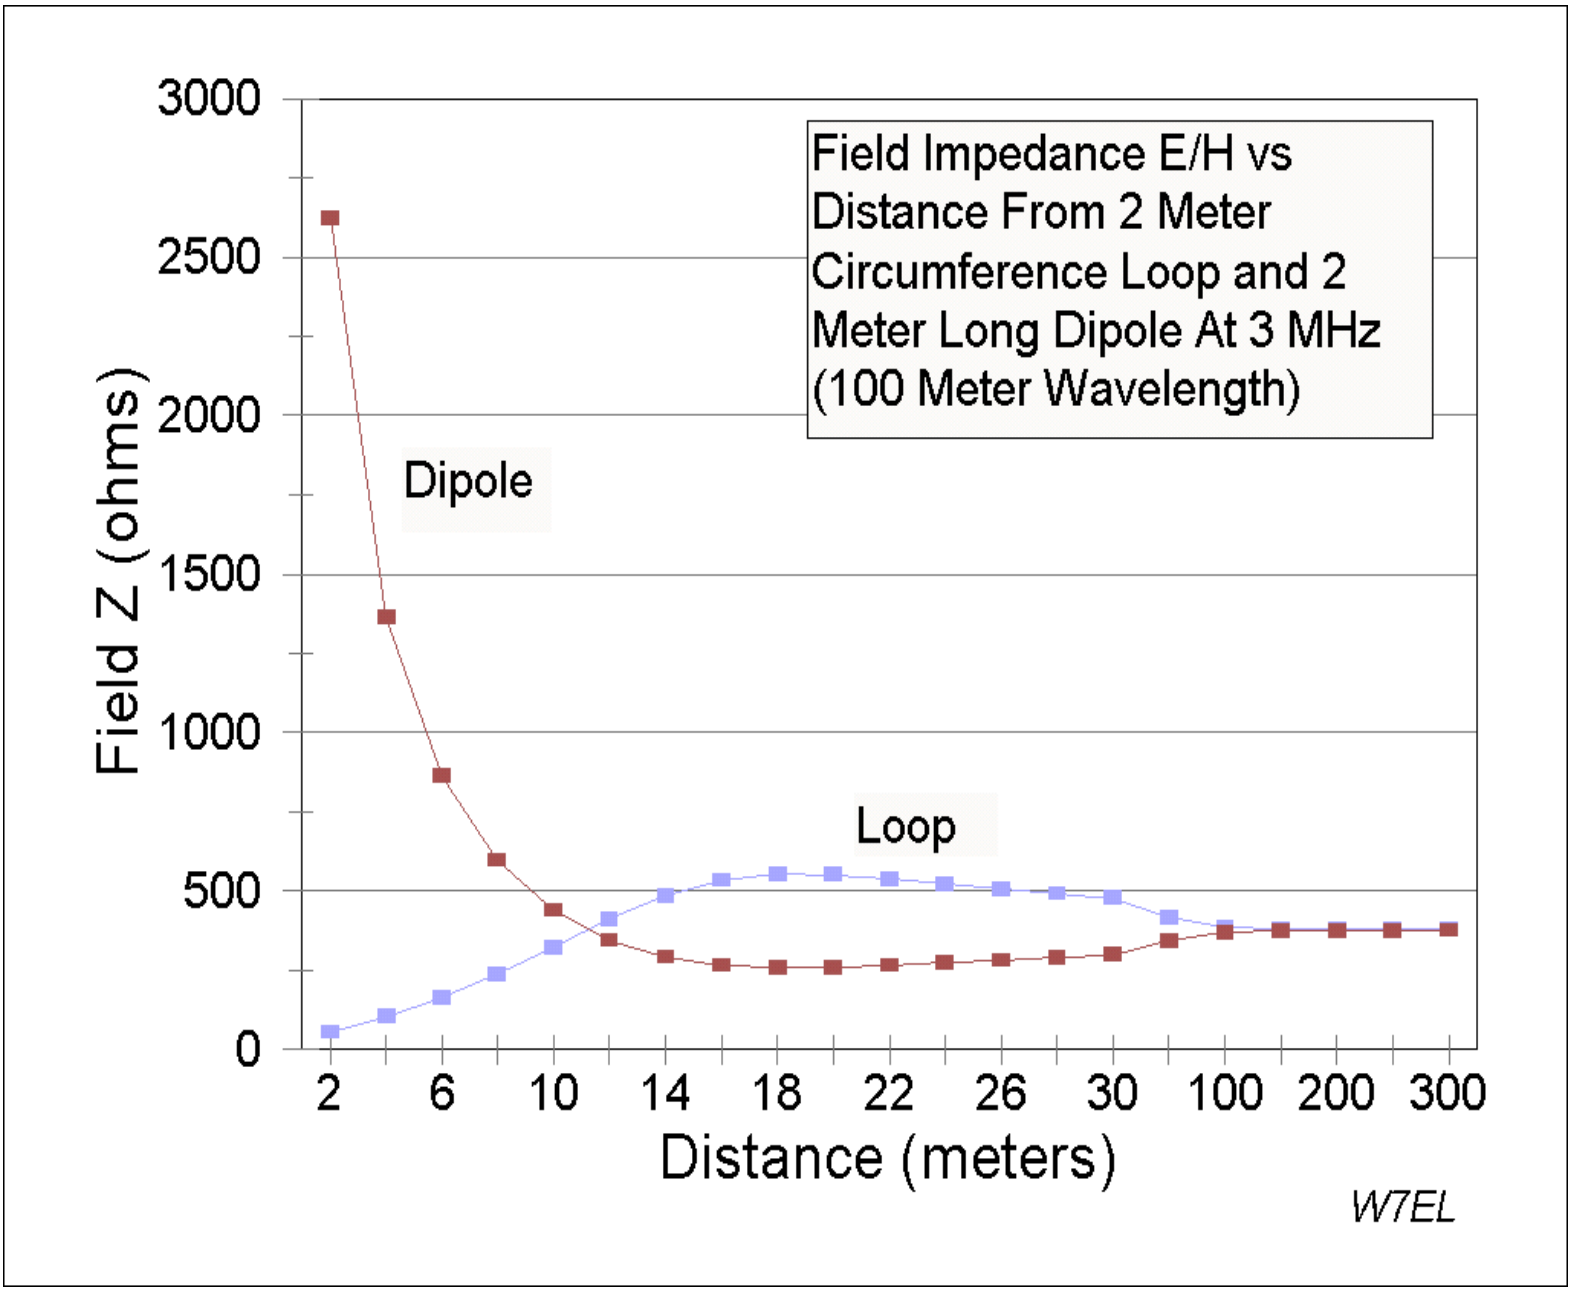
In the electrically small antennas described above, the dominant field descriptions only apply within λ/10 distance!

Radiation

The induction fields described above are NOT what radiates or receives at a distance. The induction effects are a necessary byproduct of:

1. Uneven charge distribution (a difference in voltage) causing a physical force on other charges. We call this effect an **electric field.**
2. Moving charges (a current) causing a force on other charges. We call this effect a **magnetic field.**

Accelerating charges causing a force on other charges. We call this effect **electromagnetic radiation. It is a totally different effect independent of the induction fields. This is the only effect that works at a distance.**



Since the distance of a wavelength in the above graph is 100 meters, we can considered the bottom scale as the percentage of a wavelength. We can see at about 11 percent of a wavelength (which would be about 50 feet on 160 meters), there is no difference in field impedance between a small loop and a small dipole. At distances beyond 50 meters on 160 meters, the magnetic loop actually has a ***higher*** field impedance than a dipole.

So much for the myth that a receiving antenna can sort good signals from bad signals (noise) by virtue of being "magnetic"! We not only don't have the response we might have imagined, we also almost certainly have no idea if close-by unwanted noise or signal sources are radiated from electric or magnetic field dominant sources. Successful noise reduction by virtue of by antenna "style" would mostly be a matter of hitting a lucky combination through careful experimentation.

Loop Shielding and Balance

Loop shields do not sort noise out, nor do they prevent electric fields from affecting the antenna. For a description of how shields work, look at the Concentric and Coaxial Transmission lines page. From that page, you will see the shield actually becomes the antenna in a "shielded" loop.

There are many construction articles about small loop antenna available. I'm not going to add one more to the group, but I can tell you what to watch for. It is *VERY* important that all conductors exit the loop at the ground point of the shield, and that the loop is grounded exactly at the electrical center of the shield. The loop must also be symmetrical, and you must mount the loop so the feedline and any metallic supports leave the center area of the loop with maximum symmetry. If you DON'T do this, the loop can actually use the feedline as the antenna. This can greatly increase sensitivity of the loop to conducted noises!

Remember the following guidelines:

- The shield is the actual antenna
- The shield must be perfectly symmetrical away from the inner wire exit point
- The gap in the shield must be exactly opposite the grounded point
- The ground must be at the inner wire exit point
- The shield will not make an unshielded loop that is properly balanced any quieter
- ***The shield only is a tool to help you balance the system IF the shield is properly implemented***

I hope this article is useful in helping you select a GOOD design!

E-H Antenna

[Home] [Up]

Background

Many antennas function because of common mode currents, rather than working in spite of them. Two popular examples are CFA and EH antennas. Another recent example, appearing in Antennex's compact antenna articles, is a thick stub "vertical" with no counterpoise.

All of these antennas become significantly poorer radiators if common-mode currents on feedlines are eliminated. Why? Because the feedline is the actual radiator, ***NOT*** *the tiny thing they call the antenna.*

Misunderstanding or misapplying Maxwell's equations and the principles behind radiation, in combination with missing some very key points of conventional circuit theory, causes problems. Some of us have unwittingly attributed increased feedpoint resistance and/or seemingly disproportionate amounts of radiation from very small structures to new methods of radiating EM waves. Reviewing these antennas and the theoretical or technical mistakes surrounding them will help us understand how antennas and transmission lines work. With that knowledge, we can build better antenna systems. The fastest and best way to learn is often to look in detail at mistakes!

What They Claim

Articles and user reports of CFA, EH, and thick stub verticals (without groundplanes) appearing in Antennex and other internet publications have one common thread, the operational descriptions almost always include strong indicators of problems with feedline common-mode current.

Authors commonly warn users to NEVER choke feedlines with baluns and to "be sure the feedline is straight and in the clear"! Authors lay blame for RF burns from feedlines or shack equipment on the antenna's "high radiation efficiency", claiming these small magical antennas radiate so efficiently they naturally excite the feedline and equipment more than full-size antennas.

For example, Ted Hart (of EH Antenna fame) claims the following at:

http://eh-antenna.com/documents/RF_on_the_Coax.pdf

"RF on the Coax

Due to the large radiation at the EH Antenna, there will be some RF coupling to the coax. Whether this is a problem is dependent on the radio you use. Some are subject to RF coupling into the audio system, which causes severe distortion while transmitting. On some field day setups with 100 watt transmitters we have had so much RF on the radio you can get an RF burn. Below we have suggested ways to eliminate the RF coupling problem."

In the above statement, Ted actually acknowledges current on the feedline shield and RF-voltage-on-chassis problems. The problem must be severe when a low-power 100-watt radio causes a burn. Like any good salesman, he turns a design shortfall into a feature! According to the author, unwanted RF on the feedline doesn't come from a feedpoint or antenna design problem like it does on other antennas, in this case it appears because the antenna works so well!

Here's what actually causes RF to appear on a coax shield and radio chassis. RF can only appear on the radio chassis through two methods:

1.) The antenna, from poor feedline or feedpoint design, can couple to the radio chassis through external wiring or cables attached to the radio.

2.) The radio chassis itself, being large in terms of the wavelength, can actually become an antenna and receive energy from actual desired "over the air" signals.

(Many of us have these problems. Click on this link to see one reason why.)

In this case, we can probably rule out reason two above. It is unlikely the chassis is a large portion of a wavelength long on 20-meters and that the antenna field is suddenly so strong it is "lighting up the house" with RF. After all, if power is radiating effectively it will all be going out to distant stations and NOT cooking you or the radio gear in your house! That only leaves reason one, poor feedpoint and antenna design, as the cause of common-mode feedline or wiring currents that excite the coax shield and eventually the radio chassis, as described in method one.

Actually someone has measured this, and posted it to a web page!

http://www.home.earthlink.net/~calvinf15/_technical/

When the time-varying current from the transmitter flows in any conductor, we will have charges accelerating in the cable. The outside of a shield is no exception. A feedline's shield will radiate proportionally by the ampere-feet of the cable. just as any other conductor will. Of course the antenna element will radiate also, but there is something else to consider.

A very small current flowing unopposed over a large linear distance will radiate quite a strong signal, because radiation resistance of a long antenna is generally very high compared to very short antennas. You can find this explained in the Radiation&Fields and Radiation Resistance articles on this site, and in engineering textbooks such as those written by Jasik, Kraus, and Jordan-Balmain. From all of this, we know the shield radiates.

The inventor of the E-H antenna goes on to say:

"If you use RF beads, since the coax shield is not a magnetic shield, the beads affect both the inner and outer conductors. Therefore, most of the transmitter power will be converted to heat. Not good."

Not a very knowledgeable statement at all, at least from the standpoint of how shields work!

Time-varying fields can not pass through a shield that is more than several skin depths thick. The inner part of the shield and outer part are isolated by the skin effect, and nothing passes through. The ARRL Handbook, Maxwell's book "Reflections", Reference Data for Radio Engineers, and dozens of other amateur radio and engineering texts describe this effect correctly. If we bring a time-varying electric field to zero in a system, the time-varying magnetic field is also by definition zero. The shield DOES isolate the center of the cable from time-varying magnetic fields on the outside of the cable!

If that is true, why then does a shielded cable passed through a current transformer used in a directional coupler appear to pass RF magnetic fields? Why does the RF magnetic field seem to "pass through" the shield of a shielded receiving loop antenna? The answer is quite simple. There is a gap or intentional break in the shield.

Current on the inside of the shield "spills over" the edge of the shield where the shield is broken, and causes a current on the outside of the shield. There is also a voltage across the gap at each end of the shield. We have both our time-varying voltage and current, via a circuitous path to the shield ends! Our Amateur texts explain that effect, as do all of the engineering texts dealing with shields on transmission lines. If the gap is closed and the shield's ends are shorted together, making voltage across the shield gap zero, the magnetic field no longer "seems to" penetrate the shield!

If a shield did not behave this way, we'd be in serious trouble in the radio world. Without the shield stopping both magnetic and electric time-varying fields, we could not shield our radios. We also could not shield our microwave ovens, with non-magnetic materials!

If anyone thinks a ferrite core affects the impedance inside a coaxial cable that does NOT have significant common mode current, they only need to slip some beads over a cable on a working normal "cold-for-RF" feedline. You will find absolutely no difference in system performance when

beads are added, proving Ted does not "have it right" in the text above that appeared on the E-H antenna web site.

The author and inventor of the E-H goes on to say:

"Use of a small choke made of several turns of the coax is good. We find that a wire connected to the ground side of the coax at the antenna and connected to either a ground rod or a wire laying on the ground will eliminate RF problems - in most cases. For some radios we also need to add a ground wire to the radio."

Of course adding a ground wire might help! The ground wire becomes the path for common-mode currents, or at least a portion of them. The additional wire to ground becomes part of a long-wire antenna (made by the cable shield) that actually does most of the radiating!

"A preferred method is to run the coax to ground then back to the radio. Near ground, connect the shield of the coax to a ground rod or radial. Another method is to connect a wire from the radio to ground. If the radio is very far from ground you will need to add a series resonant circuit in the ground wire to effectively cancel the inductive reactance."

It is understandable why this is a preferred method! The outside of the coax shield can remain the primary antenna, saving us the bother of installing the additional ground wire that becomes the antenna in the previous suggestion!

"It may take one or more of the above to solve your problem. Remember that if you have a good ground on the antenna, you have also minimized problems with lightning."

In the above text, we can see every solution carefully avoids installing an effective choke balun on the feedline. A properly designed and effective choke balun has no effect on a coaxial feeder or system SWR, unless the feedline is radiating!

Let's look at another E-H antenna experimenter and former proponent of the E-H antennas test of a 160-meter E-H antenna. You can read the text directly at:

http://www.qsl.net/iz7ath/web/02_brew/18_eh/english/pag11_eng.htm

Steve writes:

"With my short (and easy) tests I deduce the EH lose about 10 dB versus my short 10 mt vertical with capacitive hat in the top;
10 db is a big amount of power, but remember we are using 2 small cylinder of 37,5 cm on 160 mt band; my vertical performed better than a 40 mt long sloper, so, may be, loss versus full size dipole is not too much."

Steve claims the E-H antenna looses about 10dB compared to a 1/4wl sloper, which has an unpredictable efficiency. A typical sloper 1/4wl sloper is likely only around 50% efficient in the best situations, and more likely much worse! The actual range can be from 10 to nearly 100% efficiency. Steve's data repudiates Ted's claim and the CFA inventors claim that "crossed-field" antennas provide high efficiency.

"There seems to be something good;
May be optimizing something we can have more gain (or, better, we can lose less dB);
This antenna can be useful on the low band, expecially on 137 KHz (the EH cylinder should be 6 mt high with a 2mt diameter).
On the web I've seen an other similar antenna (ISOTRON), wich seems caming (as EH Antenna) from CFA antennas;
On the italian Radio Rivista (1995-1996) there were same informations about an "Antenna Toroidale" wich in same way remember the EH: will be interesting build and test one."

Steve seems to be saying something we all agree with. A short antenna will radiate, but not nearly as well as a full-size antenna.

"By the way, I think that my EH is not for Dxing; it will be useful for that radioamateur who have no possibility to install "long" antennas for low band, but want just to have local QSO or few contest-contact."

I agree! 10-20dB loss from a full size antenna would not make a good DX antenna! Now here come the current-on-the-feedline problems:

"Other point: tuning;
I think it's not as simple as others say; I've used an MFJ259B which tells me all about the antenna, but the tuning was critical. On the other side construction is easy;
I want suggest to you , when tuning, to connect the MFJ259B to the shack ground (if there's one). If not, EH will probably resonate higher (20-30 KHz)."

If grounding and ungrounding an antenna analyzer or any other piece of equipment connected to a coaxial cable causes resonant frequency or SWR of an antenna to change, the system has severe feedline radiation problems. See my article on testing baluns.

"Coaxial cable influence: inserting more coax cable, the resonance seems to vary a little; I suppose that's normal;

I don't know for certain if the line radiates or not; I've added two iron-powder coil forms back my TX and EH performance was unchanged. Then later I've added 2 big ferrite beads with a lot of turns on the roof (at the feed point of the EH) and all has changed. My signal was 3 S point weaker than before and S.W.R was very high.
I don't know if that loss is due to the changed resonance in EH (as I said before, outside the bandwidth performance goes down quickly)."

We see again that any attempt at reducing feedline radiation results in an antenna that does not radiate very well. With the feedline choked, Steve's EH antenna dropped 3 S-units in addition to the original 10dB from his sloper, or maybe 25dB or more!

There surely is a hidden message in all of the above contradictions!

How the E-H Antenna *Really* Works

There are many examples where designers intentionally use common-mode currents. Examples are found in textbooks, such as the "Antenna Engineering Handbook" by Jasik on and around page 22-6.

The antennas at the right, copied from Jasik's textbook, outline the derivation of a skirt collinear antenna from a simple feedline with the open end terminated into a conductor. (It could be a ground

Two or even three skirts may be added to the mast as shown in Fig. 22-5c, but reduced excitation of the lower sections diminishes the effectiveness of each additic skirt.[6] Thus, while the multiple-skirt coaxial antenna resembles a collinear arra in-phase half-wave elements, its gain is not as great. Typical gain values are ta lated in Table 22-2, but since no test data are available for this type of antenna, values given are merely engineering estimates.

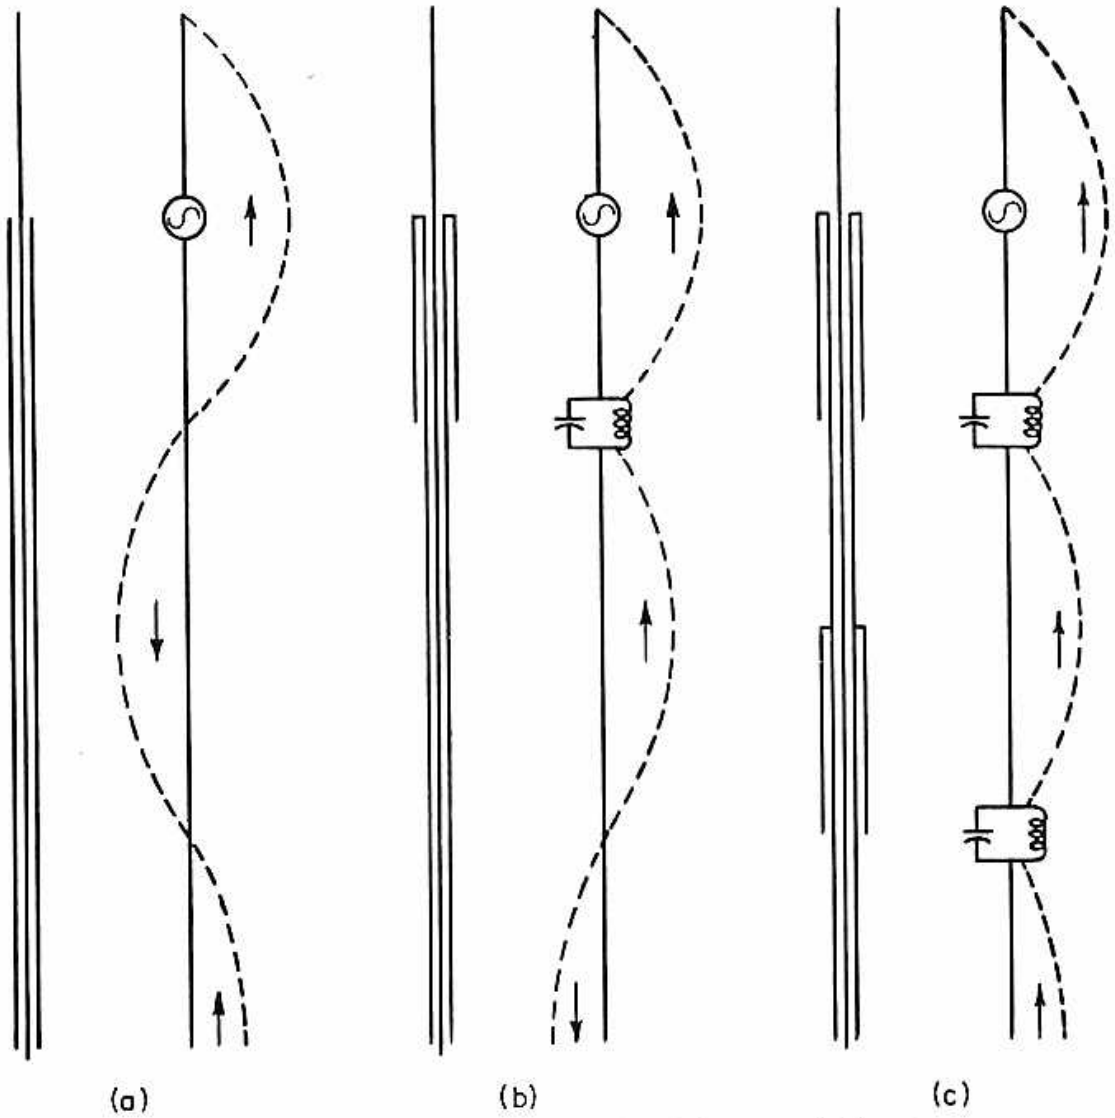


FIG. 22-5. Evolution of multiple-skirt coaxial antenna.

The relatively large diameter-to-length ratio of a practical skirt produces an effect which requires that the exterior length of the skirt be reduced by a factor of 0.8 to 0.9 and the interior length by from 0.95 to 0.98.[6] This is accomplishe cutting the skirt to the proper exterior length and inserting a dielectric slug ir skirt to increase its electrical length.

rod or an antenna, like a Beverage or large loop, the antenna does not have to be an "open circuit".

Looking at (a), we find by hanging any conductor from the end of a coaxial cable the shield is excited (on the outside) with common-mode current. The electrical equivalent of the OUTSIDE of the shield is just as if a generator located at the end of the shield was driving the outside of the shield as longwire antenna. This goes along with Kirchoff's Laws, that tell us the sum of currents entering a point must equal the sum of currents leaving that point. For any current to flow up into the antenna, and equal current must flow back down over the outside of the shield.

With one ampere flowing up the center conductor into the "stinger" at the coax's end-point, the same level of current flows back over the outside of the shield. (The shield's inside and outside are isolated by the skin-depth of the current at the operating frequency, an can be treated as two independent conductors that are connected over the open edge of the shield.) We *MUST* have this current simply because this is how coaxial cables work, the current on the inside of the shield is *ALWAYS* equal and opposite to current in the center conductor. There has to be some place for that shield current to flow, so it makes the bend over the end of the cable and flows back down the outside.

This is also why, when we use a cable's shield as a ground lead the center conductor and inside of the shield do nothing to reduce resistance. Any current that flows down the center conductor is cancelled by current flowing on the inner wall of the shield, the result is no current at all flows down the center conductor as long as the shield is several skin depths thick.

Many antennas intentionally and unintentionally use this principle, two examples are shown in (b) and (c).

A recent Antennex Article on a "magical" ultra-compact antennas claims an identical system, using a loaded fat cylinder, has an extremely high radiation resistance and excellent performance because some magical field-trickery increases the radiation resistance of a thick cylinder at the antenna end. Certainly radiation resistance is somewhat high...but not for the reason something magical or special is happening!

The small coil-loaded cylinder is actually only a fraction of the antenna length, and being so short has a very small radiation resistance. The point missed is the shield of the cable is very long, and is in series with that short section. Since the shield is long, it also has a reasonably high impedance both from radiation resistance and loss resistances. Shortening the length of the end-stub results in an insignificant reduction in radiation resistance, because the overall length of the radiating system is very long! We have a simple off-center fed dipole, with one very long leg and one very short leg!

The main radiator is the outside of the feedline shield, not the tiny thing being called an antenna!

Unless we make the coaxial shield an infinite length or pass it through what amounts to an infinite groundplane with zero resistance, current continues on down the cable shield. Looking at (c), we find even multiple sleeves appearing as parallel tuned high-impedance circuits do not fully decouple the

shield. Many collinear antennas work on this principle, yet E-H antennas and others attribute it to some form of electro-voodoo.

Ground resistance measurements

[Home] [Up]

160-meter Ground Connection Resistance at W8JI

Clay soil, dry conditions, 20-foot tall hat element resonant on 160 meters. All radials 50 ft long except for test radial, which is 1/4 wl electrical insulated counterpoise.

Ground	Ground Resistance Ω	Antenna Resonance MHz	System change with resonant test radial	System change adding one additional rod
Two 5’ rods	85	1.944	Large over 50%	Rod has large effect
One radial NE	80	1.905	Large	Rod has large effect
One radial SE	80	1.905	Large	Rod has large effect
One radial NW	77	1.931	Large	Rod has large effect
Four radials	42	1.819	Moderate 50%	Rod has large effect
Three radials and two rods	50	1.819	Moderate 50%	Rod has moderate effect
Four radials three rods	54	1.820	Low 25%	Rod has noticeable but small effect

Seven radials three rods	29	1.875	Very low <10%	Rod makes very little difference
Eight radials three rods	27	1.880	Very low	Rod makes very little difference

Performance Indications of Test

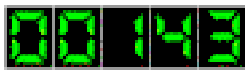
Ground systems are reactive. Poor grounds can add reactance. This is shown by the resonant frequency shift as the ground system is altered.

In slightly moist clay pastureland soil it takes about 8 short (1/8th wl) radials to stabilize the ground impedance.

In slightly moist clay pastureland soil, two or three rods make a poor RF ground for low impedance antennas.

If you use four short radials on a vertical, it is almost like no ground at all.

With small radial systems, ground rods can actually increase feed resistance. Use this particular phenomena with some caution, since I did not sweep frequency!



Echelon-Log Beverages

[Home] [Up]

Enhanced F/B Beverages

Two Beverages are paralleled a short distance apart, and stepped one in front of the other, can be phased to remove unwanted rearward response. This really just amounts to end-fire phasing two antennas. It is effective with long antennas, and also increases F/B ratio (and directivity) with very short beverages (even those approaching 1/2 wl).

Many or most previously published systems use frequency-selective phasing systems. With such systems, operation on more than one band requires switching systems and many components. "Conventional thinking" will make the system more complex than needed, and actually provide less performance! This is unfortunate, because it is possible to design a simple phasing system with almost no components that will cover octaves of bandwidth...no switching required!!

The two basic schemes I've used are very simple. One system is totally independent of grounds at either antenna end, the other system requires grounds but is more forgiving of dimensional errors in construction. I've described a model of a loaded Beverage, for those who would like to experiment with a small-space Beverage at Slinky and Loaded Beverages.

Bandwidth of Directivity

In high-efficiency unidirectional ***transmitting*** phased arrays, element impedances change significantly with frequency and phase angle changes. In unidirectional high-efficiency transmitting arrays, mutual coupling causes each element in every end-fire element group to have greatly different feedpoint impedances. This seriously complicates the design of ***proper phasing and current distribution*** as frequency is varied. It is very difficult to cover a few percent of the operating frequency, let alone multiple bands, with a high efficiency array.

Most amateur receiving antennas copy what we do with transmitting, and many of our transmitting systems copy narrow-band single-frequency systems. This is very unfortunate!

The key to broadband performance is having frequency-independent stable element impedances, and similar element impedances, throughout the system. This requires thinking "outside the box", not copying of transmitting phasing systems (often TX systems that are not that well-thought-out or planned).

Requirements for Broadband Directivity

There are three ways to obtain stable predictable impedances or broadband directive performance:

- Multiple elements can be used, such as those in log periodic or Fishbone arrays
- Active elements that are far from resonance can be used (short ***non***-resonant verticals or small ***non***-resonant loops with amplifiers)
- Very lossy elements (even large elements) can be used, with losses swamping out mutual coupling effects

While all three methods work, the simplest systems generally use lossy elements that are large enough to provide sufficient external signal levels to overcome receiver system hardware noise.

Broadband phasing systems are easily implemented in systems where feedpoint impedance is stabilized through intentional or "natural" loss mechanisms. Losses are made large enough to "swamp-out" or dilute mutual coupling and resonance effects, antenna feedpoint impedance remains stable and predictable even when elements are end-fire phased with a unidirectional pattern and close spacing!

Beverages As Elements

In the case of Beverages, ***radiation resistance*** is very low (in the order of an ohm or two). Most of the resistance we see at the feedpoint of a Beverage is from ***dissipative losses*** in soil below the antenna, not from losses associated with radiation! In addition, termination resistance adds another source of loss (perhaps 30% of overall system loss). Overall, loss resistance in a Beverage is very high (several hundred ohms). This means the Beverage's feedpoint impedance is stable, even if mutual coupling radically changes radiation related impedances.

Note: Mutual coupling still remains, since mutual coupling is a function of element spacing and position. Even though mutual coupling still exists, it only affects the ***radiation resistance*** portion of element impedance. Since the large loss resistance (mostly from ground losses below the antenna) dilutes or swamps out mutual coupling effects, mutual impedances can be ignored.

Not only is a Beverage antenna's feedpoint impedance "immune" to mutual coupling effects when phased or placed near another Beverage, terminated Beverages offer a relatively constant feedpoint impedance over very wide frequency excursions. This makes arrays of Beverages ideal candidates for wide-bandwidth phasing systems, eliminating complex phasing and/or switching systems.

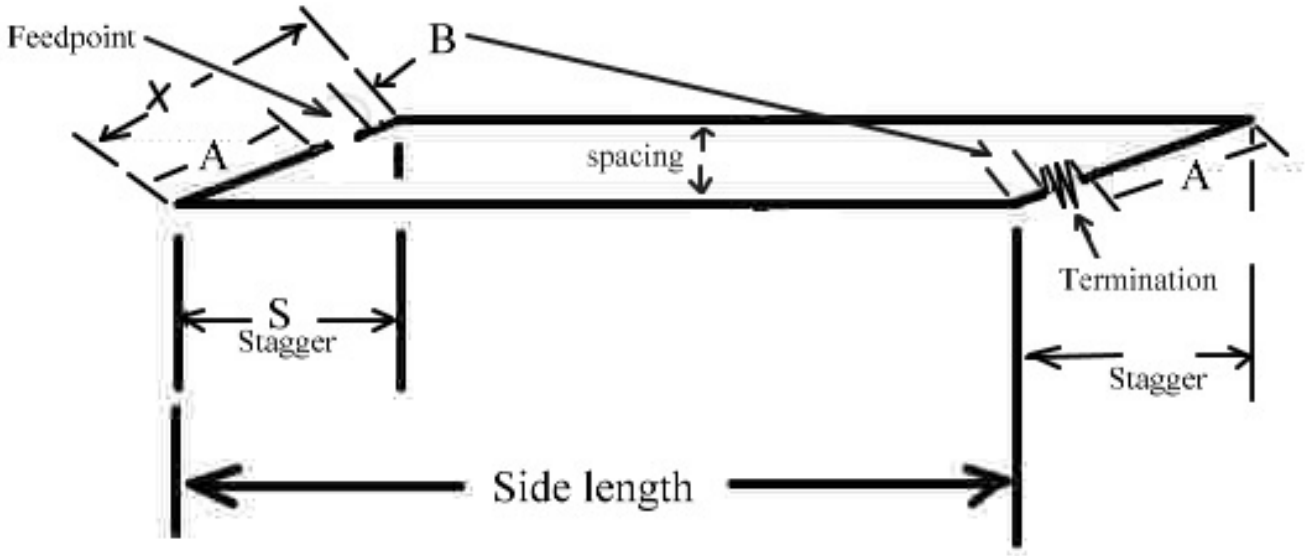
Types Of Phasing Systems

In order to better understand my antenna phasing systems, it is necessary to understand antenna phasing systems.

W8JI Parallelogram Array

Although it looks like a large horizontal loop, this antenna actually is two ground-connection-independent end-fire staggered (or stepped) Beverages. The short end wires form two single-wire feedlines at each end. One end-wire is series terminated with exactly twice the resistance of a normal Beverage, while the short wire at the opposite end is the feedpoint.

Stagger and spacing determines feed and termination location, the offset at the two ends being mirror images. A top view, looking down from straight above the antenna, looks like this:



This is an exactly "top down" view, looking down at the antenna from right above the antenna!

Click here for an Eznec file.

Notice the feedpoint is offset towards the termination end (front) of the antenna, and away from the null direction. This is typical for crossfire phased arrays. Crossfire arrays respond ***away*** from the delay line direction, exactly opposite conventional arrays. The termination is offset the same amount, but moves ***towards the feedpoint end*** of the antenna.

The feedpoint terminals, being floated (push-pull), provide 180-degree phasing between the two elements. The extra line length to the forward (left and front) element provides the "Stagger" delay.

Consider the actual wire length of a "short side" called "X" (which is the same as A+B). This length is the same on both ends of the antenna. The difference between A and B must equal or be slightly less than stagger (S).

To determine the offset of feedpoint and load:

1. Measure length of the end-wire, length "X".
2. Measure stagger in the end-fire direction, "S"
3. (X-S)/2=B
4. A=X-B

You may want to slightly offset the feed by making B longer and A shorter. This will move the null upwards, forming a cone. It is best to model the results.

Let's review a system, assuming S is 60ft and X is 100ft. We have X-S=40 divided by 2 for 20.

B is 20, A is then 80. The difference is 60, and that is the phase delay. Assuming 1.5 ft per degree that is 60/1.5 = 40 degrees delay. S is 60/1.5, or 40 degrees also.

We have a 180 shift at the push-pull feedpoint, so -40 rotates to +140. We have a 140 lead in the forward element, with a 40 degree spatial array delay. In the forward direction (towards termination) phase is (-40) + 140= 100 degrees out-of-phase. This results in nearly the voltage of one element alone, when the two element outputs of the long sides are summed. Towards the null (feedpoint) phase is +40 + 140 = 180 for a sin180=0 or zero voltage, a perfect 180 null.

On the second harmonic forward array feed system phase is -80 rotated to +100. Spatial array phase is now 80 degrees, or -80 towards termination. The result is (-80)+ 100= +20 in the forward direction. The result is nearly twice the voltage of one element in the forward direction. In the reverse direction, array phase is +80 + 100 or 180 degrees out-of-phase. We once again have zero back-fire response!

The general pattern holds true for any length of S less than 180 degrees, although grating lobes would make the pattern useless. The array, with 60ft stagger S, is usable from about 5 MHz down to VLF.

Summary, W8JI Parallelogram Array

Placing the feedpoint and termination centered on the end-wires is like using 180-degree phasing.

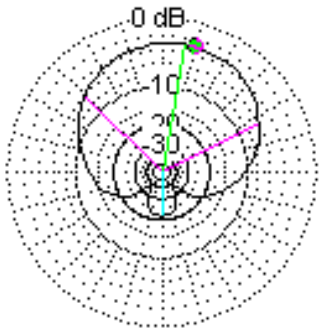
Placing the feedpoint and termination at the stagger minus side length distance is like using S-180 degrees phasing on any frequency with one exception, the antenna fires towards the feedpoint offset. This always results in a perfect backfire null, regardless of frequency.

Here is a wire table for a short 160-meter W8JI Parallelogram Array:

Wires

No.	End 1				End 2			
	X (ft)	Y (ft)	Z (ft)	Conn	X (ft)	Y (ft)	Z (ft)	Conn
1	0	0	6	W2E1	0	300	6	W4E1
2	0	0	6	W1E1	17	70	6	W3E1
3	17	70	6	W2E2	17	370	6	W4E2
4	0	300	6	W1E2	17	370	6	W3E2
*								

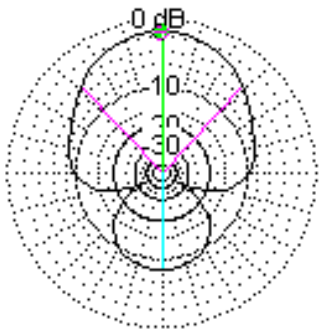
In a 370-foot length, this antenna has the following 20-degree wave angle pattern:



Azimuth Plot		Cursor Az	75.0 deg.
Elevation Angle	20.0 deg.	Gain	-18.92 dBi
Outer Ring	-15.99dBi		-2.93 dBmax

3D Max Gain	-15.99 dBi
Slice Max Gain	-18.91 dBi @ Az Angle = 80.0 deg.
Front/Back	19.2
Beamwidth	108.2 deg.; -3dB @ 26.9, 135.1 deg.
Sidelobe Gain	-37.54 dBi @ Az Angle = 270.0 deg.
Front/Sidelobe	18.63 dB

Average gain is -25dB, making the RDF about 6dB. In comparison a typical Beverage 370 feet long has this pattern:



Azimuth Plot		Cursor Az	90.0 deg.
Elevation Angle	20.0 deg.	Gain	-16.7 dBi
Outer Ring	-15.25dBi		-1.45 dBmax

3D Max Gain	-15.25 dBi
Slice Max Gain	-16.7 dBi @ Az Angle = 90.0 deg.
Front/Back	6.49
Beamwidth	84.8 deg.; -3dB @ 47.6, 132.4 deg.
Sidelobe Gain	-23.19 dBi @ Az Angle = 270.0 deg.
Front/Sidelobe	6.49 dB

If you wish to remove signals from the rear, the W8JI Parallelogram Array is a good broadband solution. It not only requires one transformer, one termination, and no ground systems at either end....it also is useful on several bands without switching anything!

Remember the above example is a reasonably short antenna, performance improves as side-length increases. There is no reason why this antenna can't be used from a band where it is only 1/2-wl long to bands where it is

several wavelengths long, as long as you properly choose stagger and width.

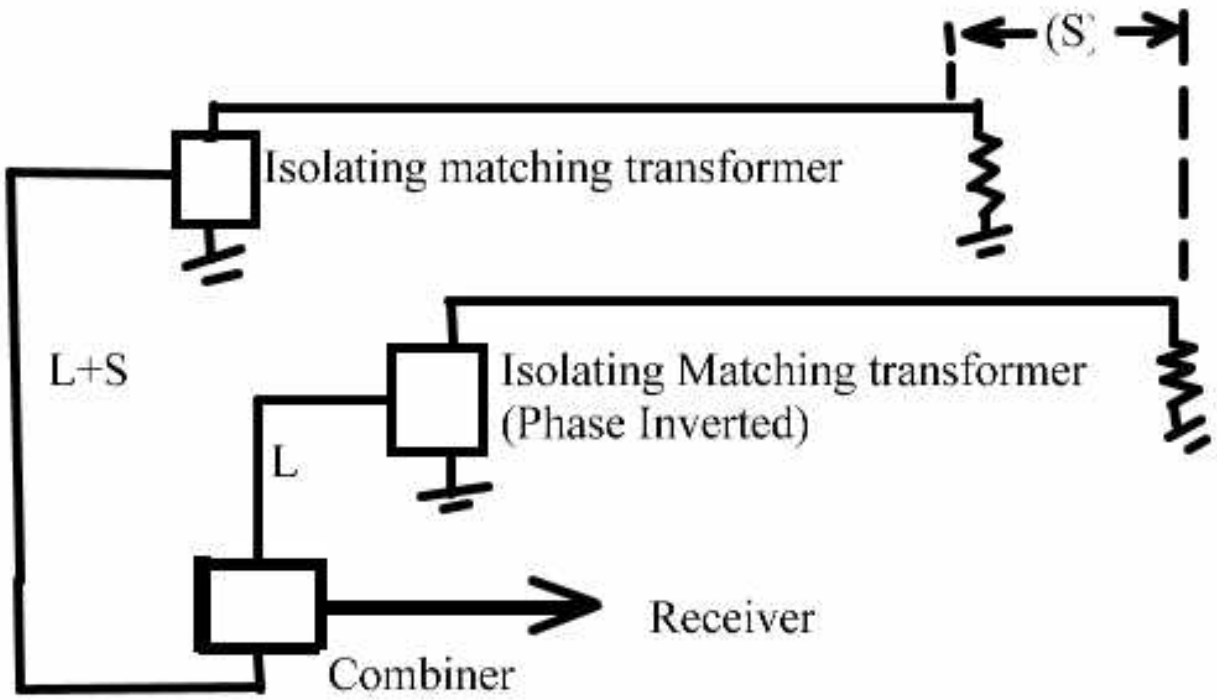
Crossfire-Echelon Beverage

This antenna is another frequency-independent antenna. It requires no band switching to work multiple bands. Because it uses cross fire phasing, rather than conventional phasing or hybrids, one phasing and delay line system covers several octaves of bandwidth.

A second feed method involves installing a pair of typical Beverages using isolation-type matching transformers, and inverting the phase of one antenna. Instead of being fed through two equal lengths of transmission line with a conventional splitter or combiner, the rearward stepped antenna (null direction) has an additional electrical delay equal-to or slightly-less-than the system's stagger distance in degrees. The delay line calculation can be done at any frequency, since stagger and delay change in step with frequency!

Performance is nearly identical to the above array, even very short antenna lengths (down to 1/2 wavelength) provide good F/B ratio. Of course the antenna will work better if length is increased. This arrangement is slightly more forgiving of dimensional errors than other systems, because each antenna is independent.

Remember you need a 180-degree flip at one feedpoint!! When you do this, the electrical delay of the antenna located towards the NULL must be S or slightly LESS than S. Using slightly less than S elevates the null and forms a cone, improving null usefulness and RDF of the array.



It is important to makes sure antenna feedpoint impedance is correctly matched to the transmission line. Be sure to measure SWR with an antenna analyzer!

You can also use a balanced wire feed, here is an EZnec model of an array using a combination W8JI parallelogram and Echelon-Crossfire feed.

Slinky and Loaded Beverages

[Home] [Up]

Slinky and Loaded Beverages

When space is limited and a Beverage antenna is too short for normal operation, increasing inductance (or capacitance) along the length of a "Beverage" will increase directivity. Inductance must be adding in series with the antenna, and doing so will increase the antenna's surge impedance.

Capacitance must be added in shunt with the antenna, and the extra capacitance reduces surge impedance. Additional shunt capacitance is very difficult to implement because each capacitor would need a ground, or you would need to surround the antenna with a slow velocity factor ***very*** thick dielectric. (Most of the air between the antenna and ground would have to be replaced with the dielectric.) There aren't any practical or easily implemented methods of slowing Vp to anything near the amount required through increased capacitance (at least none I could think of), so I will set that method aside.

There are three practical ways to slow velocity of propagation through inductance:

1. Use a spiral or zig-zag element
2. Use lumped inductor loading
3. A string of beads

How They Work

Contrary to what we might intuitively think, loaded antennas ***DO NOT*** work because we pack 800-ft of wire in a 200-ft area! They exhibit improved directivity because wave velocity is slowed, altering phase shift along the length of the antenna. Slinky (helical) and loaded Beverages show increased directivity because velocity of propagation along the antenna is ***decreased***.

As Vp is slowed, the antenna shows increased end-fire response and a gradually narrowing pattern. End-fire arrays fire in the direction of lagging phase, and the slower Vp causes more optimum phasing but only within certain limits. If phase is retarded too much, it actually starts to bring the signal back out-of-phase. With too much delay, the array tries to fire in the reverse direction.

Because of the reverse firing effect, there is a definite limit in phase delay (or Vp slowing) a system will tolerate. If the design goes beyond the optimum value, the antenna pattern tends to reverse direction, causing directivity to decrease. I've found optimum Vp for a 1/2 wl wire is generally around 0.5 times freespace velocity.

Slinky users should be particularly cautious to extend the coils an optimum amount. With 1/2 wl of distance, you would want somewhat less than 1wl of total conductor length. Too many "turns-per-foot" and the slinky, like any loaded Beverage, will try to fire backwards (towards the feedpoint).

Optimum termination impedance will always be somewhat higher than a conventional Beverage antenna. Surge impedance of the antenna is increased by the additional series inductance.

Helices vs. Lumped

For all practical purposes helices and lumped antennas are electrically identical. It doesn't matter at all if the antenna uses a string of soft-iron beads, a series of lumped inductors, zig-zags, stubs, or helices (a Slinky). The only criteria is the spacing between lumped loads must be a small fraction of a wavelength. For all practical purposes, 1/8th wl or less load spacing distance will make a lumped system perform identical to continuously loaded systems (slinkies).

Lumped reactances, whether in the form of a bead, stub, or conventional coil should have at the minimum a somewhat modest Q. This is just another way of saying the inductances should not add excessive series resistance. ***Total*** reactance of ***ALL*** loads should be between two and fives times the surge impedance of the antenna. With nine inductors along a 1/2 wl wire, I've found optimum reactance to range between 150 and 250 ohms. Surge impedance was about 700-1100 ohms in systems I tested. A Q of 20 or more would be acceptable in each inductor.

Attached Model

I've added an Eznec file of a loaded Beverage. A few things to note are I used radials to avoid a connection to high-accuracy ground at the termination. The feedpoint isn't critical, since it does not greatly affect directivity in this antenna. Unlike many antenna models, it appears a Mininec ground can be used without harming results.

Using a variety of ground-types I've found RDF remains at about 6dB. This places this antenna slightly below most elongated terminated loops, but well ahead of conventional short beverages.

loaded_bev

Phasing Systems

[Home] [Up]

Standard Delay Line Systems

Many phasing systems use standard ***180-Spacing=Delay line*** phasing. In other words, the end-fire distance in degrees is subtracted from 180-degrees, and the result is the delay line length. This is an acceptable method in ***single frequency or narrow-band*** systems.

Conventional delay line systems have the following problems when used in endfire unidirectional arrays:

- Phase shift almost always generally changes the wrong direction as frequency is varied
- Phase shift only equals line length when the line is perfectly terminated or when the line is lossless and an exact multiple of 1/4wl
- Voltages or currents at both ends of the line are equal only when the line is perfectly terminated or an exact multiple of 1/2 wl and has negligible loss
- Currents at the load end of an odd-quarter wave (or multiple) line are only equal when the lines are fed from the same voltage and have negligible loss

Hybrids

Some systems use ***90-degree Hybrids or L/C phasing systems.*** Hybrids offer ideal distribution of power and provide the expected phase-shift only when perfectly constructed and terminated. While there is some tendency to self-compensate phase, they still suffer bandwidth limitations. Hybrids are very useful in electronic systems, amplifiers are one example. In an amplifier system, we might want a constant 90-degree phase shift despite slight frequency shifts.

Unidirectional antenna systems are never optimized when phase shift is fixed at some arbitrary value that remains constant as frequency is varied. ALL *unidirectional endfire* arrays require phase to track with element spacing change in degrees, as frequency is varied. Lumped component systems and Hybrids might save space, but they do not enhance array performance over the proper choice and design of transmission line phasing systems. This is true in both transmitting and receiving antenna systems!

If hybrids are so poor, why do we see so many of them in antennas? There are a few reasons

authors and manufacturers use hybrids. They often think:

- Hybrids assist in maintaining proper currents in elements
- The dump resistor only absorbs a portion of reflected power that would be wasted anyway
- Power is wasted only when the load SWR is high
- The association with Collins engineering must mean the system works well in any application
- Well-tuned Hi-Q components must work better than transmission lines

In reality, none of the above are true in a broad sense. Hybrids have their place, but it certainly is not in wide-bandwidth phased arrays.

Transmission-line phasing systems are a bit more tolerant than Hybrids. For example, a 90-degree long transmission line has zero degree phase error, even when grossly misterminated. A 90-degree phase delay transmission line has less phase error than a quadrature (90-degree) lumped component Hybrid when mismatched. Phase error peaks in misterminated transmission lines when the line is any odd-multiple of 1/8 wavelength, and is minimum with lines any multiple (even or odd) of 1/4-wl. For example, a 45-degree long transmission line provides 27 degrees phase lag when terminated in 25 ohms...not the 45 degrees people often expect! (Remember this when you see phasing designs that just throw a certain length of cable in series with a mismatched impedance!)

With all systems, amplitude errors are a problem. There isn't any passive system that provides correct phase ***and*** amplitude when load impedance changes, especially over a wide frequency range.

Crossfire Phasing

I prefer ***cross-fire phasing***, rather than the conventional narrow-band phasing methods discussed above. Cross-fire phasing, when designed properly, ensures phasing is always correct regardless of frequency. When elements (in this article Beverages) offer a near-constant impedance that is almost entirely resistive over a wide frequency range, cross-fire phasing can function perfectly from VLF to LF all in one antenna. Phase and amplitude can be designed for a back-fire null, with the upper limit in frequency set by element spacing and the lower limit set by array sensitivity. It is possible to design cross-fire receiving arrays that maintain the same basic directional response over several octaves of bandwidth.

Crossfire Phasing

[Home] [Up]

Crossfire Phasing

Most amateur antennas are copies of the ideas used in single frequency systems, like AM BC stations. Most of my work has been in HF systems in and around amateur bands. Generally these systems require wide bandwidth, rather than a certain pattern on one single frequency.

The proper way to extend bandwidth is to use cross-fire phasing, where one element's phase is rotated 180-degrees and the delay is set approximately at the spacing. Here's how it works:

We have two elements with spacing "s" at X and Y. The signals come from direction 1 or 2.

1-----X-----s------Y------2

Let's assume X and Y are 90-degrees apart on 80 meters.

A traditional array would delay the array feed to X and Y by 180-s = 90 degrees. Assuming X lags Y by 90 degrees, the phase of a signal arriving at X from direction 1 would be 0 degrees for the reference. The signal continues on to arrive at Y 90 degrees later because of the physical distance in space. Since X lags Y in the array phasing, the phase at the common point of the feed system is now X's phase of zero plus -90 delay is -90. The additional signal delay in space to Y is also -90. The signals are in phase, and the result is the in-phase sum of the two signals. Our receiving level has doubled over one element.

For a signal coming from 2, the phase of element Y is zero. Element X receives the signal 90-degrees later for -90 phase. That -90 adds to a -90 in the delay lines, and the result is -180 at the common point. The signals subtract exactly to zero, and there is no response.

Now assume we move the array to 160 meters, where our fixed length delay line and spacing are both 45-degrees long. The in-phase direction of 1 is still the direct sum of the two signals, but the out-of-phase direction becomes (-45) + (-45) degrees or -90 degrees at the common point. The signal vector addition is now unity. We have a very poor null!

Now let's go back to 80 meters and invert one element 180-degrees someplace in the system. In this case, we have:

From 1 we have X=0 degrees plus -90 though air is -90 at Y. Assume Y is inverted (it also works if we invert only X). The phase at Y is -90 but rotated to the opposite side of a "phase circle" by the mirror flip of 180 in element Y's inverted driving system. A -90 with a 180 flip is now +90. This combines with the -90 delay from element X through it's phasing line delay, and the sum of two equal signals of -90 and +90 is zero. -90 is exactly 180 degrees from +90, and the array now has no response towards 1.

When the signal arrives from 2, the phase is now inverted the same way and the result is perfect addition. We have Y =0 plus invert 180 is -180. Space delay is -90 plus -90 in the delay line for a net delay of -180. The result is signals from 2 are now in phase from both elements. The only change by adding a 180-degree element flip is the array inverts direction!

Here is where it gets interesting, and I am amazed so many amateur antenna designers miss this. Y is still inverted 180. When we move to 160 meters, the delay from direction 1 is:

X=0 The delay line adds -45, the same as the distance through space to Y. Since the delay line and space are the same, the delays effectively cancel. Since element Y is inverted, the combined phase at the common point is now exactly 180-degrees out of phase. the result is zero response towards 1!!!

More amazing, this is true for any frequency! There is always a perfect null towards 1 as long as the signal levels are even and impedances are matched from the two antennas, and we use a physical delay line rather than lumped components.

From direction 2 we have:

Y=0 plus a 180 flip for -180. At X we have -45 space plus the delay line of -45 for -90. We have -90 difference. The signal is the same as the signal from one element.

The only effect, as frequency is reduced, is sensitivity of the array drops. We have less signal, but we would have that anyway even if we used the narrow band phasing systems commonly used!

Why do amateurs, who almost always move around in frequency, use single-frequency 180-s phasing systems? Probably for the same reason we use 90 and 180-degree shift in a four square. We started out wrong, and just kept doing the same thing. While this won't provide octaves of bandwidth on transmitting, it does reduce phase errors across a single band substantially. It also provides a phasing method that allows us to build receiving arrays covering octaves without any loss of null direction or depth!

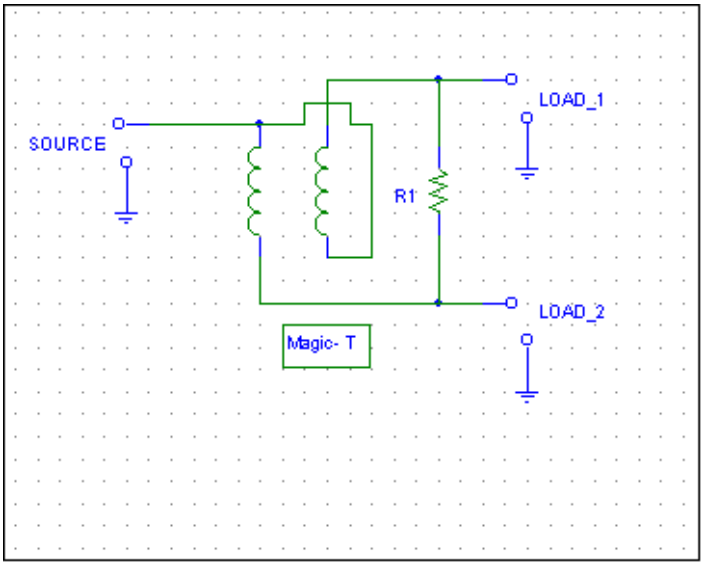
Combiner and Splitters

[Home] [Up]

Combiners and Splitters

The magic "T" is a very useful device. It can provide equal voltages, equal current, or equal power to matched or unmatched loads. It is not a magic bullet.

The basic element looks like this:



For 0.1 to 30MHz applications, the transformer is a twisted pair of small (number 18 to 26 gauge) enameled wires with five to seven passes through a 73 material one-inch binocular core. The source impedance is parallel combination of the two load impedances, and generally is stepped back up through a 5:7 turn ratio (1:2 impedance ratio) transformer. R1 is twice the load impedance in splitter/combiner applications.

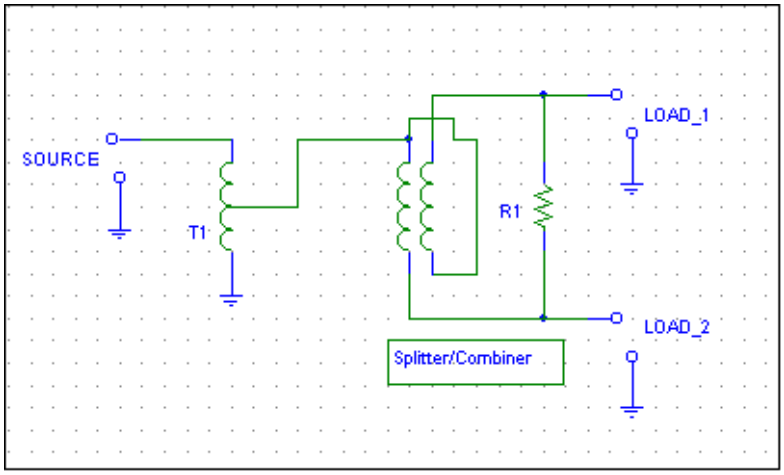
Like all passive splitters and combiners, this device is less than ideal. Isolation is only maximum when at least one port, and often two, are properly terminated.

This system does have an interesting characteristic, it can be used to force equal current into two different load impedances (or equal power by adjusting R1 to some value between zero and infinity). If R1 is open, each load is forced to have equal currents. If R1 is shorted, the loads naturally see equal voltages (T1 can be removed and the entire circuit configured as a T connector).

By forcing equal currents, a 1/2 wl transmission line can be used to feed a directional array instead of the more typical odd-1/4 wl line. With a 2:1 load resistance unbalance, I measured less than 0.1dB current error in such an application.

Receiving Splitters

Virtually all splitters are based on the Magic T with a matching transformer on the input. This splitters are certainly less than ideal, but they are simple and many times (but not always) better than a direct parallel connection.



T1 is a 7-turn transformer tapped at 5 turns (1.4:1 turns ratio, 2:1 impedance ratio) step-down transformer. 73 material binocular cores are ideal for 100kHZ to 30MHz.

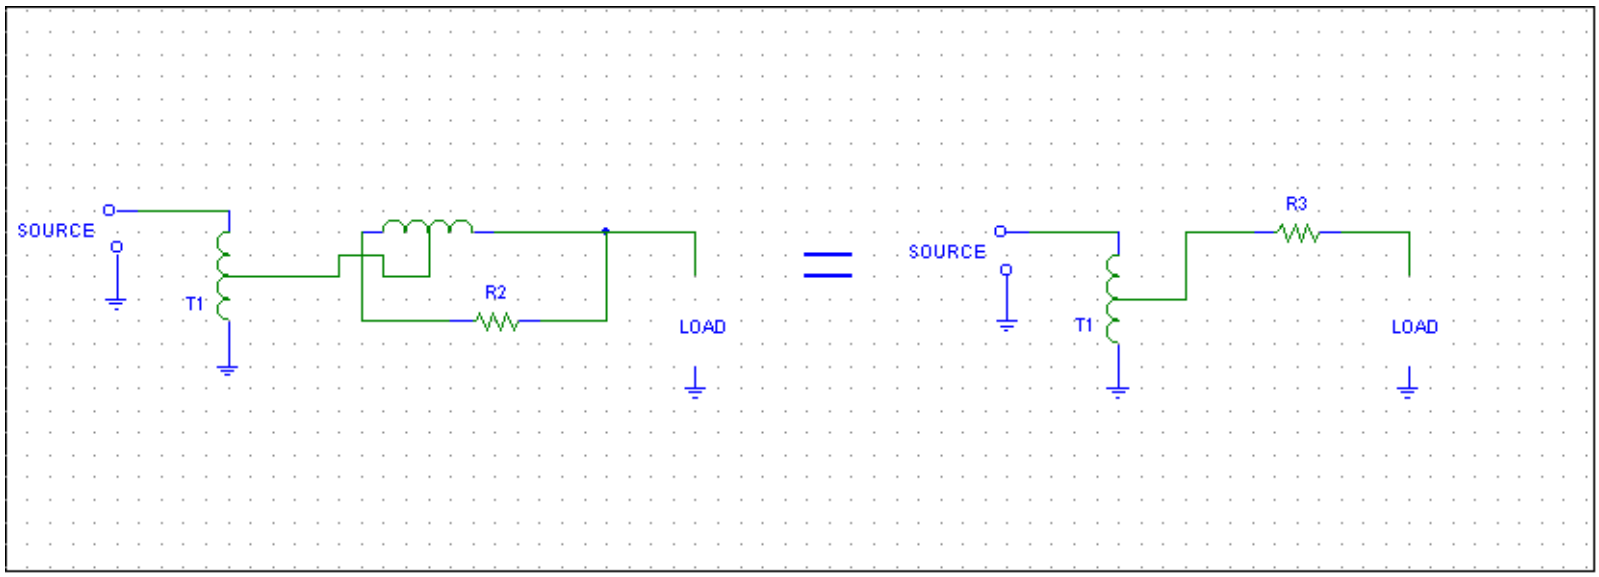
The magic T transformer is 5 to 10 turns of twisted pair wire through a 73 material binocular core. Configured as a center-tapped winding.

R1 is twice the expected load impedance. For 50- ohm systems use a 100 ohm resistor.

Losses

Typical loss of the Magic T is 3dB per port. The only other significant loss, when properly terminated, is a slight loss in T1. Normal loss of the entire system to either output port is 3 to 3.5dB. When combining in-phase signals, loss is only the loss in T1, there is no "combining loss".

When the Magic T splitter or combiner is open-circuited on one port, the electrical equivalent is:



R2, normally twice the value of any port, is stepped down by the impedance ratio of 4:1 in the Magic T transformer when a load port is opened. In a 50-ohm system, this effectively results in 25 ohms (R3) in series with the load impedance of 50 ohms. The resulting impedance of 75 ohms is doubled by T1 to 150 ohms. The equivalent input SWR, when open on one port, will be 3:1.

Loss will be 1.25dB from mistermination of the source by the 3:1 VSWR (assuming it is a 50 ohm source) with an additional loss of 1.7dB as power divides between R3 and the output port. The **theoretical open circuit loss (including transformer losses) is about 3 dB, the same as if a load were connected.**

The Magic-T behaves in a similar manner if one output port is shorted, with the exception R2 appears directly across the load. This is the equivalent of a 100-ohm resistor shunting a 50-ohm load. This impedance (33.34 ohms) is quartered by the center tapped winding of the Magic T

to 8.3 ohms. T1 steps this impedance up to 16.6 ohms. The result is, once more, a 3:1 VSWR.

This means signal level at port 1 theoretically does not change when port 2 is open or shorted, or anything in between.

Like many systems, these losses are based on source and load impedances being ideal. This is almost never the case, and the optimum value of R2 is often significantly different from being twice the load resistance. Because of that, our actual systems may show significantly more level change than the theoretical value (which is no change) when one port is incorrectly terminated.

If the system does not divide signal properly, the systems requires additional gain. This gain comes at the expense of lower IM performance. This is particularly true if the low-headroom amplifiers typical of amateur radio "preamplifiers" are used.

Even with high dynamic push-pull CATV transistor amplifiers, I've often found it necessary to optimize the splitting system. For example, stock my R4C's typically have ~20-ohm input impedances on 160-meters. Using R4C's on one port and higher-impedance receivers (or worse yet an open-circuit) on the other port results in starving the already low-sensitivity R4C receivers for signal (despite the use of a "splitter") if they are used in conjunction with higher sensitivity higher impedance receivers like FT1000's. The solution is to make every load (all the receivers) look like 50-ohms, readjust R1 to a new value, or use emitter-follower "active splitters".

I opted to make all of my receivers "look like" 50 ohms, but your choice may be different.

Amplifiers

Caution must be used in selecting amplifiers. Virtually all commercial amplifiers I have tested have very limited dynamic range. They are fine for amplifying high-loss antennas like Flags and EWE's, but terrible when connected to large Beverage systems. Adding an additional 6dB or more gain to the output of a Beverage just to overcome splitting losses (plus problems associated with uneven power division) almost always pushes these amplifiers "over the top". If you are going to use single-ended amplifiers with small low-power devices, be prepared to use multiple amplifiers (one for each receiver) and place them after the splitter system.

It is far better to buy or build one good amplifier, but it should be a very high dynamic range device!

Elongated Terminated Loops

Terminated loops have only recently become popular, even though such systems were available commercially in the 1960's and earlier. Sometime in the early 1970's, I received an advertisement from the late W1BB. That advertising brochure described arrays of receiving loop antennas marketed by a Canadian manufacturer for commercial and military use. The brochure had pictures of diamond-shaped terminated loops, individual small loops, and loop arrays that looked like a number of Flag antennas strung end-to-end where each rectangular "loop cell" fed the next loop. The brochure gave directional patterns of the arrays, and the patterns looked much better than those of other antennas. Unfortunately the price, as I recall, was in the tens of thousand dollars for even the least expensive array! Although detailed technical information was withheld, it wasn't difficult to figure out the electrical design of each array.

That early brochure started me thinking in terms of antennas other than Beverages. I experimented with small loop antennas, and eventually installed an array of eight in-line loop cells. That system allowed me to be the first eastern USA station to work Japan and other Asian countries through interference from multiple multi-KW LORAN transmitters, and as the system was refined I could work JA's on a regular basis long before the broad LORAN pulse transmitters were removed from 1900 kHz. This is a testimony to the clean pattern and wide deep nulls possible using arrays other than traditional Beverage antennas.

Are they quiet because they are loops? Not at all!

One of the most damaging rumors to good antenna science are claims that loop antennas have a mystical property that somehow rejects noise. Nothing is further from the truth, with one exception. Corona.

Loops do not have sharp points sticking out into air at high impedance points, and that can be an advantage in limited cases.

Any sharp point extended from the area of anything, even wooden ship's masts in old sailing vessels, is more subject to corona in inclement weather. Sailors feared St. Elmo's Fire long before anyone knew what electricity was, and amateurs fear it today when trying to receive. We often just don't know what to call it, and can't see it in our brighter skies, so we call it "precipitation static".

The sharp point in a dipole where the wire or tubing ends not only promotes corona by virtue of the

fact it is "out in space by itself", it almost always has the disadvantage of being at a high impedance point in the system. The tiny random charge movements with little current and very high voltage (high impedance source) inherent in conductors around the corona discharge are driving a high impedance part of the system, an ideal situation to maximize transfer of tiny amounts of noise power into the system!

That is almost certainly where the rumor that loops reject noise comes from. We forget it is a function of the sharpness and impedance in the area where the antenna is sharply shaped, and instead fixate on the fact it is "a quiet loop".

Are terminated loops actually loops?

Terminated loops do not behave like small conventional loop antennas. They do not carry uniform in-phase currents throughout the area of the antenna. They don't behave like directional couplers either, they are antennas...not nearfield coupling devices coupled to other conductors (we hope). Terminated loops are really just short verticals, with the phasing inherent in the long horizontal wires. The loop's vertical areas receive the desired signals, while the horizontal conductors merely serve to act as transmission/phasing lines for the vertical (or sloping vertical) ends. A small elongated terminated loop acts like a simple two-element vertical array with integrated phasing lines.

This is true even in the K9AY Loop and Pennant antennas, which have sloped conductors. The sloped conductor behaves as a vertical (think about this when people follow the mistaken advice that sloping the last few feet of a Beverage "stops noise pickup of vertically polarized signals"), ten feet of vertical drop is still ten feet of vertical conductor exposed to vertically polarized signals. The fact the antennas work so well is testimony to how sensitive a sloped wire is to vertical polarization. If sloped wires weren't sensitive to vertical signals, the Pennant and K9AY Loop wouldn't work!

Elongated terminated loops, and arrays of elongated terminated loops, are a special form of short phased verticals where phasing and feed systems are an integral part of the antenna. This integrated system of elements, feed system, and phasing solves construction problems associated with arrays using more recognizable vertical elements. With any system there are tradeoffs, elongated loop antennas only allow very limited control of phase and unwanted high-angle response. We can't obtain optimum patterns (although a properly placed series capacitance will help) because this system only allows limited control of current distribution and phase shift.

These antennas "want to" be verticals because the earth below them and somewhat closer spacing prevents the horizontal components from being efficiently coupled to space while the earth simultaneously enhanced the vertical radiation component of the gradually sloped conductors making up the antenna. The horizontal sections act as a wide-spaced air dielectric transmission line.

These antennas work best when propagation time of signals along the horizontal wires matches propagation time of the wave in space around the antenna, and when the earth or a ground system below the antenna is good. Suppression of high-angle horizontally polarized radiation, and maintaining velocity of propagation near unity, are why EWE antennas (and other forms of this family of antennas) thrive on good ground systems or good earth below the antenna. The desired earth effects are opposite those desired with Beverage antennas, an ideal situation for highly conductive soil!

Why use terminated loops?

It is easy to understand why "loop" systems, even very small loop systems, have become popular. Arrays of terminated loops vertical elements produce effective low-angle receiving performance along with a relatively clean pattern. EWE's, Flags, Pennants, and K9AY loops are effective methods of building two element vertical arrays. They are easy, small, and inexpensive! They are noticeably less directive than two phased verticals would be, because the horizontal components are not totally cancelled by ground effects and the opposing wire, but they certainly are easier to construct than phased verticals (with all their loading, grounds, and coaxial cables). It's all the standard old tradeoff we just can't seem to get away from, we always must balance complexity against performance.

Many people are working with the various arrays of elongated loop antennas, so there are few contributions I can make other than describing how or why they work. I would like to suggest it is possible to extend the arrays end-to-end for some distance without external feed systems, and well-placed reactances can be used to modify patterns. Very little work has been done in that area. I'd suggest experimenting with series capacitors, perhaps placed mid-way in phasing (the horizontal wires) areas to increase velocity of propagation through elongated loop arrays and increase directivity.

Are small loops hyper-sensitive to vertical masts?

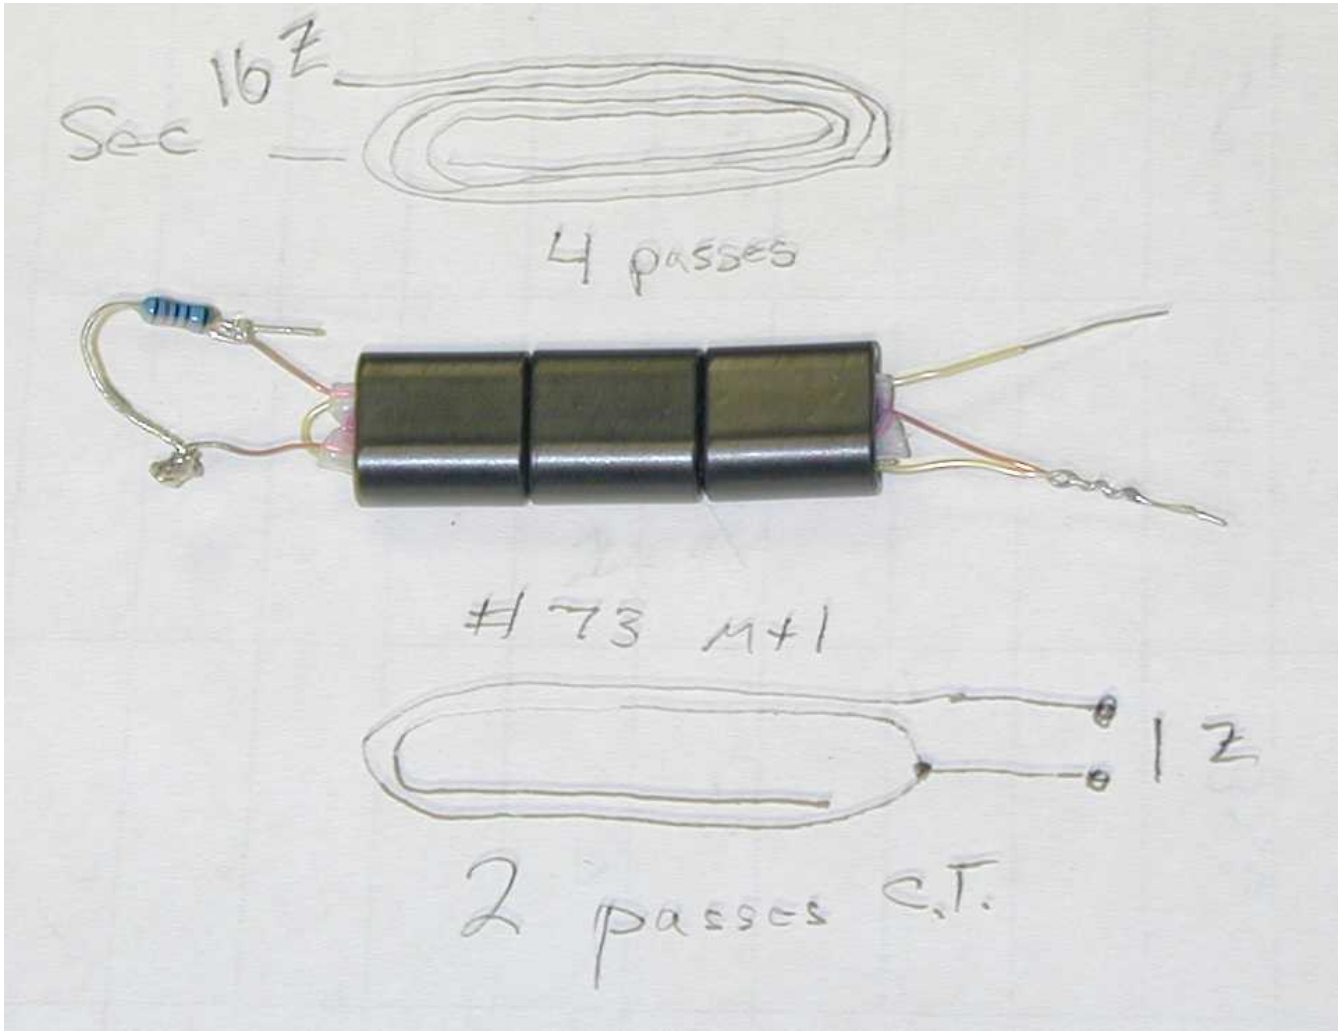
There is no compelling evidence that any of these antennas are more sensitive to vertical metal masts than any other antenna would be. As a matter of fact, the only basis for such claims appears to come from models that fail to pass simple recommended tests for model accuracy and stability. If we build a model that is flawed and oversensitive to changes in things like the number of segments used in the model, we can expect it to be sensitive to nearly any change!

Everyone is free to say and do what they like, but other than keeping a short mast a few feet away from vertical wires and NOT connecting that mast directly to the antenna or feedline, I wouldn't hesitate for a second using metal supports. My large arrays of loops in the early 70's used metal masts, my arrays in the 80's did, and as have commercial arrays.

Feedpoint Matching

Great care must be taken in decoupling the feedline from the antenna in the balanced versions of these antennas, although the EWE (being unbalanced) is relatively immune to such problems. Keep in mind the antenna generally looks capacitive as a common-mode structure, so inductive decoupling (i.e. a choke coil of coax) can actually ***increase*** system problems. The best common-mode isolation system would be an isolated winding transformer designed with minimal capacitance between the antenna winding and the rest of the system. I use a small transformer with stacked 73 material binocular cores in feeding some of my high impedance "log-Beverage" arrays, and similar transformers should work with ~1000 ohm impedance elongated loop antennas.

Because this transformer only has a single turn primary (two turns with the balancing pass), I'm able to reduce stray capacitance to a dozen pF or less. It has excellent balance, low SWR over a wide bandwidth, and very low loss. The reasonably low transformer capacitance, when used in concert with proper feedline grounding and routing, should make the system relatively immune to common mode problems. I'd route the feedline horizontally directly away from the end of the antenna for a few dozen feet (but never a distance approaching 1/10th wavelength or longer), and then drop the feedline to ground earthing the feedline shield at that point. Decoupling beads or sleeves belong on the receiver side of the shield grounding point, not between the ground and the antenna!



I wind this transformer on three Fair Rite Products 2873000202 cores (about 1/2 inch square and 1/3 inch thick 73 material). The high impedance (secondary) winding is #26 enameled wire through Teflon tubing, while the primary is Teflon coated wire-wrap wire wound outside the tubing. The small extra pass that "dangles" on the low-Z primary winding helps balance the system, even though it adds a few pF of capacitance.

By the way, a Faraday shield will only make things worse. It will increase unwanted stray capacitance and might deteriorate the high impedance winding's balance if it is not properly grounded. The proper grounding point for a Faraday shielded primary is *opposite* the exit point of the primary winding, or on the secondary winding's exit side of the transformer. Most Faraday shields described for Beverage and other transformers are not only useless, they are often incorrectly grounded and actually increase unwanted coupling!

Receiving Antenna Design

My local wintertime 350Hz BW noise (after amplifier) compared to a sample of signals on one night was:

Noise -127dBm

9H1BM -122dBm

OM0WR -95dBm

DF2PY -88dBm

WA8OLN -78dBm

W3GH -60dBm

W4ZV -32dBm

The dynamic range between noise and W4ZV was 95dB! It also illustrates how important antennas, location, and propagation are rather than power. The dB difference between signals from the same area is profound. Many signals run at or near noise floor. This may not be typical of every night, but it shows how large the signal level variations between weak DX and strong signals are.

Before talking about receiving antennas for lower frequencies, it is important to understand a few basics. We all understand the primary reason we use special receiving antenna systems is to improve signal-to-noise ratio. On the surface this sounds like the same reason we use directional transmitting antennas, but there are some very important differences between transmitting and receiving applications.

One thing we often hear is how a 7dBd gain yagi will improve receiving by a similar amount over a dipole, the logic behind that idea is the gain works both ways. I've read that time and again as justification for using a high gain transmitting antenna. On the surface, it does sound reasonable and correct. Yet it's really not correct in most (if not all) cases! A 7dBd gain antenna with 20 dB nulls can improve receiving an amount from nothing to 30 dB or more, depending on many things we often don't consider.

When transmitting, we can not tolerate much power loss. The most important antenna characteristic, other than a reasonable SWR and having the antenna remain in the air for a while, is having maximum possible field strength in a given direction or directions. In general, the single most important parameter is having maximum gain in all the desired directions and at the most useful wave angles. We know, for a given polarization and wave angle, the highest gain antenna will deliver the strongest signal to our target area. Transmitting antenna choice is reasonably simple, we want properly positioned gain. Take-off angle, side-lobe strength, and F/B ratio take a back seat to maximum gain at the desired wave angle and direction. We can generally model the antenna and confirm the results with a few simple

measurements, and be confident we have made a good choice. By the way, if you hear anyone selecting an antenna based on take-off angle help him out. Take off angle is not important, what we actually need is maximum possible gain at the desired angle and direction. After all, we don't care where the peak is as long as the antenna we pick has more signal (gain) at the desired spot than other antenna choices!

When receiving, the system has a much different design priority. If we consider gain, we can be totally misled. It's easy and somewhat common to make poor choices when picking receiving antennas, mostly because we often don't know what to look for. What we look for can also be different depending on the actual application. A system that works extremely well in some applications can be a real dud in other applications. I'll explain how to make the best choice and what the pitfalls are, but first we have to understand some basics. ***If you would like to hear a demonstration of how excellent directivity reduces noise, listen to QRN_JA2ZJW on the DX Signal Recording page.***

Antennas and Fields

If we are going to pick the best receiving antenna, it is important we understand how antennas respond to "signals" and "noise". Unfortunately, this is probably the single most misunderstood part of receiving antenna design. This a problem mostly because we are constantly bombarded with folklore giving us the wrong impression of how antennas work.

One example that comes to mind is small loops, often referred to as "magnetic radiators". Folklore often considers the radiation or response of these antennas as somewhat magical, with the antenna behaving like a sieve that sorts "good magnetic signals" from "bad electrical noise". Nothing is further from the truth! At a relatively small distance the small magnetic loop is more sensitive to electric fields than a small electric field probe. The ratio of electric to magnetic fields are sometimes called the "field impedance" of the antenna. An antenna with a high field impedance has a dominant electric field, and an antenna with a low field impedance has a dominant magnetic field, when both are compared to freespace ratios at a large distance from the antenna.

At distances of about $\lambda/2$, the field impedances of all by physically large antennas are almost indistinguishable from each other, no matter what the antenna type. Strange things happen at closer distances, as we will soon see. Once we understand the basics, we might picture our antennas differently. We might find antennas don't respond to signals and noise like we thought, but at least we won't be as susceptible to the "noise" caused by rumors and folklore!

Induction field

The induction-field area involves the energy storage area around the antenna, and involves both electric and magnetic fields. These energy storage fields dominate the system near the antenna, although the radiation still exists. Contrary to some bizarre claims (i.e. CFA or CTHA Antennas), there is no possible way to "mix" induction fields and create a radiation field. The effects that cause each are different, and they follow different rules. The induction fields fall off much more rapidly with distance than radiation does, even though we "measure" or talk about each in terms of magnetic and electric effects.

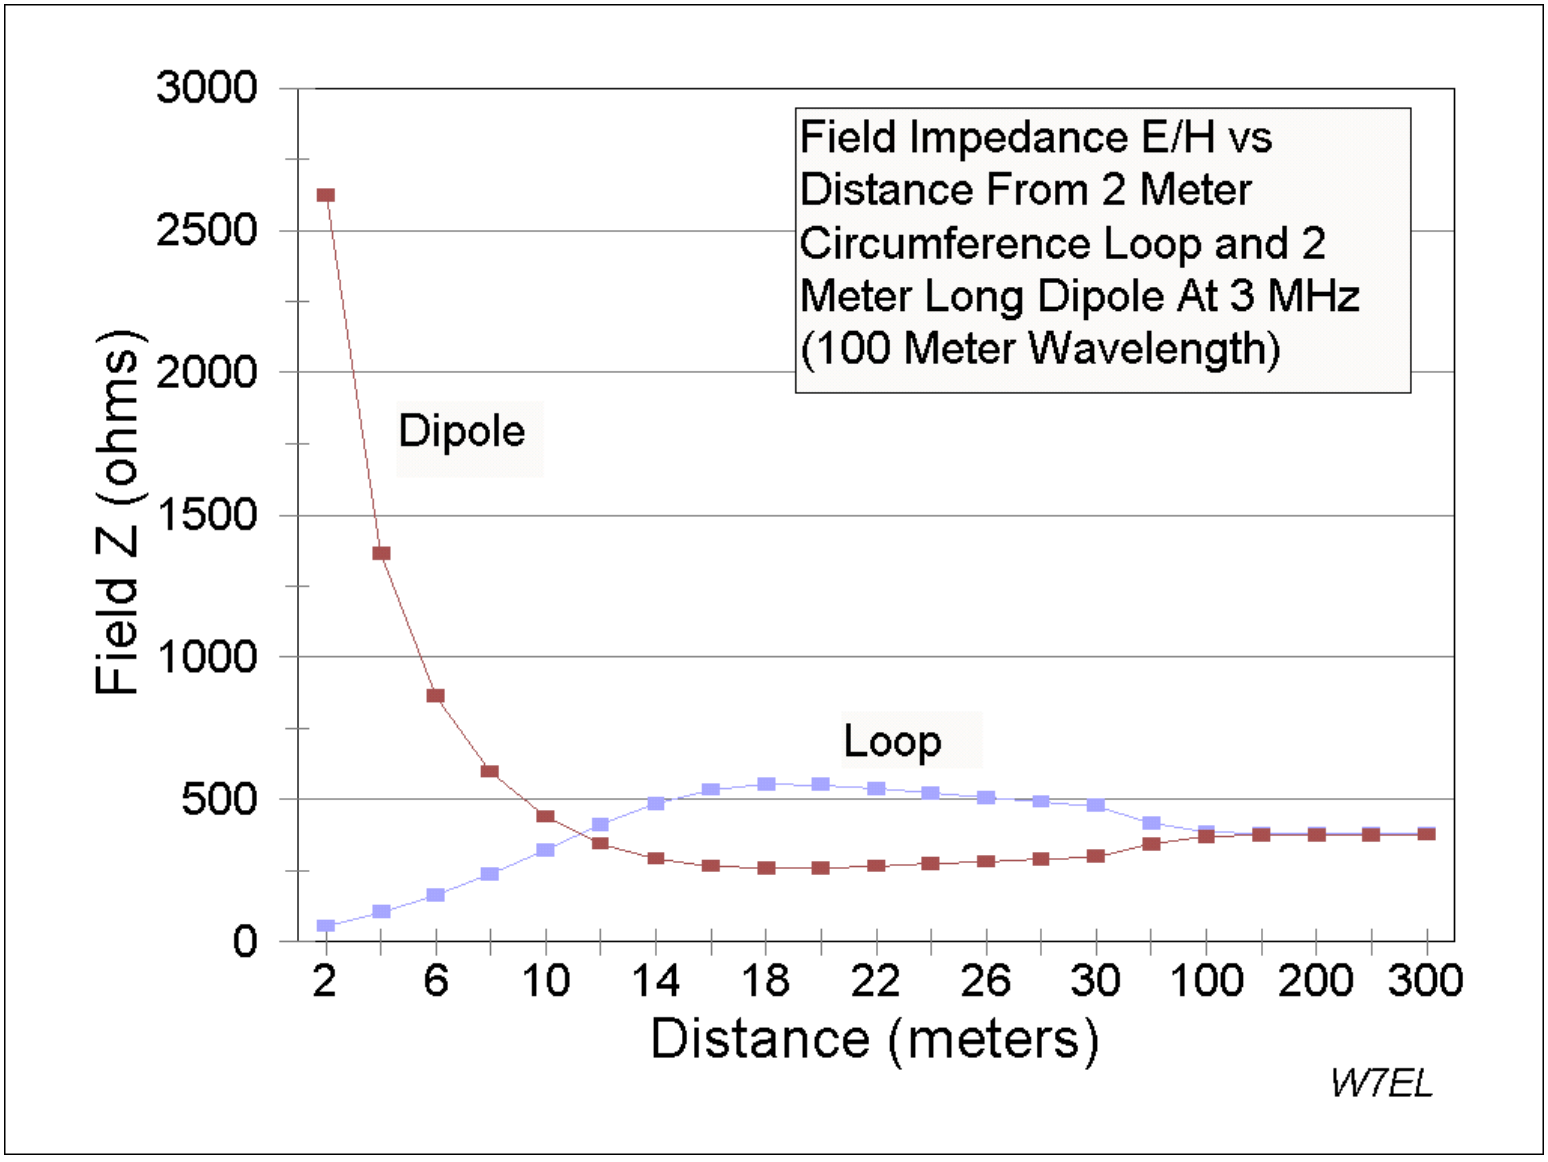
We can move the fields around, concentrate them or spread them out, and even change the ratio of these fields...but every antenna has both electric and magnetic induction fields. ***Whenever we have a time-varying electric field, it must be accompanied by a time-varying magnetic field.***

We might consider induction fields part of direct capacitive or inductive coupling between areas of the antenna and objects or space around the antenna. Close to the antenna, field intensity might not fall off as the rules normally predict with distance. Very near an antenna, fields are an accumulation of effects from sources at multiple directions and distances. It isn't always easy to understand what actually is happening very near an antenna, where the area of the

antenna is large compared to the distance where we are observing the effects. Near the antenna, pattern and field impedance is generally nothing like we might intuitively imagine.

It is the response in this area, generally within λ/10 distance from the antenna, that small "magnetic loop" and "electric dipole" antennas get their names.

Very close to a small loop antenna (but not necessarily very near the open ends), the magnetic field dominates. We could describe that effect by saying say the field impedance is "low". Conversely, near a small dipole or monopole the electric field dominates, the antenna has a high field impedance. Remember, this generally applies only with λ/10 distance from the antenna.



The since the distance of a wavelength in the above graph (thanks W7EL) is 100 meters, we can also considered the bottom scale as a percentage of a wavelength. We can see at about 11 percent of a wavelength (which would be about 50 feet on 160 meters), there is no difference in field impedance between a small loop and a small dipole. At distances beyond 50 on 160 meters, the loop actually has a ***higher*** field impedance than a dipole.

So much for the myth that a receiving antenna can sort good signals from bad signals (noise) by virtue of being "magnetic"! We not only don't have the response we might imagine, we probably have no idea if the close-by unwanted signal source is radiated from a source that is electric or magnetic field dominant. Successful noise reduction by virtue of

by antenna "style" would mostly be a matter of hitting a lucky combination through careful experimentation.

Near Field

The near field area is an area where the ultimate pattern is not fully formed. It is possible, with large arrays of small elements, to be out of the induction field region but still well within the near field area. Let's consider individual groups of elements as "cells", and the array a combination of small directional cells occupying a very large physical area.

This occurs in some of my broadside/end-fire combination arrays because physically small antennas forming individual end-fire cells are combined forming an array more than one wavelength across. The array is physically large, and at a distances of several wavelengths the combined field clearly originates from multiple sources that vary in distance or direction. The pattern is not perfectly formed because the signal from closer elements is less attenuated by distance, and the phase difference between the cells at a given azimuth is not the same as the ultimate phase further away at the same azimuth.

This applies to utility line radiation, where distant noise sources are conducted along the entire line. To the receiving array, it might appear that a single arc on an insulator a mile away is actually radiating from multiple directions with many phase relationships. The field the receiving antenna "sees" might appear to arrive from multiple directions, making it difficult or impossible to null the noise with a simple directional cell or more complicated array of directional cells. This would be a good application for a device like an antenna noise canceller, because the noise at the antenna terminals will be the vector sum of response to multiple radiated fields reaching the receiving antenna from a single noise source. In this situation a sample of noise taken near the power line could be combined out-of-phase with the sum of radiation points along the power line to null the noise.

Clearly a noise source or sources might also be outside the induction-field dominant area, and still not have a fully formed pattern. Antennas must be in the far field of the noise source, and the noise source must be in the far field of the antenna if patterns are to be predictable when nulling noise. Besides the fact larger distances provide greater attenuation of noise, it is also very desirable to locate our receiving antennas in the far field of noise sources, and noise sources in the far field of the antenna. This makes a good case for placing receiving antennas as far from other conductors (such as power lines) as possible.

This doesn't means urban or suburban dwellers should give up and move to rural areas, it just means the results will be less predictable and actual experimentation is likely required. Results aren't always predictable, unless the antenna is a few wavelengths from other potential unwanted signal radiators or objects that might affect antenna pattern.

Noise

The noise that limits our ability to hear a weak signal on the lower bands is almost always an accumulation of many signal sources. Below 18 MHz, the noise we hear on our receivers (even at the quietest sites) comes from terrestrial sources. Receiver noise is generally a mixture of local groundwave and ionosphere propagated noise sources, although some of us suffer with dominant noise sources located very close to our antennas.

Our locations fall into three basic "radio" categories that may or may not be related to our actual communities:

Note: noise levels quoted in this text are the average of three independent studies by Bell Labs, FCC Land Mobile Advisory committee, and the Institute for Telecommunication Sciences. Rural data are actual measurements of summer noontime and winter midnight noise at my location, several miles from high voltage transmission lines and far from any industrial or suburban populations.

Urban

In urban-type noise situations, noise arrives from multiple random sources through direct and groundwave propagation from local sources. One or more sources can actually be the induction-field zone of our antennas (in most cases the induction field dominates at distances less than 1/2λ). Urban locations are the least desirable locations because typical noise floors average 16dB higher than suburban locations. There is often no evidence of winter night noise increase on 160 meters, since ionosphere-propagated noises are swamped out by the combined noise power of multiple local noise sources. Much of the noise sources are utility distribution lines, because of the large amount of hardware required to serve multiple users. Other noise sources are switching power supplies, arcing signs, and other unintentional man-made noise transmitters.

Suburban

Suburban locations average about 16 dB quieter than urban locations, and are about 20 dB noisier than rural locations. Noise generally is directional, arriving mostly from areas of densest population or the most noise-offensive power lines. Utility high-voltage transmission lines are often problematic at distances greater than a mile, and occasionally distribution lines can be problems. The recent influx of computers and switching power supplies has added a new dimension to suburban noise.

There is often a small increase in nighttime winter noise at exceptionally quiet suburban locations. This increase occurs when propagated terrestrial noise equals or exceeds local noise sources.

Rural

Rural locations, especially those miles from any population center, offer the quietest environment for low-band receiving. Daytime 160 meter noise levels are typically around 35-50 dB quieter than urban, more than 20 dB quieter than suburban locations. Nighttime brings a dramatic increase in low-band noise, as noise propagates in via the ionosphere from multiple distant sources.

Primary local noise sources are electric fences, switching power supplies, and utility lines. I can measure a 3 to 5dB daytime noise increase in the direction of two population centers, Barnesville (population 7500, distance 6 miles) and Forsyth (population 10,000, distance 6 miles) Georgia.

Typical daytime noise levels, measured on a 200 foot omni-directional vertical, are around -130 dBm with a 350 Hz bandwidth (noise power is directly proportional to receiver bandwidth) . Noise power increases about 5 to15 dB at night, when the band "opens". As in the case of suburban systems, directional antennas reduce noise power.

Nighttime is the "big equalizer", reducing the advantage of location as distant noises increase with improved propagation.

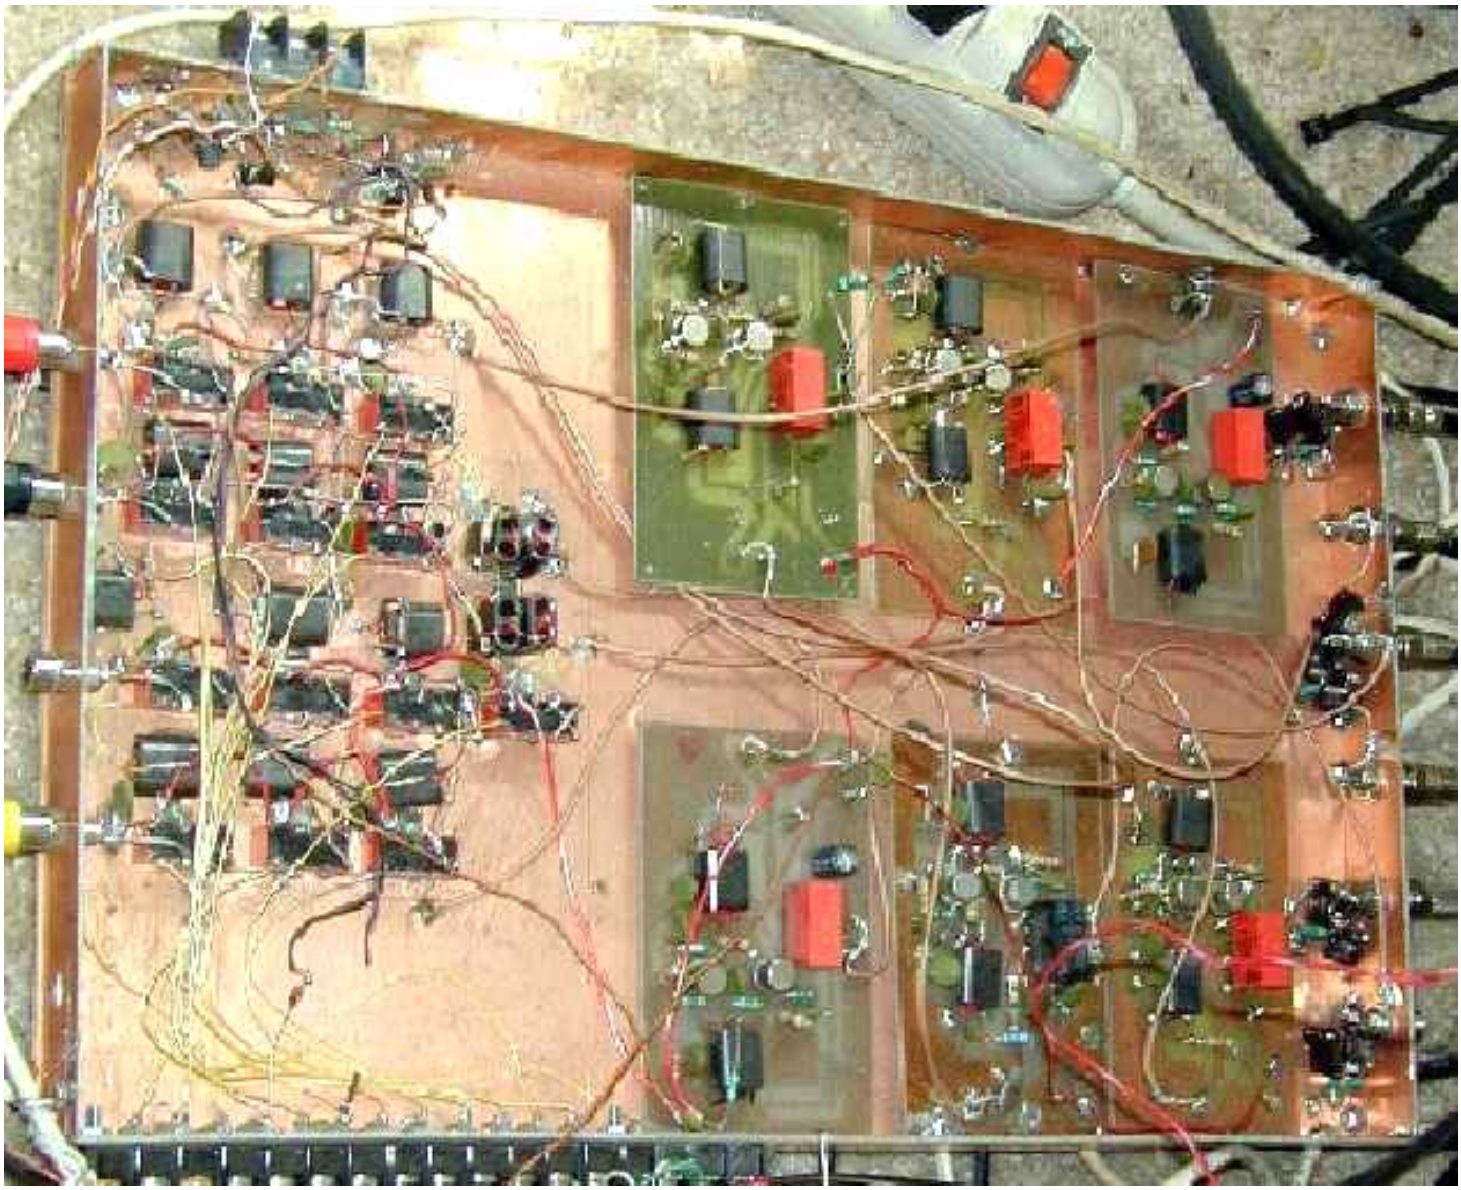
How Important is Gain?

When choosing one receiving antenna over another, never select an antenna by comparing antenna gain. Gain only affects receiving performance when the receiving system noise floor is determined by internal system noise. If we hear a definite decrease in noise when replacing the antenna with a dummy load of the same impedance, gain by itself is not a factor.

Noise not only varies with the hour of day, it also varies with direction and season. Further complicating matters, noise power is directly proportion to receiver bandwidth. Going from a 2.5kHz filter to a 250 Hz filter with the same basic shape-factor reduces noise by 10 dB. When determining if system gain (for a given directivity) is adequate to establish system noise floor, tests must be made at the quietest operating time using the narrowest selectivity. In general, we should set system gain to allow a comfortable increase in noise when the antenna is connected at a time when propagation is poor but adequate to allow some contacts. This sometimes results in excessive gain when propagation is more favorable, but it is simple to remove gain (either by adding an attenuator or removing an amplifier) when using wider bandwidths or if conditions are noisier.

My receiving antennas have high dynamic range amplifiers using push-pull 2N5109 transistors. Amplifier gain is approximately 15 dB, and noise figure is approximately 5 dB. Gain compression occurs at approximately 30 dBm (1 watt) output. The blocking dynamic range of the amplifiers (using a 250 Hz bandwidth on the receiver) is around 180 dB, making my receivers the limiting factor. The amplifiers have internal bypass relays, allowing them to be easily bypassed when required by removing amplifier power.

Each of these amplifiers drives a four-way splitter, allowing any one-of-four receivers to connect to any antenna. Multiple receivers can select the same antenna simultaneously. Splitter system loss is 7 dB. Typical net system gain is around 8 dB to each receiver. Some amplifiers are designed to have slightly more gain and some less gain, because some antenna systems have a lower noise floor than others.



What Antenna Parameter is Important?

Once any receiving system limits on *external* noise, antenna pattern becomes the only thing that matters. Here are the patterns of two Beverage antenna systems, each with different gains. One antenna uses two side-by-side Beverages, while the other is a single Beverage. I'll include Eznec wire tables so you can model the antennas, and see the mistake we often make.

First, the wire table can look like this:

Wires

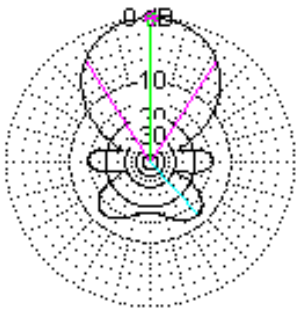
Wire Other

Coord Entry Mode Preserve Connections

Wires

No.	End 1				End 2				Diameter	Segs
	X (ft)	Y (ft)	Z (ft)	Conn	X (ft)	Y (ft)	Z (ft)	Conn	(in)	
1	0	0	0	Ground	0	0	7	W2E1	#16	5
2	0	0	7	W1E2	0	780	7	W4E2	#16	50
3	70	0	7	W5E2	70	780	7	W6E2	#16	50
4	0	780	0	Ground	0	780	7	W2E2	#16	5
5	70	0	0	Ground	70	0	7	W3E1	#16	5
6	70	780	0	Ground	70	780	7	W3E2	#16	5
*										

This is two Beverages 70 feet apart. If we terminate both of them and set the source of one at zero (so only one Beverage is active), the following pattern results:



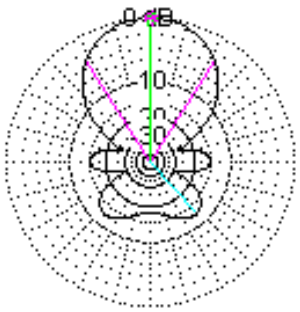
EZNEC

1.83 MHz

Azimuth Plot		Cursor Az	90.0 deg.
Elevation Angle	20.0 deg.	Gain	-11.24 dBi
Outer Ring	-11.24dBi		0.0 dBmax

Slice Max Gain	-11.24 dBi @ Az Angle = 90.0 deg.
Front/Back	18.11
Beamwidth	65.7 deg.; -3dB @ 56.8, 122.5 deg.
Sidelobe Gain	-23.33 dBi @ Az Angle = 312.0 deg.
Front/Sidelobe	12.09 dB

Now we add the second source, so both parallel Beverages are active. The pattern and gain is now:



EZNEC

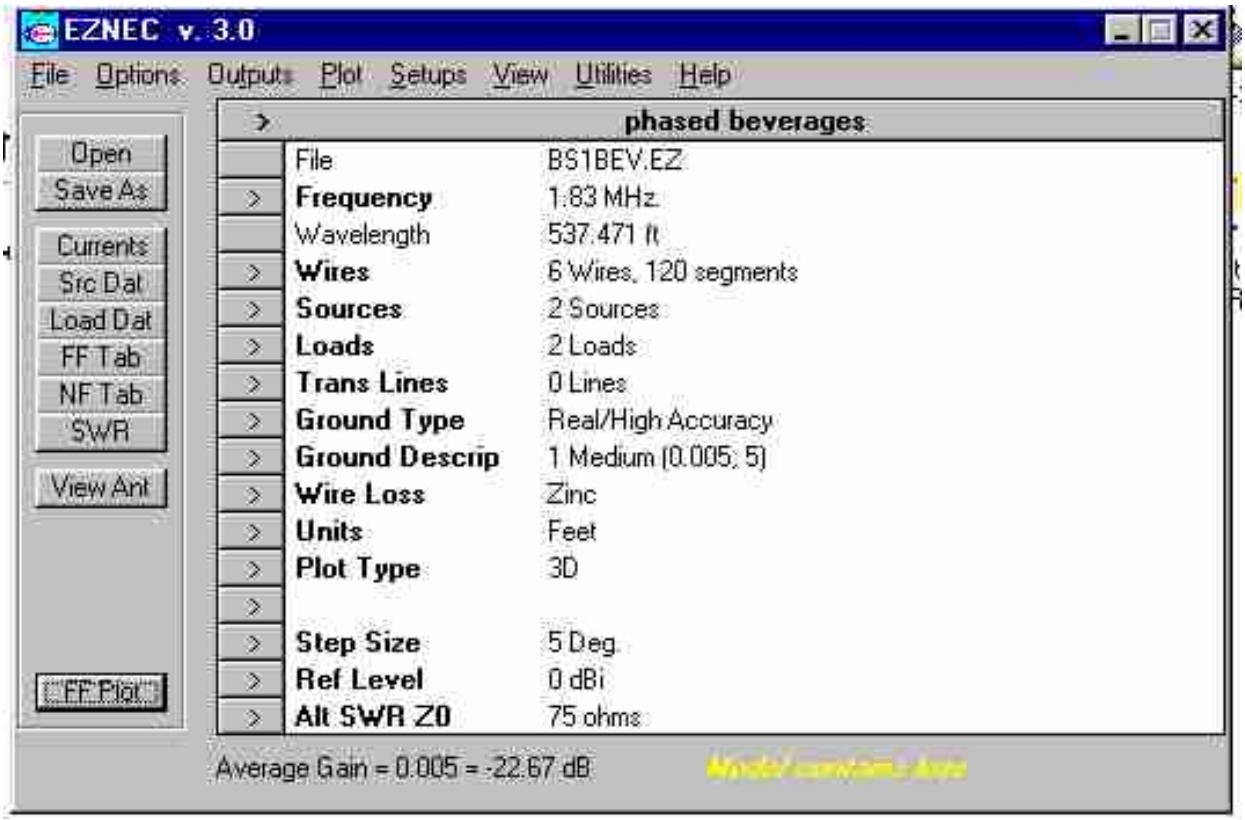
1.83 MHz

Azimuth Plot		Cursor Az	90.0 deg.
Elevation Angle	20.0 deg.	Gain	-8.2 dBi
Outer Ring	-8.2dBi		0.0 dBmax

Slice Max Gain	-8.2 dBi @ Az Angle = 90.0 deg.
Front/Back	18.11
Beamwidth	63.8 deg.; -3dB @ 58.1, 121.9 deg.
Sidelobe Gain	-20.76 dBi @ Az Angle = 312.0 deg.
Front/Sidelobe	12.56 dB

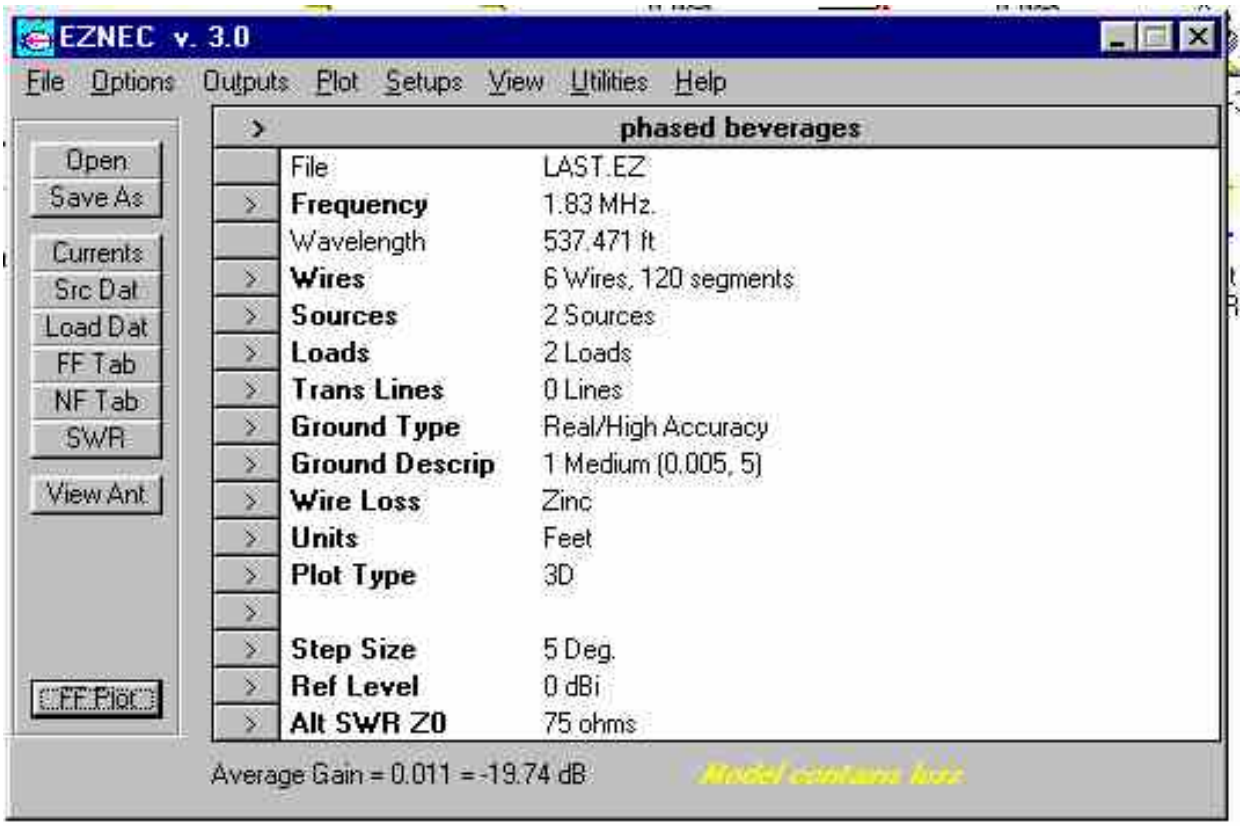
Gain is now -8.2dBi, about 3 dB better than the single wire's -11.24dBi. Did we gain any signal/noise ratio, for all the work of adding a second antenna? ***Not a bit...the S/N ratio is exactly the same because the directivity is the same.*** Since unwanted noise is external to the antenna, unless we have a change in pattern we can not have a change in S/N ratio. It is a common mistake, and absolutely incorrect, to compare gain and use gain to estimate receiving ability.

Eznec version 3.0 allows us to estimate directivity by modeling the antenna in three dimensions, and looking at the pattern. Here is the first Beverage modeled that way:



One source is set to 0 amperes, turning off one wire. Notice the "Average Gain" that appears in the lower area, -22.67 dB. If we subtract the average gain from the -11.24dBi gain at 20 degrees, we will have the ratio of response in the desired direction (from a two dimensional plot) to the overall gain of the antenna. This will be a positive number. The result is what we can consider a "receiving directivity factor" of the antenna expressed in dB. In this case, the RPF is 11.43dB.

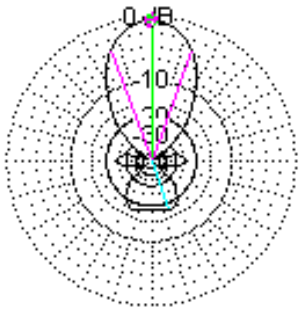
Now let's look at the two wire antenna, using the same method:



Notice I modeled this with both sources at 1 ampere, so both Beverages are active. Using the same process we used for the single source (which was the same as only having one Beverage) we see the RDF at 20 degrees is now (-8.2)-(-19.74) = 11.54db!

The effective receiving performance only increased 0.11dB, not worth the effort of adding a second antenna!

Changing spacing to 350 feet, we have the following two dimensional pattern:



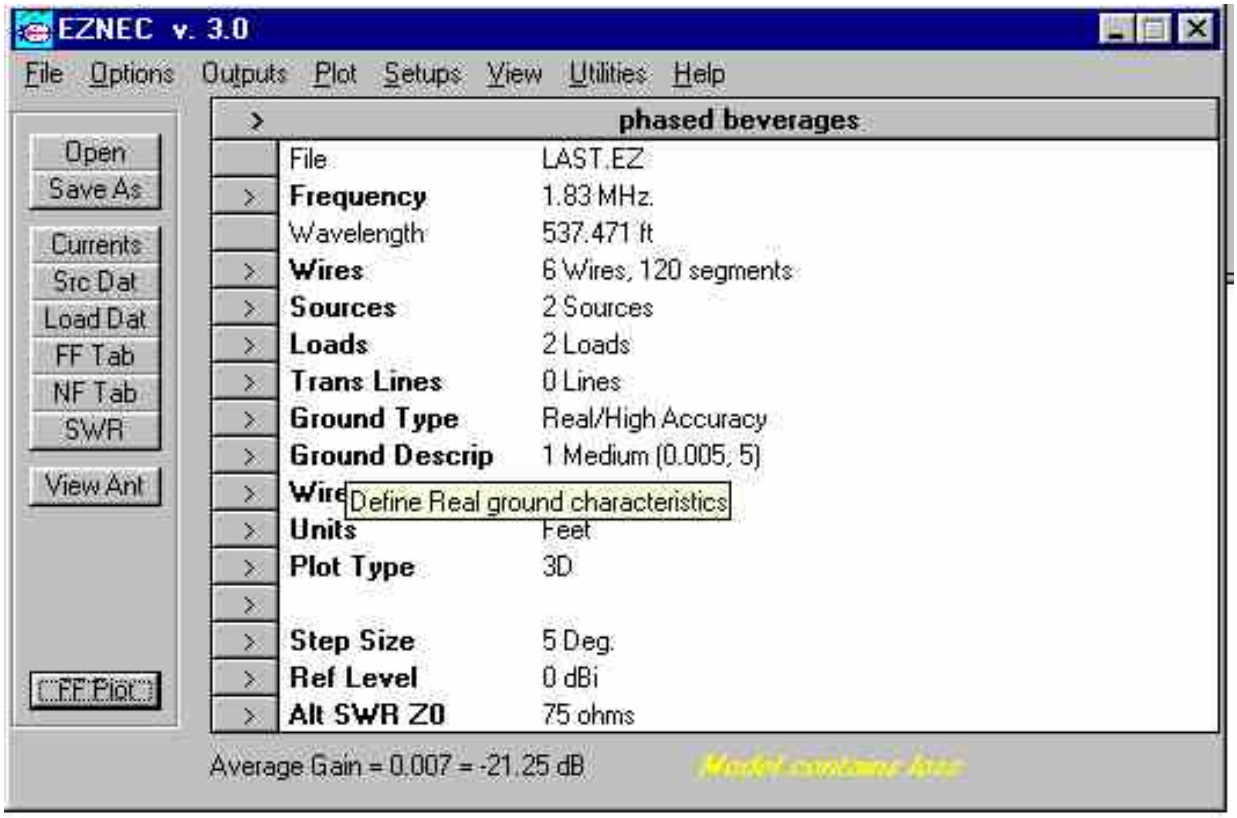
EZNEC

1.83 MHz

Azimuth Plot		Cursor Az	90.0 deg.
Elevation Angle	20.0 deg.	Gain	-7.86 dBi
Outer Ring	-7.44dBi		-0.42 dBmax

3D Max Gain	-7.44 dBi
Slice Max Gain	-7.86 dBi @ Az Angle = 90.0 deg.
Front/Back	17.83
Beamwidth	40.0 deg.; -3dB @ 70.0, 110.0 deg.
Sidelobe Gain	-25.1 dBi @ Az Angle = 290.0 deg.
Front/Sidelobe	17.24 dB

.....and the following data in the main menu of Eznec after modeling a three dimension plot.....



Taking (-7.44)-(-21.25) we now have a RDF of 13.81dB at a wave angle of 20 degrees. Comparing the three systems:

Antenna	Gain @ desired elev & azmth	Average gain	Rcvg Directivity Factor
single Beverage	-11.24dBi	-22.67dB	11.43dB
70 ft spaced Beverages	-8.2dBi	-19.74dB	11.54dB (+.11dB RDF)
350 ft spaced Beverages	-7.44dBi	-21.25dB	13.81dB (+2.38dB RDF)

Summary

Until Eznec's Windows version came along, it was very difficult to estimate performance. We often made mistakes, because we only compared gain. Using the above method, we can estimate antenna performance for evenly distributed noise. If there is no change in the Receiving Directivity Factor for similar pattern antennas, we can be sure we haven't changed overall performance for distant signal and noise sources.

There are a few things we have to keep in mind:

1.) If noise is not evenly distributed (which is often the case) performance will depend on the gain difference between desired signal direction (azimuth and elevation) to gain in the direction of noise(s). A 20dB null on the noise compared to gain in the desired signal direction will actually improve S/N ratio by 20 dB, if the noise from the null direction totally dominates all other noises.

2.) If noise arrives primarily from the same direction and angle as the desired signal (and assuming polarization of signals and noise is the same), there will be no S/N improvement.

3.) If noise originates in the near field of the antenna, all bets are off. Anything can happen.

All in all, the above method gives us a rough idea how various antennas compare in a environment with reasonably even noise distribution.

Small Vertical Arrays

[Home] [Up] [Receiving 4-Square]

Small Vertical Arrays

While this is mainly intended as a guide to help install arrays, I have stock of all components in these antennas. If you are really stuck, I can provide turn-key systems that are tested and tuned, include phase-matched cables and phasing systems. I can supply custom arrays of up to eight directions using up to 16-elements from stock components and assemblies, tested on reliable commercial test equipment.

Never Pick Gain, F/B, or Take-off Angle as a Parameter for Weak Signal Receiving!

Arrays of small verticals provide excellent receiving performance when systems are designed and installed properly. As pointed out in other articles, there are key differences between receiving and transmitting systems. Parameters considered important in large transmitting systems are sometimes far from optimum in receiving applications, especially systems using small antennas. One key item is gain. Contrary to common opinion, more gain does not translate to better receiving, once the receiver is limited by external noise reaching the receiver. The key parameter is directivity, which may or may not have a parallel relationship with gain. Gain includes efficiency, directivity excludes efficiency. This important consideration applies to systems discussed below.

Noise rarely comes from one direction, or a narrow range of directions. With that in mind, antennas will be compared by a receiving directivity factor calculated with Eznec's (version 3) average gain. Removing efficiency from the equation allows direct comparison of receiving systems since directivity, not gain, is the determining factor in selecting an HF or LF receiving array. S/N ratio is very dependent on nulling or rejecting unwanted signals or noise.

It is important to locate receiving antennas as far as possible from radiators or re-radiators of unwanted signals and noise. Always remember noise has exactly the same characteristics, so far as an antenna is concerned, as signals from *intentional* transmitters. There is no way to sort "good signals" from "bad noise" except through the directional characteristics of your receiving antenna. Noise is not electric field dominant. Desired signals are not magnetic field dominant. The field impedances are all the same except near the antenna or source, and near the antenna or source coupling to multiple unknown sources is largely unpredictable. The truth is, it is anyone's guess what field impedance is actually best!

A small loop antenna, at a distance of a few meters, is magnetic field dominant. Here is an important fact few people, outside of those who work with nearfield systems know. At a distance of an eighth wave and larger a small magnetic loop becomes electric field dominant! Conversely, a small voltage probe becomes magnetic field dominant at about the same distance! The fields reverse dominance because of phase shift between the fields as the radiation fields start to overtake the induction fields.

Susceptibility to unwanted near-field and induction field coupling between receiving antennas and large transmitting antennas or noise sources is obviously largely unpredictable, although many problems can be corrected through changes in antenna placement or detuning structures and/or canceling the radiation from surrounding structures. When dealing with nulls, a modest amount of re-radiation from surrounding conductors can make a large difference in system performance, but the key is to watch overall directivity. Anything that reduces directivity will reduce the S/N ratio of a receiving system. The reduction is directly by the amount of null reduction ***ONLY*** when noise comes very predominantly from within the area encompassed by the deeper areas of null. ***We always, unless we have noise from a specific direction and angle all of the time, want a wider more modest depth null in favor of having a sharp point with a deep null and a wide-nosed response.***

One of my best arrays on Europe is only a few hundred feet from a transmitting four-square, clearly in the near field of the four-square. There is no detectable influence on this array when it "looks away" from the four-square, although there is a quite noticeable reduction of F/B ratio when beaming back into my transmitting antennas. The null to the SW is very deep, in excess of 35dB, regardless of four-square tuning. The converse is not true, the null NE when looking SW is only 10-15dB deep unless I detune the antennas. Yet the lower null depth barely causes a detectable noise increase, because the directivity does not change much. It is only when a very dominant noise (or QRM) arrives from the NE that this array becomes almost useless (compared to other arrays with deeper nulls in the NE direction). Of course detuning the transmitting antennas completely restores southwest performance, even though spacing is close.

Building Blocks For Arrays Using Verticals

There are four key areas overlooked in most published receiving arrays using small elements. Common oversights in element and phasing system design cause the antenna to be more critical to adjust, less stable, and provide a poorer pattern even if array elements happen to be working.

The most aspects are:

1.) Elements must be very low Q (wide bandwidth). They should have little reactance change with frequency or weather.

2.) Elements must be heavily swamped with loss. Mutual coupling effects must not change

element impedance.

3.) The phasing system must be designed for the impedances that actually appear at the phasing system. Transmitting-type boxes, because the systems have low loss, must have high mutual coupling effects and radically different element impedances. By definition, any given system *must* be seriously flawed in one application or the other!

4.) The phasing system must be stable and have very broad bandwidth characteristics.

Before building an array, we must select an element style that we can live with. Eznec and other programs have made this process simple.

The Basic Element

Length

A receiving array element should be as short as possible but still maintain sufficient sensitivity (gain) to ensure external noise exceeds receiver noise. My 160 Meter Band elements are about 20-foot vertical height. I've found all of my arrays with elements that height have overall sensitivities (gain) on par with my Beverage antennas, and that the signal levels are very easy to deal with.

Keep in mind that our systems require more gain as receiver selectivity is decreased. The noise floor drops in direct proportion to selectivity increase, and a change from 2.5 kHz selectivity to 250 Hz selectivity reduces noise voltage or power by 10dB. Signal level, however, remains the same for the same transmitted power within our receiver's bandwidth.

20-foot tall elements with reasonable element spacing always provide more than enough signal to operate through nearly 1/2 mile of F-11 CATV cable (similar to RG-11 or RG-8 cables in size) at my very quiet rural location ***before amplification.*** 3-5dB noise figure amplifiers are adequate to establish S/N ratio by arriving noise even when placed after the signals travel through those long cable lengths. To gauge my noise floor, a standard FT1000 with preamplifier "on" on my 200-foot vertical has less than S3 noise in the SSB position at mid-day. Unless you have less noon-time noise than that, you will certainly not require an amplifier at the antenna! The only exception is if you have very close element spacing, because close spacing decreases antenna sensitivity (gain).

Mechanical and Electrical Concerns

I use two basic mechanical configurations of elements. One system uses steel electrical conduit on 1/2-inch fiberglass rods (rods driven directly into the ground) with four "loading" wires, while my other system uses stronger chain link fence top-rail mounted on wooden posts. Both systems handled weather from ice storms (where the antennas were coated with almost a radial inch of ice) to high winds without problems. I have had no electrical connection problems, and no weather

detuning problems. ***It is not necessary to "insulate" the antennas mounted on wooden posts because system Q is very low and impedances are modest.*** Wet posts will have no deleterious effect on performance, although I would always place the loading system (and the base of the verticals) above snow depth. ***It is not necessary to use high-Q loading inductors.*** The only requirement is that inductors remain relatively stable in characteristics with climatic changes.

My systems are normalized at 75- ohms for several reasons:

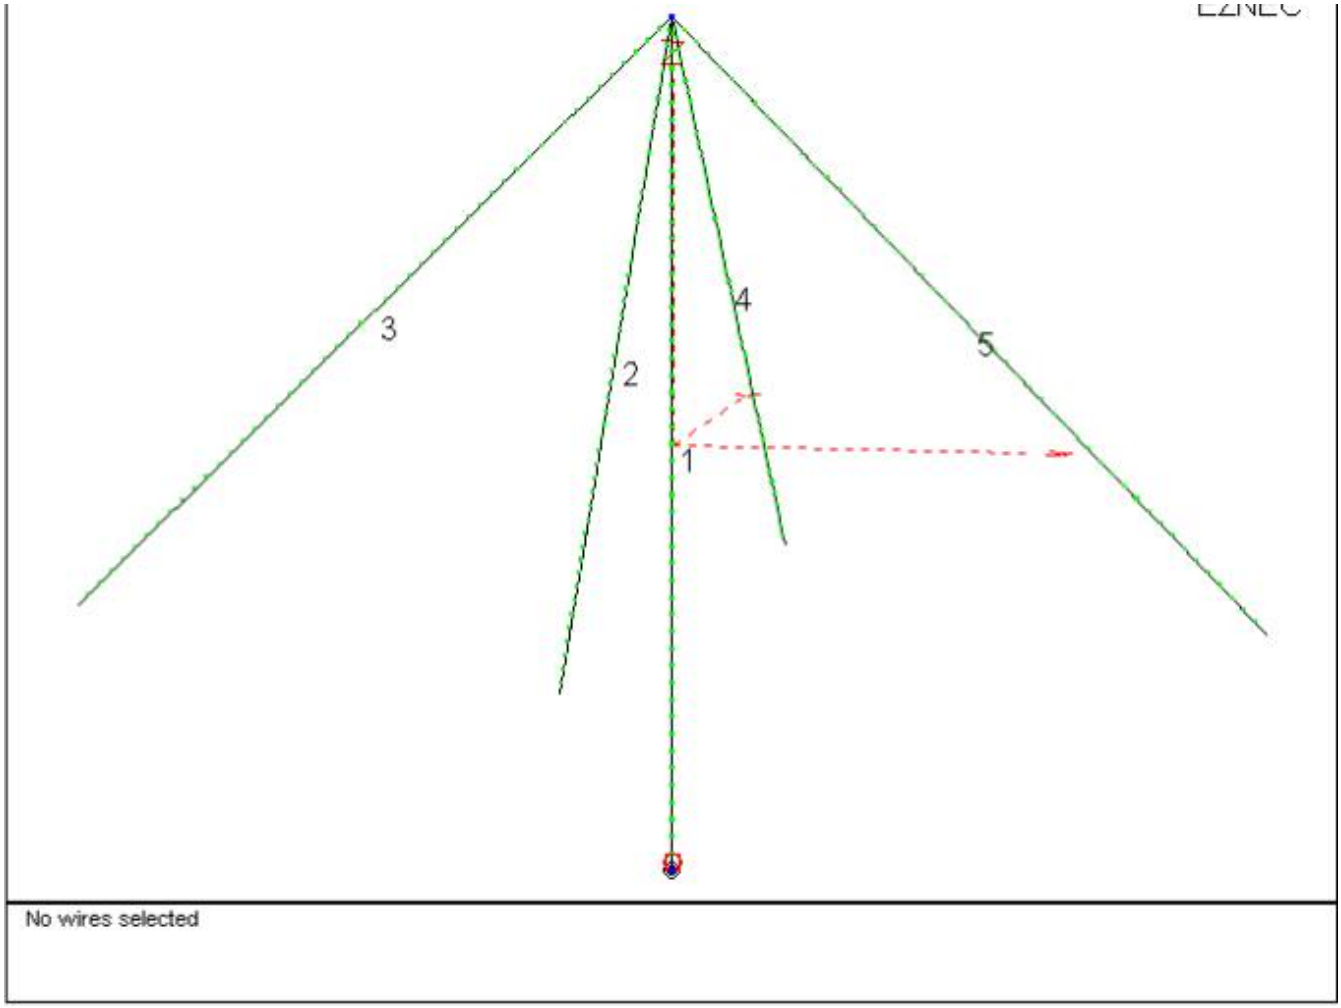
1.) 75-ohm feed produces a wider VSWR bandwidth than 50-ohm feed systems, the swamping resistive losses are about 50% higher.

2.) CATV cable suitable for direct burial is inexpensive and connectors are inexpensive, reliable, and easy to install.

I use F6 flooded CATV cable for local cables in arrays, and F11 (RG-11 size) or 5/8" flooded CATV cable for trunk leads. It is NOT necessary to use double or triple shielded cable, you gain nothing. But you do want to use good quality cable that will last years without weather changes.

Practical Verticals

My rectangular arrays use elements with four 20 foot long #16 loading wires, insulated by fishing line used to support the wires. I terminate the guying 20 feet out from the base of the antenna. The entire structure is self-resonant on 80 meters. The large "hat" makes current essentially uniform throughout the vertical element while minimizing unwanted sensitivity to high angle radiation, and also supports the elements.



Eznec Download

Eznec RXvrhat

This structure is base loaded with a series L/R combination of approximately 30uH and contains a ***total*** loss resistance of 75 ohms. This resistance includes resistive losses related to inductor Q, as well as ground system loss resistance. I used small molded choke inductors, although other components will work. My system requires only 56 ohms of lumped resistance to bring base resistance to 75 ohms.

Each element requires a ***stable*** ground system. Ground loss is not important, but long and short term loss stability with climatic changes is very important. I use a minimum of four buried radials, each 1/8- to 1/4-wl long, on each element. Always place radials directly under each hat wire. Do ***NOT*** use small elevated radial systems or grossly non-symmetrical radial systems! Elevated radials will reduce VSWR bandwidth of the array, introducing unwanted phase shift. They also make the system susceptible to high angle signals, and are more susceptible to common-mode noise on feedlines and other conductors around the antenna than buried or earthed radials. It is not necessary to bury radials, but if the radials aren't buried multiple ground rods are a good idea. The feedline should also be buried or if laid on the ground "choked" with high permeability ferrite beads near

each element.

Feedline Length

Unlike transmitting arrays, it is not necessary to use odd-quarter wave lines. It might be a tiny bit better if you use exact multiples of 1/4 wl, but even 1/2 wl lines work perfectly fine. Multiples of 1/4 wl work better in cases where you might fail to match antenna impedances to the transmission lines correctly. The reason of this is that phase shift in a transmission line is independent of line SWR when the feedline is ANY multiple of 90-degrees. With ANY phasing system having standing waves on the feedline, you can properly feed the system by supplying equal currents to any feedline an even multiple of 1/2 wl. Any feedline having odd multiples of 1/4 wl requires equal voltages feeding the line. The phasing systems I use, unlike transmitting systems, are designed to supply either equal voltages or equal currents! The proper ratio adjustments are easily made. You will, however, have slightly less phase error if you use any multiple of 1/4 wl when the lines are mismatched.

Beware that foam cables are NOT .82 or any other standard velocity factor. They range from the .70 range up to around .92 in velocity factor, depending on the ratio of gas to material in the dielectric. Only solid dielectric cable are predictable without measuring the cable.

Tuning the Elements

After careful planning and selecting the type of array, you should install the elements and the array's internal feedlines. Each element must be evaluated with an antenna analyzer that measures resistance and reactance. Connect the analyzer at the element's feedpoint, and follow these steps:

1.) Using a two foot long or less jumper cable, measure the antenna without a loading coil. Check the resonance for predicted values. It should be within several percent of the modeled self-resonant frequency.

2.) Touch the shield of the feedline in the array to the case of the analyzer or the vertical's ground. If impedance changes more than five percent, you need a better ground system.

3.) Install the loading inductance predicted, and sweep the desired frequency range for lowest SWR and zero reactance. If your analyzer is working correctly the lowest SWR will be at zero reactance, or very close to that frequency.

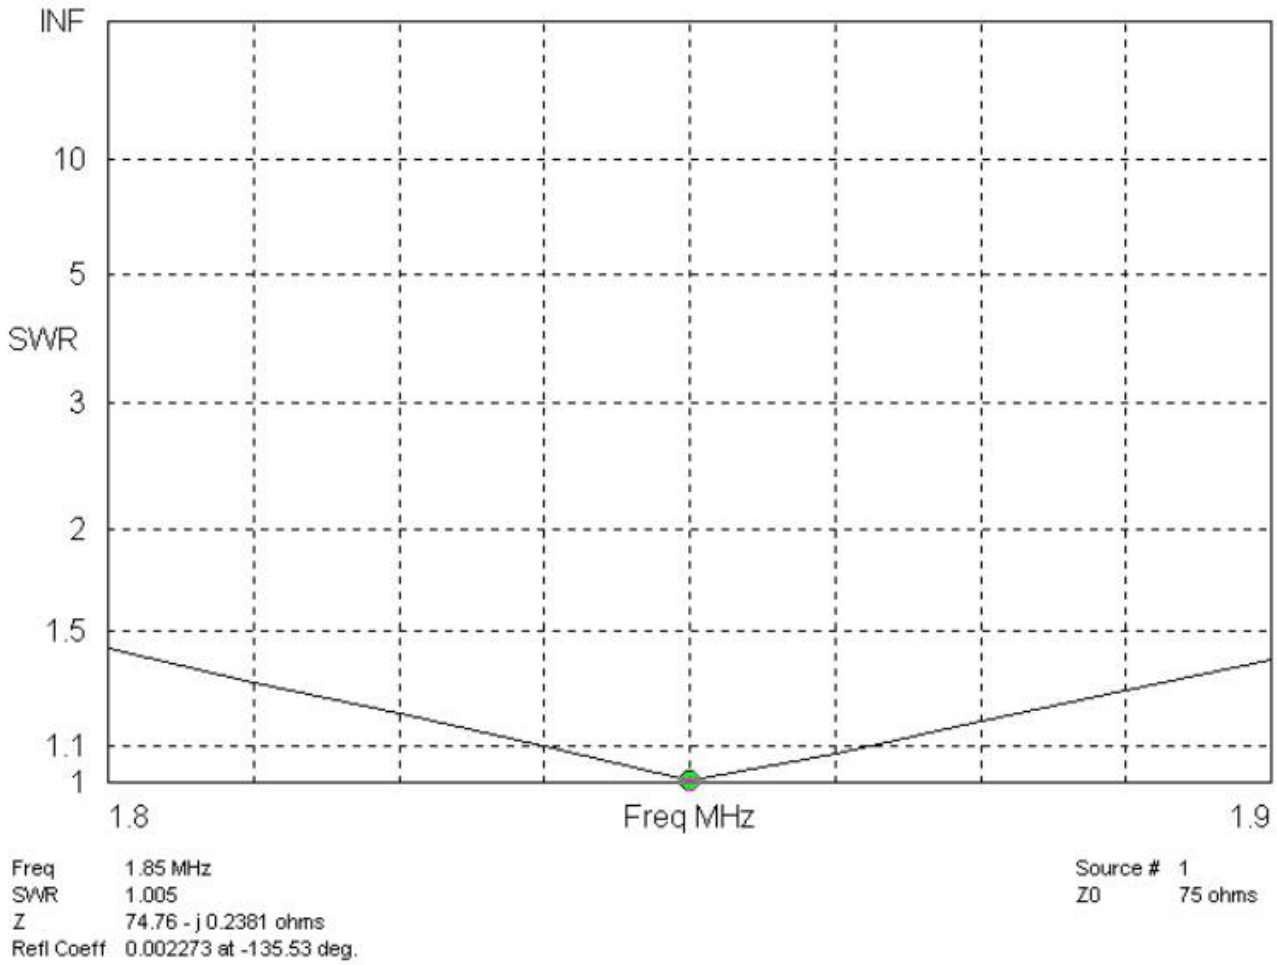
4.) Fine tune the inductance to make the antenna resonant at the desired frequency. You do this by adding or removing small inductors in series with a main inductor, or by adding or removing turns. Fine adjustments can be made by squeezing or spreading turns on the main loading coil's form, if it is a toroid or non-potted construction.

5.) Add enough series resistance to bring antenna impedance to 75 ohms at resonance (assuming you use 75 ohm cables).

6.) Check the feedpoint again for stability by connecting and disconnecting the shield of the unused array transmission line from the case of the analyzer or the ground system connection point. Again it should remain within 5%, or you need to improve the ground. If you can not improve the ground, you will have to isolate the ground by using a choke balun on the feedline.

Once one element is tested and proven, you should be able to duplicate that element with near-perfect results. I remove the matching system and take it to the test bench, and find a series C/R combination that produces the same resonant frequency. Multiple networks can be constructed on the test bench, and then moved to each element. My elements normally fall within 20 kHz of each other, any large difference in impedance or resonant frequency is a sign of potential performance problems.

Here is the 75 ohm SWR plot of this element:



Bandwidth is excellent, and sensitivity (gain) including all losses is -13 dBi. This element is almost perfect for use in small receiving arrays, since signal level and bandwidth are very good. Because of

the large amount of capacitance and the resistance loading, the element will not significantly change phase or sensitivity with frequency over the entire 160-meter band! In addition, it has very little response to high angle signals (and noise).

In circular arrays, hat wires can be extended to ~35 feet with only three loading wires used. My 350-foot diameter arrays position two loading wires (using tarred nylon fishing net string for insulation) in line with the perimeter of the antennas, while the third wire on each element is used to "pull out" from the array center. This tensions the perimeter wires and guys the entire structure. Even though hat wires are not spaced exactly 120 degrees apart, the effects on sensitivity to high angle signals are insignificant.

Arrays of Elements

Arrays of short verticals have both advantages and disadvantages compared to other antennas, such as Beverages and elongated loops. The comparison is:

	Elongated Loops	Beverages	Verticals and Wide-spaced Beverages
Area required	small <3/8-wl	large >1-wl	1/2- to 3-wl
Effort	modest	minimal	modest to large
Pattern	worse than 2-el vert, poorest	about same as 4-sq, middle	middle to best
Bandwidth	multiple bands	multiple bands	single/multiple band
Signal level	Low	Modest	Modest

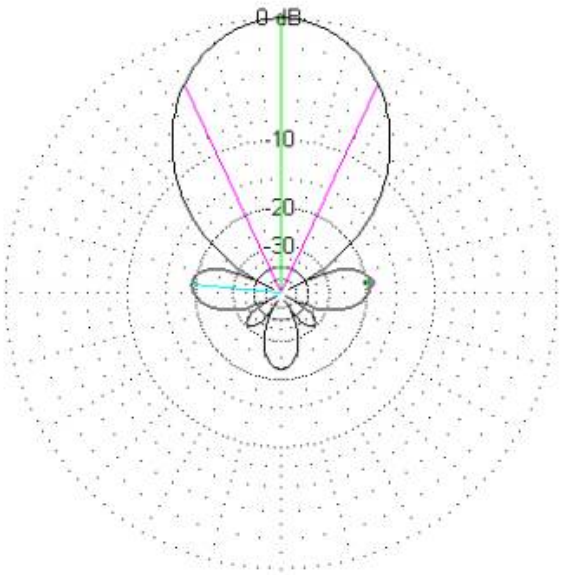
The primary advantage of arrays of short vertical arrays are excellent pattern and reasonable signal levels. Unlike balanced elongated loop systems, they are non-critical for feedline routing (other than keeping the feedline on the ground), matching transformers (transformers are not even required!), and earth conditions around the antenna. They have the same approximate output as simple Beverage arrays, and can still be made to work over very wide frequency ranges. The disadvantage is they are more complex, and require bandswitching to work on two bands.

Note: *I am finishing the layout of an FET amplified array that will allow ten-foot non-hat verticals that work from VLF to 80-meters and above, with the same basic directional characteristics over that range without switching.*

Broadside-Endfire Array (soon to be an

article)

The most directive four-element antenna possible is a broadside-endfire array. I use 70 feet endfire spacing and 330 feet broadside spacing between endfire cells, and get a pattern like this:



This array has an RDF of 13dB (two dB more than the large 4-square), and a HPBW of 47 degrees! The performance is similar to a circular array with eight elements in a 350 foot diameter circle, that allows directional selection every 45 degrees. The circular array uses techniques similar to the broadside-endfire, except the relay system is modified to switch eight antennas.

My next planned array is an array of four four-squares modified to fire eight directions, with 500 foot center point separation between each four-square array. I've found that 1000 feet is about the maximum physical separation allowing signals to be reliably combined on 160-meters. Arrays occupying areas larger than 2 wavelengths have far too much random phase and amplitude shift, preventing reliable combining of signals.

Receiving 4-Square

[Home] [Up]

Receiving 4-Square Array

Four small elements in a square layout, between 1/8- and 1/4-wl side length, can be used to form a four- direction array. Performance will be approximately equal to a 1 wl Beverage. The elements can be similar to those described in small vertical arrays.

As mentioned earlier, conventional transmitting phasing systems might be easy to obtain, but they are *NOT correct* when used in receiving arrays with short elements. Since each element has the same impedance in a lossy receiving array, the phasing unit "sees" 75-ohms from each element. When the antenna presents equal impedances at each port, the phasing system should source equal power at each port (which is also equal voltage and equal current)!

Use of a single 180-degree phase-inversion transformer for the center element along with delay lines approximately equal to effective element spacing create a very wide bandwidth phasing system. ***The phasing system is usable over at least one octave with appropriate element spacing and design!***

Upper and Lower Frequency Limits

Assuming you have ***broadband active elements*** of good design, the array will be useful when array side-length ranges from ~1/16wl spacing to 1/3 wl. The phasing system and delay lines are usable at any frequency, but the array spatial delay will provide useful end-fire patterns where array side-length is approximately 1/3-wl or longer. The appearance of grating lobes and dimpling of the front lobe limits upper frequency usefulness.

As frequency is decreased, ***array sensitivity*** eventually drops to unusable levels. The effect comes from two effects:

- Elements become electrically shorter, reducing element and array sensitivity.
- Element spacing becomes smaller in electrical degrees, reducing array sensitivity.

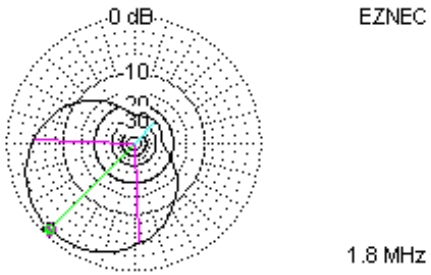
Shorter elements, in electrical degrees, mean less sensitivity. Sensitivity obviously must drop with frequency, for a fixed element height.

Element nulling always fully subtracts with reduced spacing. With any fixed spacing distance, a lower frequency array sensitivity limit appears when "forward" voltage phase vectors become too close to -180 degrees.

Element and array phasing-sensitivity eventually push the antenna into the receiver system's noise-floor, and this becomes the lower frequency cutoff. Pattern is maintained down to that cut-off, assuming the elements remain matched to the feedlines.

Even without broadband active elements, multiband or broadband arrays are practical with ONE fixed element group and a single unchanged phasing system. Element resonance and resistance would be the only parameter that would require switching.

Pattern with 70- foot per side spacing, on 1.8 MHz is:

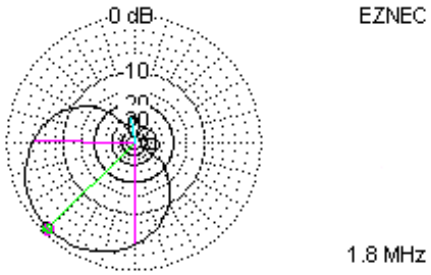


Azimuth Plot		Cursor Az	225.0 deg.
Elevation Angle	20.0 deg.	Gain	-11.51 dBi
Outer Ring	-10.59dBi		-0.92 dBmax

3D Max Gain	-10.59 dBi
Slice Max Gain	-11.51 dBi @ Az Angle = 225.0 deg.
Front/Back	23.19
Beamwidth	95.0 deg.; -3dB @ 177.5, 272.5 deg.
Sidelobe Gain	-34.7 dBi @ Az Angle = 45.0 deg.
Front/Sidelobe	23.19 dB

There is a slight distribution problem with smaller size arrays because of mutual coupling. This can be compensated if 1/4-wl feedlines are used on the lowest band with the phasing coupler shown. RDF (receiving directivity factor) is around 10dB. This is about 3dB higher than the best single Pennant antennas, and on par with a very long Beverage.

If the array is 140 foot per side, the pattern is:

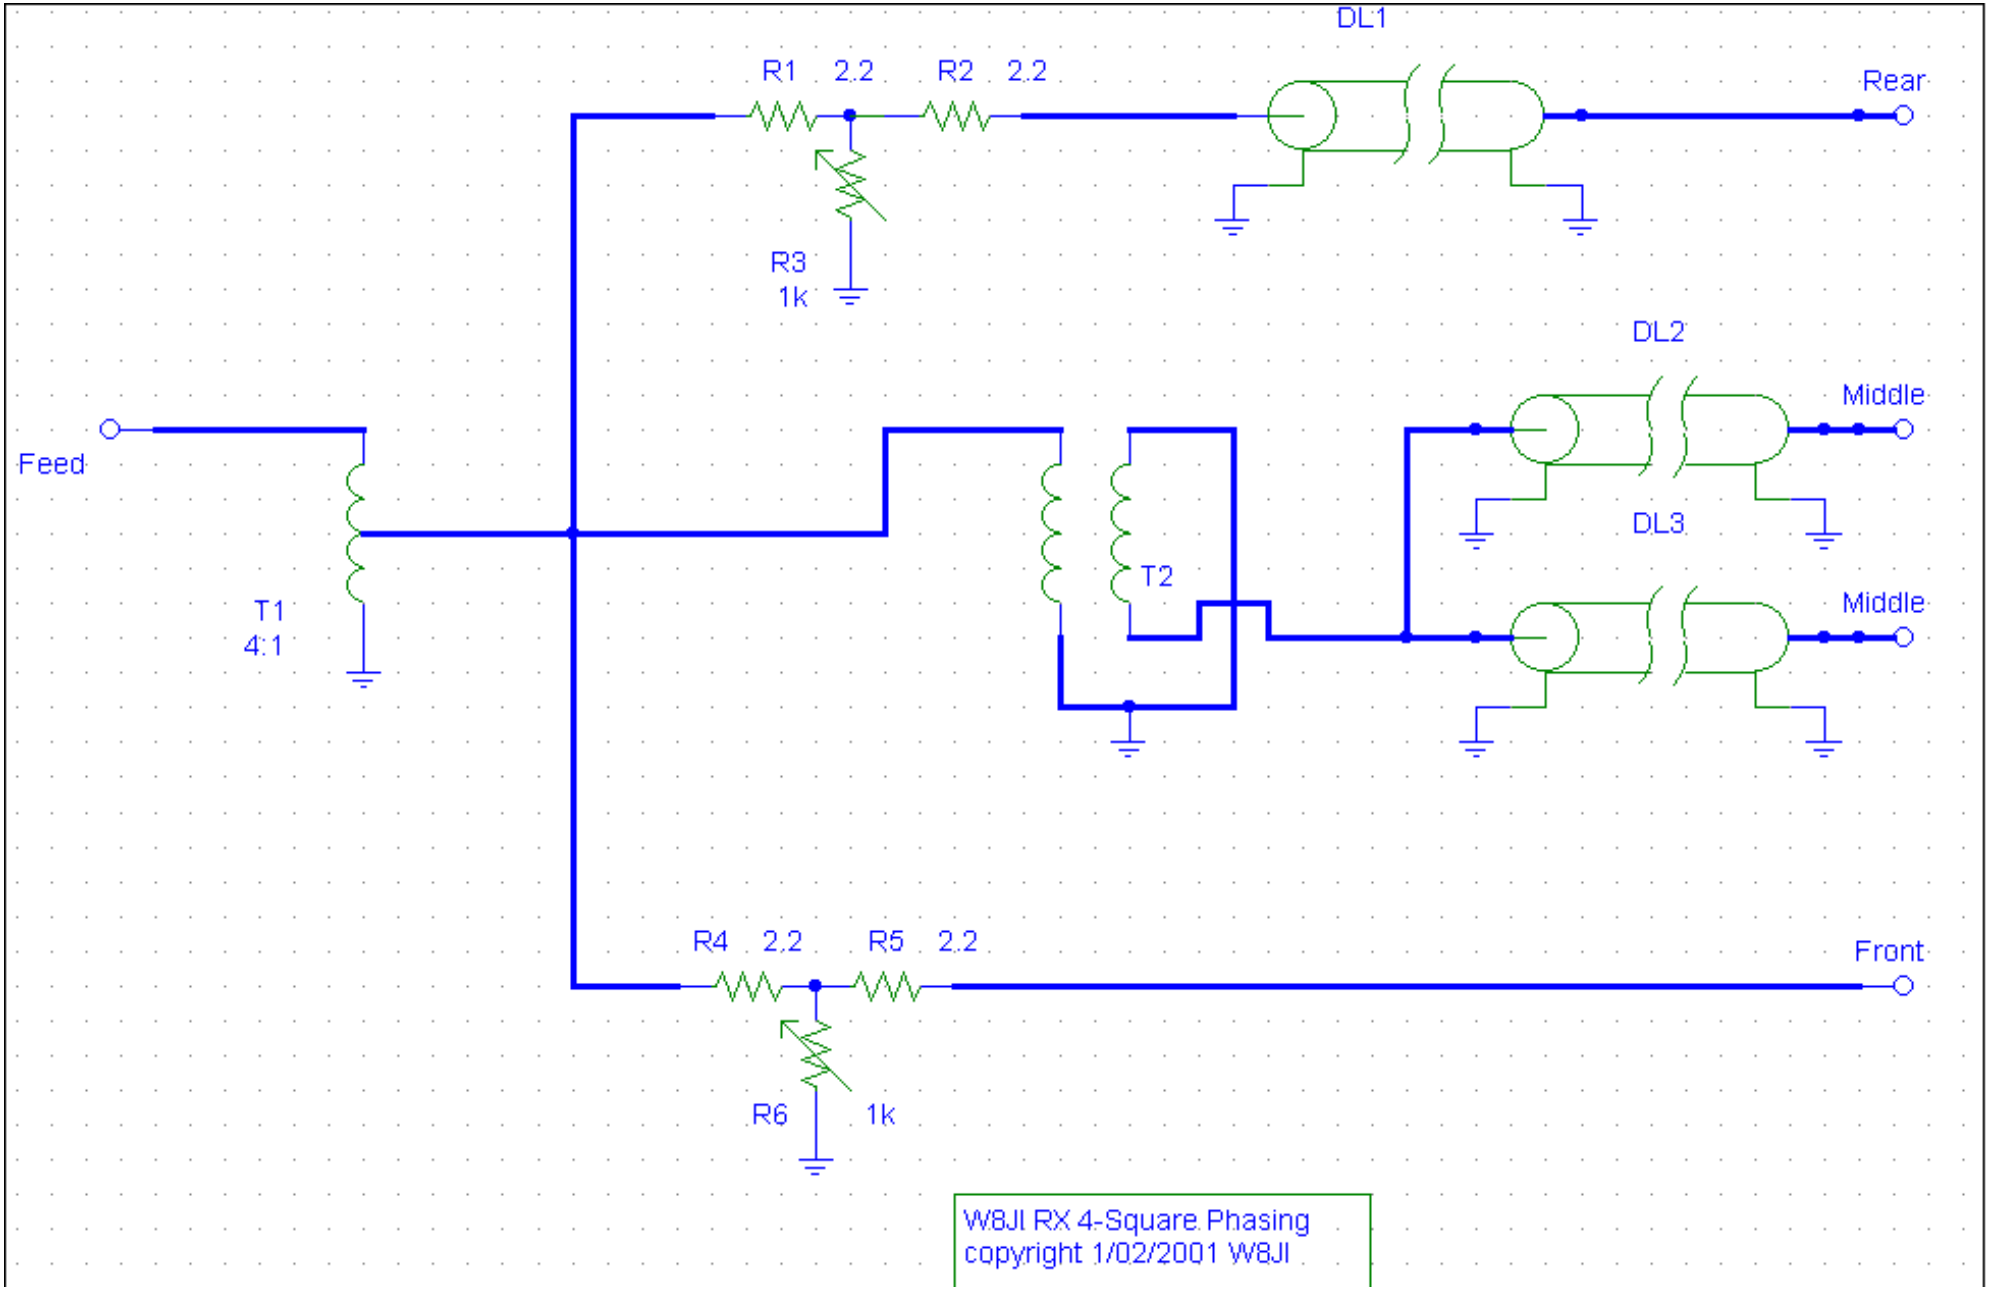


Azimuth Plot		Cursor Az	225.0 deg.
Elevation Angle	20.0 deg.	Gain	-6.88 dBi
Outer Ring	-6.14dBi		-0.74 dBmax

3D Max Gain	-6.14 dBi
Slice Max Gain	-6.88 dBi @ Az Angle = 225.0 deg.
Front/Back	31.17
Beamwidth	91.2 deg.; -3dB @ 179.4, 270.6 deg.
Sidelobe Gain	-33.16 dBi @ Az Angle = 95.0 deg.
Front/Sidelobe	26.28 dB

Doubling array size only provides about 1dB more directivity (note that HPBW only changes a few degrees), although signal level increases about 4dB! This array would make an ideal portable antenna for limited-space two-band operation, a SPDT relay at each antenna could be used to switch loading networks for each band.

The phasing system should look like this:



T1 is a 4:1 impedance ratio (2:1 turns ratio) auto transformer. A suitable 100 kHz to 20 MHz transformer would use 5 to 10 turns of #22 wire (wire size is not critical) in a twisted pair, connected with opposite ends in series. A Fair Rite Products 2873000202 core is recommended, and available from me if you can not find one. (A turn is one complete pass of the twisted wires through both holes in the binocular core). This transformer steps the 18.75-ohm impedance, produced by paralleling four 75-ohm lines, up to the feedline output impedance of 75-ohms.

T2 is a 1:1 ratio phase inverting transformer. Wire size is not critical as long as the winding fits the core. A good choice is a twisted pair of #22 wires, making five to ten passes through a Fair Rite Products 2873000202 core. This is the proper core! This is the same transformer used in T1, with a different circuit connection. Again, I will help you with complete tested transformers if you can not locate materials.

A low attenuation value ~ 75-ohm attenuator is inserted in the line to the front antenna and rear antennas. This attenuator compensates for slightly different losses in transformers and delay lines. Although it absolutely isn't a requirement when using wider spacings (1/4 wl) with proper transformer and element construction and materials, they can be used to "tweak" the array to extremely high F/B ratios. The attenuators become more and more important as the array becomes smaller or less perfectly constructed and tuned.

DL1 should be slightly shorter electrically than the (around .9 times the) corner-to-corner distance across the array (diagonal distance). This line MUST be the same impedance as the element feedlines.

DL2 and DL3 are exactly half the length of DL1. These lines must be the same impedance as the array's element feedlines.

NOTE: *The delay lines are slightly shorter than element spacing. This elevates the null a small amount above the horizon directly off the rear, forming a cone-shaped null reaching the ground an equal number of degrees either side of the rear. I generally use about 10-20 degrees less than the element physical separation distance of a line running between diagonal corners of the array for delay lines on the highest band.*

If you model this antenna, remember phase is inverted. Effective phase shift from the delay line actually becomes a phase lead that is 180- degrees around a circle from the delay you might expect. For example, a 90- degree delay line actually provides 90- degrees phase advance (or -270 delay) because of the inversion, while a 60- degree delay line provides 120- degrees advance (which is the same as 240-degree delay) .

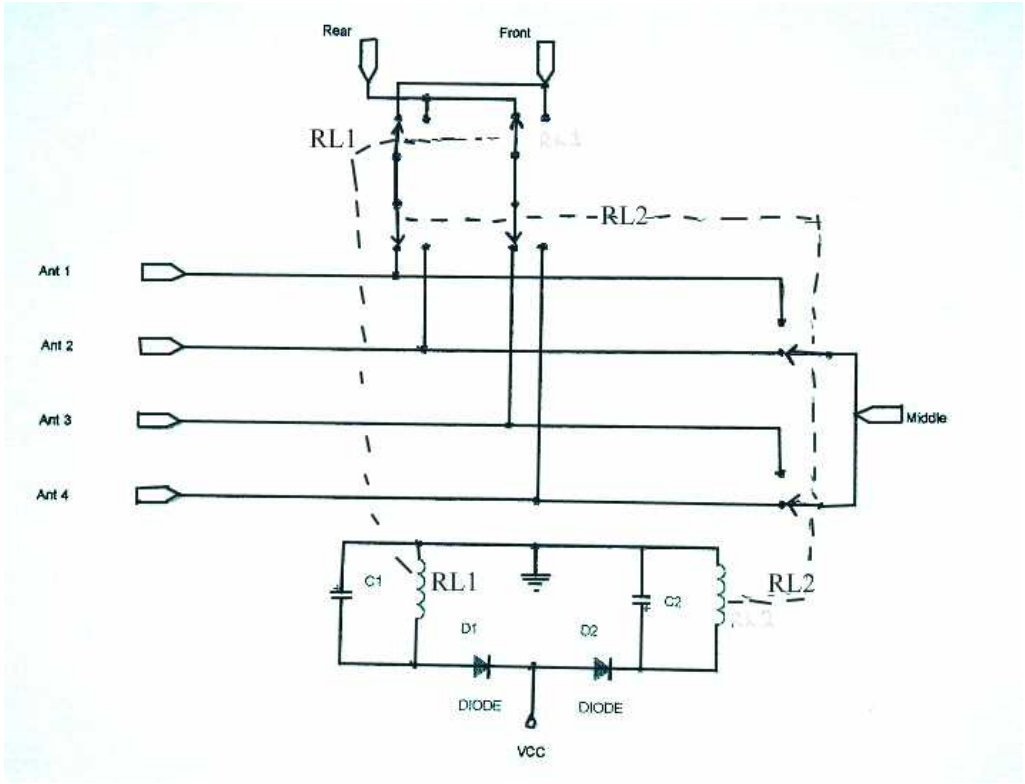
This "trick" causes phase-shift to track changes in element spacing with frequency, allowing the same delay line to work on multiple bands. The delay always is the proper length, which is slightly shorter than element spacing. It also causes the array to fire in the direction of the common-point element, since the feedline attachment point is the direction of lagging phase.

See the Crossfire phasing article.

Why Are the Lines nearly equal to the spacing for the elements they serve?

For an explanation, see the Cross-fire phasing page on this site!

The following system is useful for electrically rotating the array:



The antenna ports on the left from top to bottom start at the front of the antenna and from a top view go clockwise around the antenna. Zero voltage is position one at zero degrees, + is 90 degrees CW, - is 180 degrees, and AC is 270 degrees.

RL2 can be two separate DPDT relays with coils in parallel. I use 12V DIP relays with 220 uF 25v capacitors across relay coils. Any common silicon power rectifier will work for the diodes. If you have high RF levels near the control line, bypass it with a .1uF disc 50v capacitor. I route control signals through the feedline, but you must not have water in the feedline or poor shield connections to do that!

If you can not find parts, I have parts. I'm in the process of ordering commercial PC boards right now, to supply turn-key components kits or systems. I'd be happy to help with anything you need, as these projects move along.

W8JI_RX_ANTS

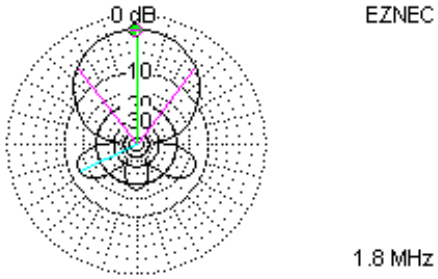
[Home] [Up]

W8JI's Receiving Antennas

Conventional Beverage's ~580 feet long. Currently only two left, all others removed over the past two years due to lack of performance.

Specifications @ 15 degree wave angle:

Every 45 degrees from NE to NW. Directivity factor 7.29 dB, Half-power Beamwidth 78 degrees

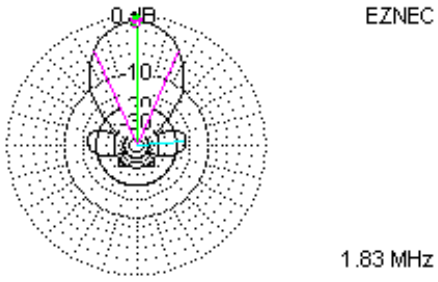


Arrays of Broadside Beverages 780 x 350 feet. Currently two duplicate systems (spaced ~1500 feet apart with antennas NE, E, SE, S, SW, W, and NW (28 individual Beverages make up this system):

Specifications @ 15 degree wave angle:

Europe, Africa, Asia/Japan, South America, ZL/South Pacific, VK/Pacific.

Directivity factor 13.8 dB, Half-power Beamwidth 42 degrees

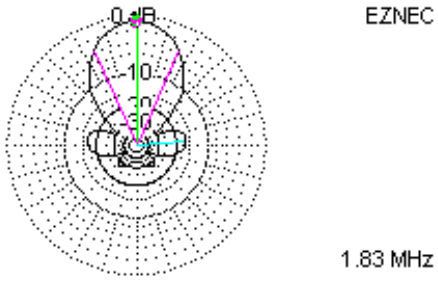


Arrays of Verticals 70 x 330 feet. One system:

Specifications @ 15 degree wave angle:

ZL/South Pacific, Europe.

Directivity factor 13 dB, Half-power Beamwidth 47 degrees



350-foot diameter circular eight-element array. One system:

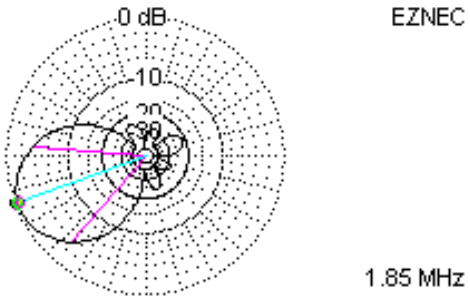
This array covers eight directions, spaced every 45 degrees around the compass. It has 22-foot tall top and base loaded elements. Over 1/4 mile of 75-ohm cable is used in this array (and 2500 feet of cable to reach the house).

Each antenna element is made from 1-1/2 inch chain link fence top rail. The fence rail hinges on these wooden posts with a bolt through the bottom of the vertical rail. The top of the wooden post has a steel pin that fits in a hole in the metal railing, and it is lashed in place.

Specifications @ 15 degree wave angle:

All compass directions. Electrically rotatable.

Directivity factor 12.1 dB, Half-power Beamwidth 53 degrees



RADIATED and CONDUCTED NOISE

[Home] [Up]

Switching mode power supplies, light dimmers, computer networking systems, poor connections that arc, and other "accidental transmitters" that either switch or spark can create considerable RF energy on wiring. It is helpful, when attempting to reduce such noise, that we understand how the noise travels from the source into the receiving system.

Definition of a Source

Let's consider the problematic device a "thing in a black-box", and call it the "***source"***. It doesn't matter if it is a computer, the spark in an electric fence, a light dimmer, or a doorbell transformer. The smallest area we can isolate creating the unwanted energy will be the ***source***.

Radiation from a Source

There is very little radiation from a source. As a matter of fact, even a very powerful single-terminal source can't transmit at any distance. In order to be an effective radiator, the source must have two or more connections to the outside world. The multiple connections (two or more) could be the two (or three) wires in a power cord, or a insertion point in a single wire. It could also be a connection to two totally different sources. Let's look at examples of each.

Arcing Splice

Consider a poor slice in a conductor carrying more than a few volts can cause a RFI generating arc. Two of the most common examples are an electric fence or power line.

The noise results when an insulated area with an electrical open circuit at low voltages breaks down as sufficient voltage appears across the gap. This ionizes air in the gap, and the resulting plasma conducts heavily. Such arcs can be particularly noisy at radio frequencies, because resistance can fall faster than voltage increases creating a negative-resistance. Negative resistances created in spark plasma were actually used as the amplifying element in crude oscillators. The plasma excited resonant circuits in the very first "single-frequency" transmitters, and at times those transmitters spanned distances of thousands of miles to very poor receivers using what were very poor antennas by today's standards!

Each conductor direction leaving the arc forms half of a large antenna. The entire system, from the source out in both directions, radiates. There isn't any effective way to cure or substantially reduce the unwanted radiation except by stopping the arc. Poor slices can become quieter in heavy rain, and can be broken up by wind or wire movement.

This type of arc excites the conductor entering the splice from one direction as one terminal, and the wire exiting the splice as the other terminal! The coupling mechanism is like a dipole feedpoint, and is very efficient at radiating over very wide frequency ranges.

Arcing to Another Conductor

A poor insulator or a close-spaced gap can break down and generate noise.

Once again, the noise results when an insulated area with an electrical open circuit at lower voltages breaks down when sufficient voltage appears across the gap. This ionizes air in the gap, and the resulting plasma conducts heavily. Such arcs can be particularly noisy at higher radio frequencies, because resistance can fall faster than voltage increases creating a negative-resistance.

Shunting-arcs generally have poor low-frequency energy, because the gaps are almost always connected to a very high impedance at low frequencies. This makes a very poor antenna connection for the arc, and reduces low-frequency response. If the gap had a path to a low resistance, the plasma would form a dead-short in the path. This would quickly cause a catastrophic system failure in systems able to supply sufficient current.

Non-arcing RF Generators

Many devices contain high-speed switching systems. These devices include but are not limited to televisions and monitors, computers, lighting systems with dimmers, and low-voltage lighting systems using switch-mode power supplies.

These non-arcing sources are similar to arcing sources, in that they require at least two terminal paths to become effective radiators. They generally are frequency selective or frequency periodic, and produce a broad buzzing signal that drifts around.

Common Characteristics

No matter what source is at work, we can be sure more than one conductor is at work in coupling from the source. If we disturb that path by isolating one conductor with a high RF impedance, we can reduce the interference. But by far the most effective way to remove or reduce interference, other than by removing the actual offending source, is by "shorting" the RF path with a bypass capacitor. As we will see later, this is almost always much more effective than adding series

impedance.

Common Noise Sources

Arcing Powerline Insulator or Hardware

The bell-insulator in a power line is probably the most common noise source. Older bell insulators has two interlocking but well-insulated metal posts. These metal posts have considerable area, because of the required mechanical strength. This results in considerable capacitance, in the order of a few dozen picofarads or greater. The ends of each bell terminal are held by a loose-fitting pin assembly. This pin assembly is the root of most powerline noise problems.

Bell insulators are often misused by power line crews. They are sometimes used to terminate short spans between poles, where the correct insulator would be a rigid post type or a polymer insulated fiberglass rod. The bell insulator, used in a short span, often is installed without sufficient tension. The lack of tension allows corrosion to set-up on the loose-fitting pins, and the capacitance of the insulator creates a voltage divider. Since the pin capacitive reactance is very high compared to the insulators leakage resistance and capacitance, a very large voltage can appear across the pin. This is true even when the pin is connected to grounded hardware! These loose short spans are called "slack spans", and bells should NEVER be used on slack spans! Slack spans with bell insulators generally become quieter during damp weather or in or just after rain, and can often be broken up by wire movement.

As the sine-wave peaks, the corrosion or oxides in the joint of the loose-fitting pin break down and arc. This causes an unintentional electrical noise to be generated, and the two terminals for the transmitter become the power line conductor and the grounded pole or hardware on the pole. With a wooden pole, the entire upper area of the can be excited with leakage currents from leakage capacitance and leakage resistances. Even if an insulator isn't arcing, a loose metal staple over a grounded wire or other poorly connected metal-to-metal joints will arc. Even a very tiny arc can excite the ground wire running down the pole and the power line wires as two (or more) terminals for the source.

To a much lesser extent transformers, lightning arrestors, fuse assemblies, and disconnects can have internal arcs.

Trees and foliage may also contact HV power lines and "burn" against the wire. Generally foliage noises are not extremely loud sources at low frequencies because one terminal of the source is through the tree, but occasionally they can be strong at lower frequencies.

As a general rule, but not always:

- Series-connection arcs from loose or corroded metallic hardware are reduced by wet weather. Water, contaminated by the corroded metals, forms a path around the poor connection and stops or reduces the arc.
- Shunt connection arcs from poor insulation are often reduced and may disappear in dry weather. They are caused by dielectric (insulation) failures.
- Corona noises are stronger at very high radio frequencies
- Hardware arcs and bells are generally strongest at higher radio frequencies
- Hard arcs like splices, clamps, transformer insulation, and switches are generally worse at lower radio frequencies
- The arc can be a very long distance from the point where you hear it on LOWER radio frequencies

Electric Fences

Older electric fences had a few-second timed off-and-on buzz. Newer fences have a "popping" noise, because they charge the fence in "tics". Fence problems are similar to power line problems, except of course the hardware is much smaller! Most severe problems are related to poor insulators, bad splices, or loose hardware.

Computers, TV's, and Switching Systems

In older times, TV sets created problems from sweep circuits. The horizontal sweep circuit operates with a saw tooth shaped waveform that was rich in harmonics. Early video systems overpowered the horizontal sweep system, and used the extra energy to supply high tension for the CRT. This resulted in many point-to-point wires carrying high power harmonic-rich 15kHz RF energy. A typical 25-inch television would use about 15 watts of the horizontal sweep system power for sweep, and perhaps 30 watts for powering the CRT second anode!

Wasted energy from the 50-75 watt sweep system was often coupled to the outside world a push-pull signal between the antenna leads and the power cord.

Modern computers and TV's mostly create noise-problems from internal switching power supplies, rather than sweep systems. The sweep systems, if ever even required, now generally only power the sweep. The HV often comes from separate HV power supplies.

Switch mode power supplies, whether in a TV, computer, telephone, video, or lighting system are rapidly becoming the most common source of modern RFI problems. Most of this has to do with poor testing techniques, lack of good standards, poor enforcement of the few poor standards we have, and a lack of skill or knowledge in power supply and device design and installation.

Fortunately most problems can be corrected by external filtering, but it generally needs to be done at the offending device.

Curing RF Egress or Ingress

Once the outside world is reached, the push-pull nature of the source can appear as a common-mode signal following a group of wires for many miles. We can think of this as one very long wire with the earth as the return path. The signal either directly radiates into our antennas, or it excites our antennas via common mode paths along cable shields.

While power lines and high-tension electric fences must be cured by removing the arc at the source, lower voltage systems can almost always be cured through proper external bypassing.

As a first response, we often like to throw a few ferrite beads at the problem. In more sophisticated approach, we might use multiple-turn series inductors. What these approaches miss is the great difficulty in obtaining adequate series impedance. When we consider the series impedance has to be totally *ISOLATED* for each conductor, and further consider core saturation from low-frequency operating currents we quickly realize series impedance is ***NOT*** the most effective method. It is helpful and may reduce RFI to acceptable levels in mild cases, but it certainly is an ineffective cure. Even if we are successful at one frequency range, it becomes virtually impossible to have a high series impedance over very wide frequency ranges.

The best approach is to add some RF series impedance and to augment it with excellent bypassing of all leads entering or leaving a device to one common point. That common point generally is connected to a safety ground, available in the USA at the third ground terminal of every modern-code electrical outlet.

Coaxial or audio cables should all leave the device through a bulkhead plate with all shields grounded. The power cord should pass through that bulkhead, and be bypassed to the bulkhead with properly selected UL/CSA/VDE approved line-bypass capacitors. Any chokes should be installed between the source device and the bulkhead. When this happens, the device becomes an isolated entity all by itself. It can not excite outside world conductors with unwanted RF.

It is indeed fortunate that the very same things that cure RFI often lead to greatly improved lightning protection.

Pre-amplifiers

[Home] [Up] [Preamp Summary]

For the summary page click here pre amp_summary

The following is a comparison of HF low noise receiving preamplifiers. More amplifiers will be added as they become available to test. All instruments used for these measurements are currently calibrated newer-production laboratory grade instruments.

Detailed graphs will only be added if specifically required. The .jpg pictures on this page are examples of how measurements are displayed on the instruments used in tests.

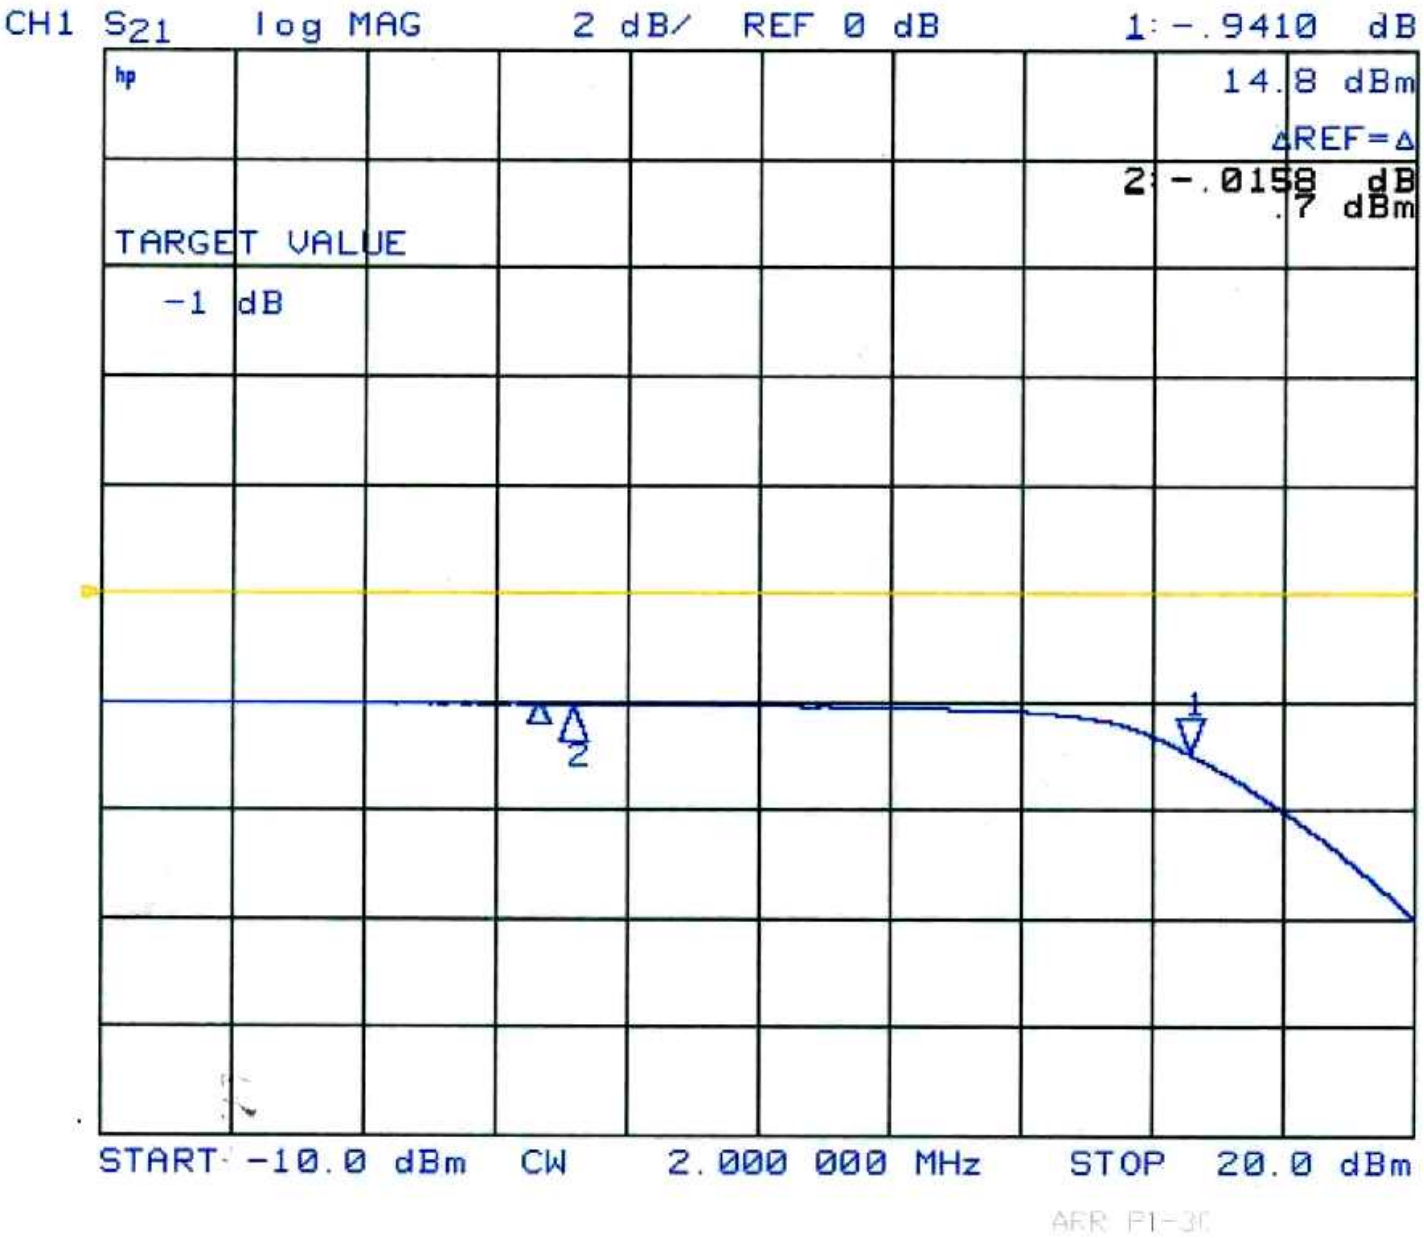
Gain Compression Tests

Pre-amplifier gain compression is measured on an HP (Agilent) Vector Network Analyzer and S-parameter test set using the power level sweep function at 2 MHz. A gain compression test shows loss of gain as input power is increased, or the input level where the amplifier starts to saturate.

This test indicates how much overall signal power the amplifier will handle before gain is reduced by non-linearity or saturation. This is power or gain non-linearity, and really does not directly represent distortion level vs. input or output signal power. A correction is applied to results for amplifier gain and equipment protection attenuators.

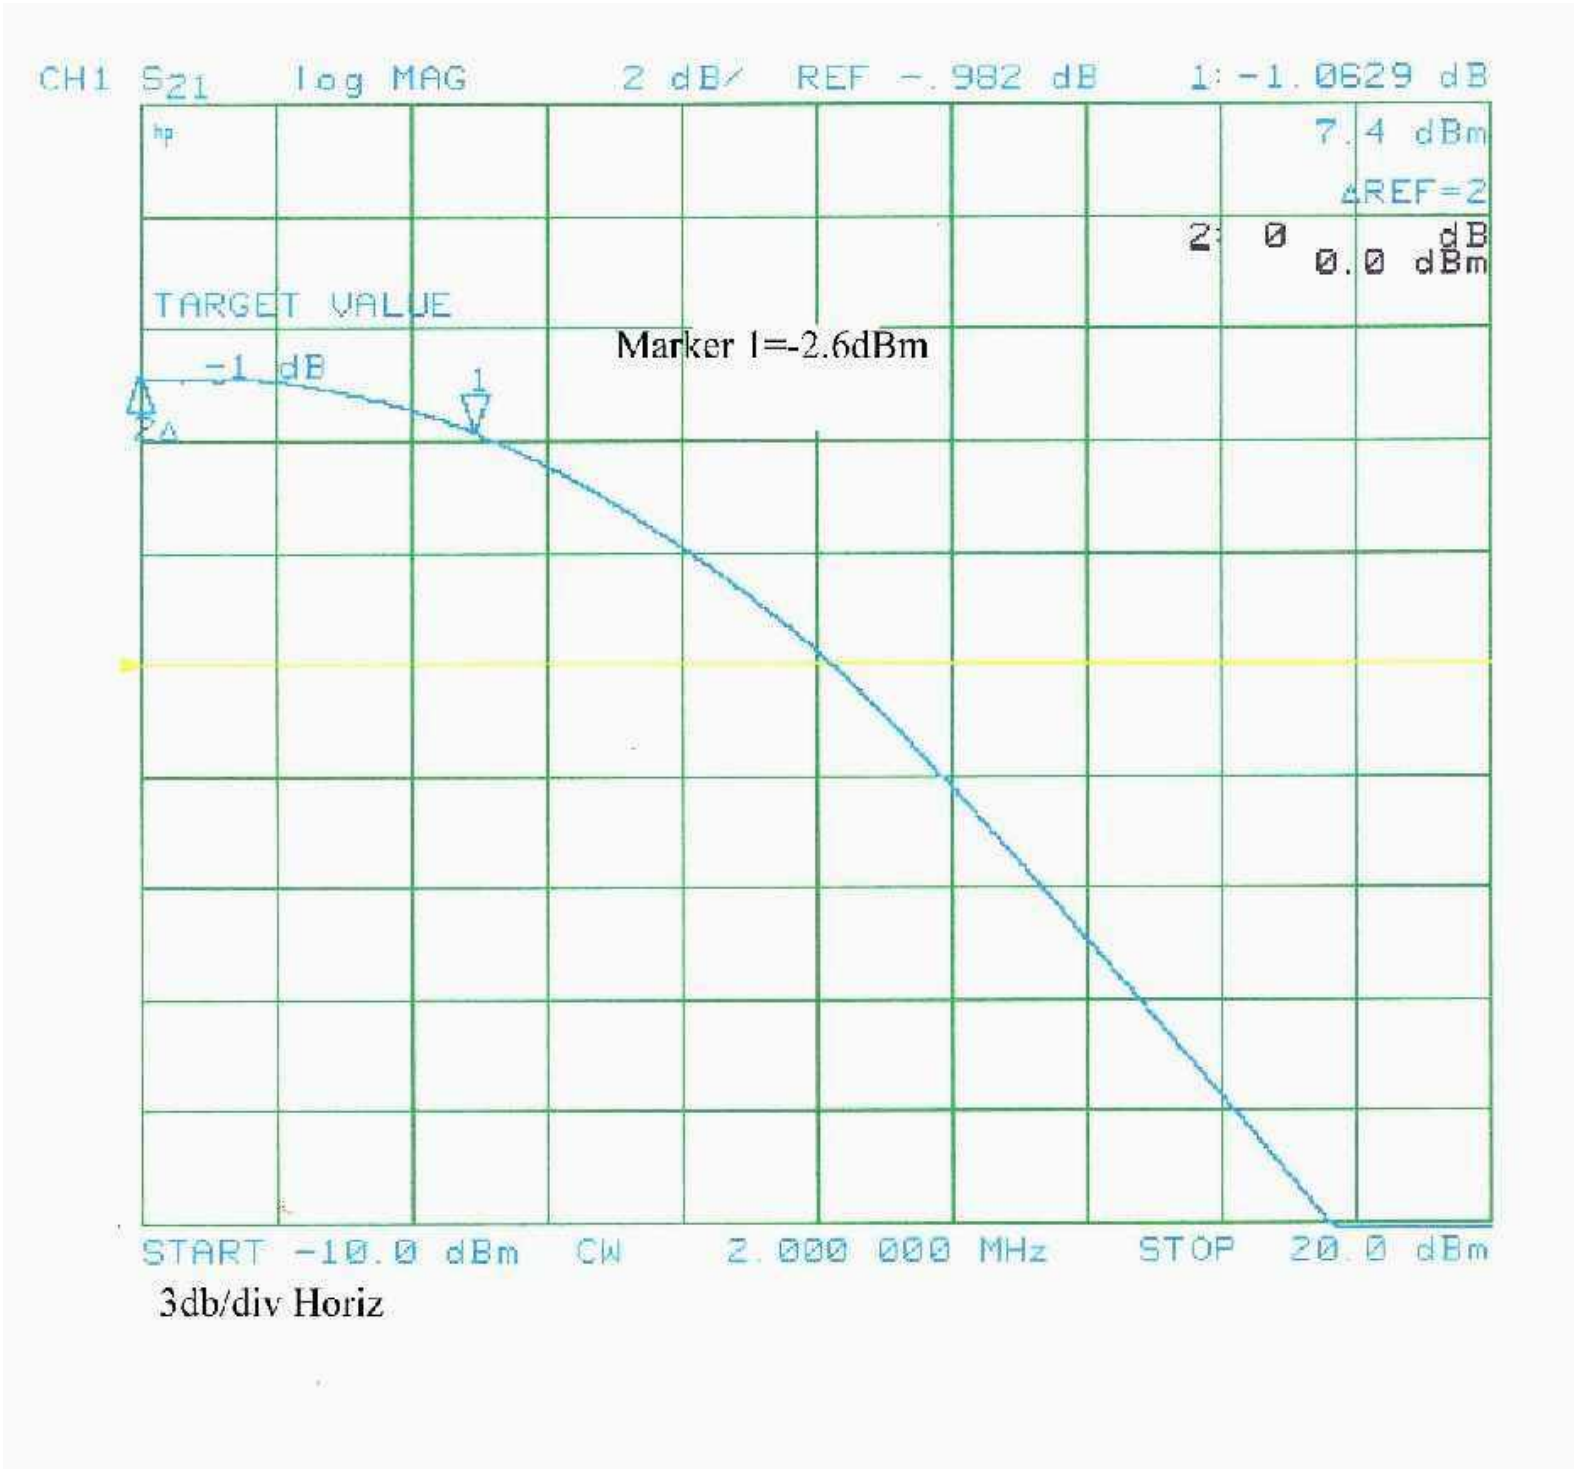
Note: *Third-order intercept is a better demonstration of signal level capacity. Third-order intercept better indicates immunity of an amplifier to producing unwanted signals (mixing products) from multiple strong signals.*

ARR 1-30



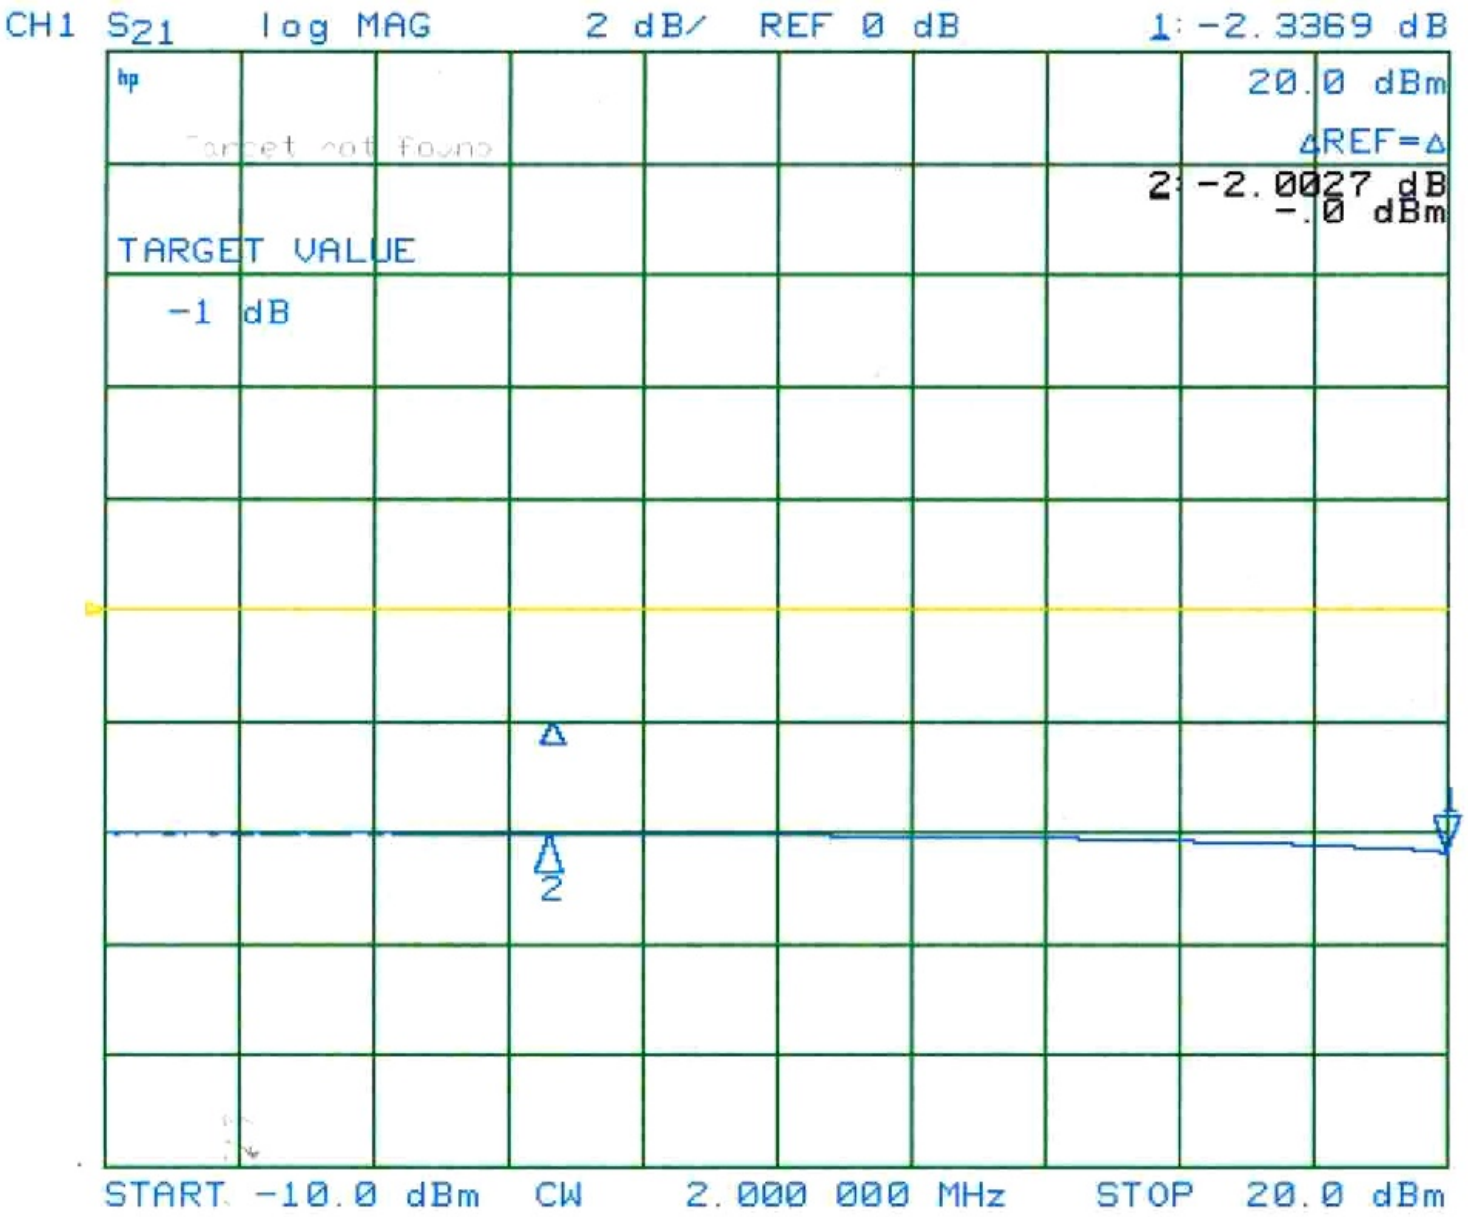
Amplifier input power (horizontal sweep) is 3dB per division. Measured 1dB compression is corrected to **21.5dBm output power @1dB compression**.

ARR GAsFET (1.8-2 MHz model)



1dB compression is corrected to 8.1dBm output power.

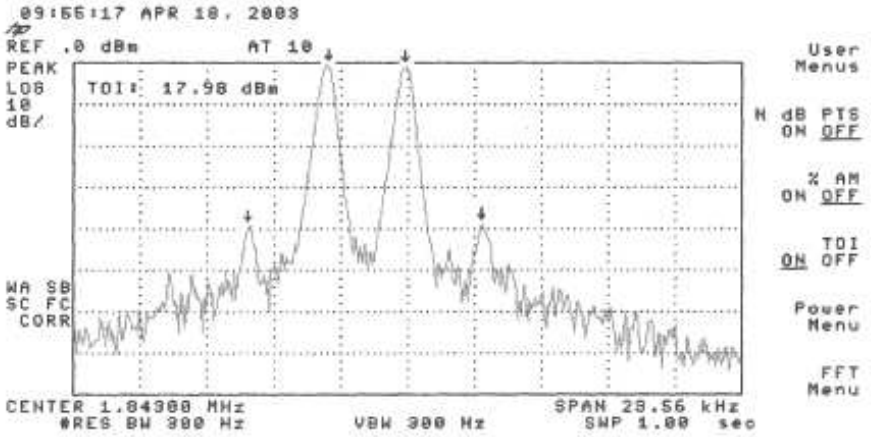
DX Engineering Push-pull HF preamplifier



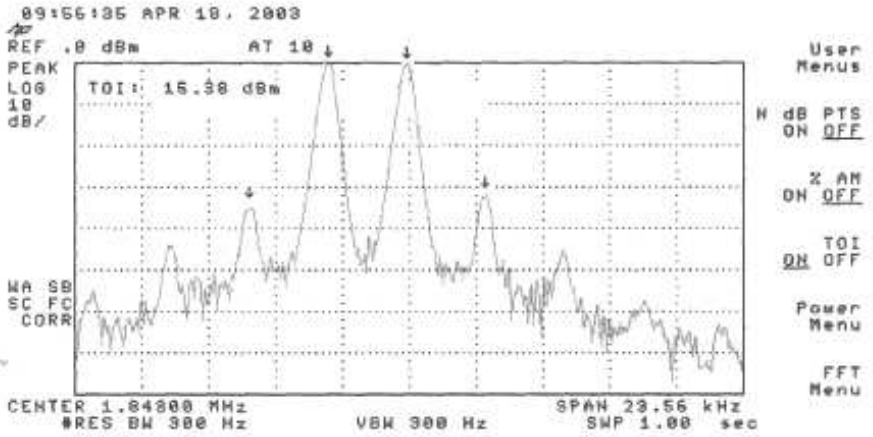
Gain compression beyond power output limit of analyzer. In other words, my test equipment does not have enough output power to drive the RPA-1 preamplifier into compression. Actual corrected gain compression (manual test) is approximately +26dBm (400-milliwatts output).

Comparison of Third Order Intercept

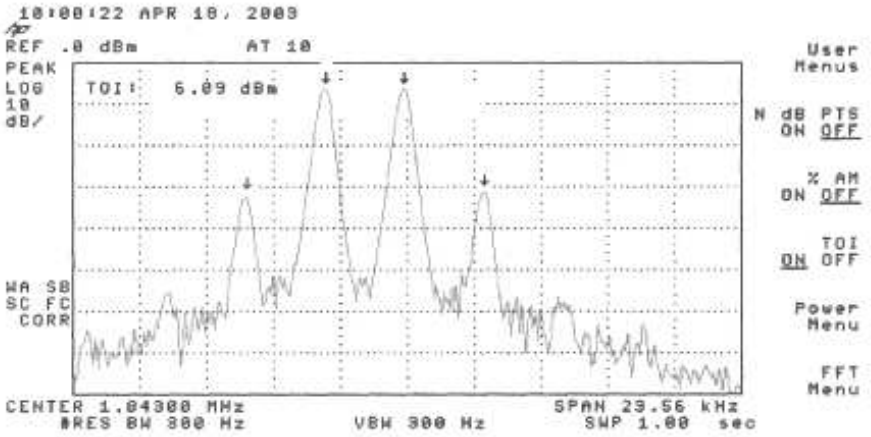
Third-order intercept tells us the immunity of the amplifier to generating spurious signals in the presence of multiple strong signals. This test was at 1.85MHz using the automatic IM3 test measurement. A stepped attenuator pad at the amplifier output was initially used to prevent analyzer damage during testing. Because of this "protection" attenuator, actual TOI must be increased by adding the attenuator value to the analyzer display reading.



DXE Preamp



ARR1-30



ARR-GAsFET

Third-order IM3 levels occur at the following single tone (of an equal two-tone test):

DXE (early model) -0dBm input power (instrument TOI 17.98+20.2dB pad= 38.18dB TOI)

Note: Later model RPA-1 measured 43dB third order intercept

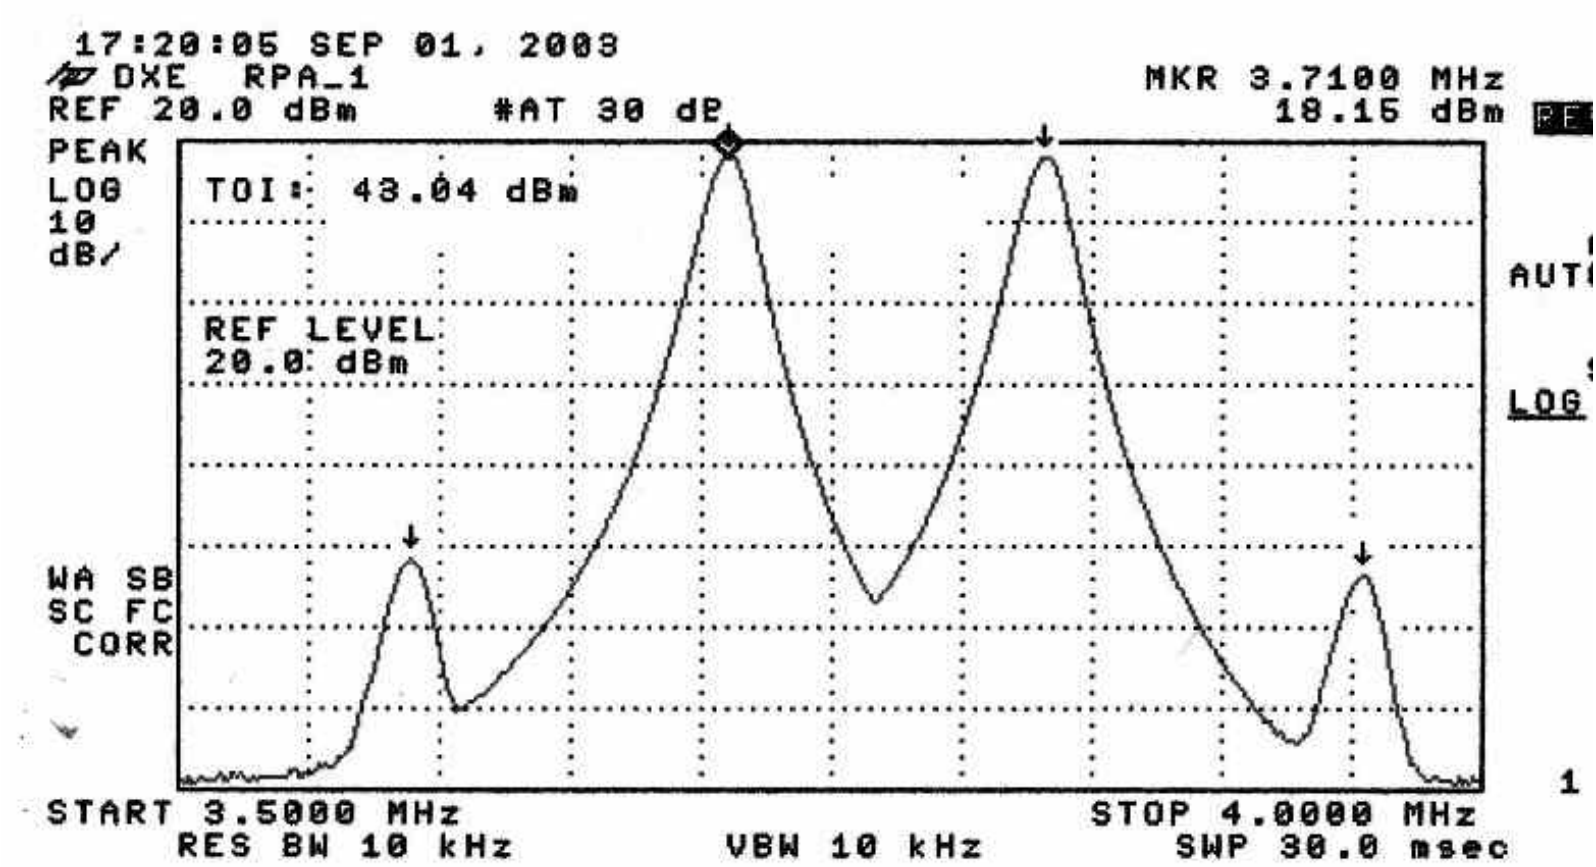
ARR P1-30 -5dBm input power (instrument TOI 15.38dB+15dB pad= 30.38dB TOI)

ARR GAsFET -16dBm input power (instrument TOI 6.09dB+5.3dB pad= 11.39dB TOI)

If you look at the above measurements, you will see third-order intercept in the DX Engineering amplifier occurs almost 8dB higher than in the better performing of the two ARR amplifiers that were tested. Not only is the DXE 3rd order intercept higher, higher order products are substantially less than the other two amplifiers produced.

DXE-RPA-1 Test

This is a later model DXE preamplifier model RPA-1. This measurement has no external attenuator, TOI in this case is a direct reading.



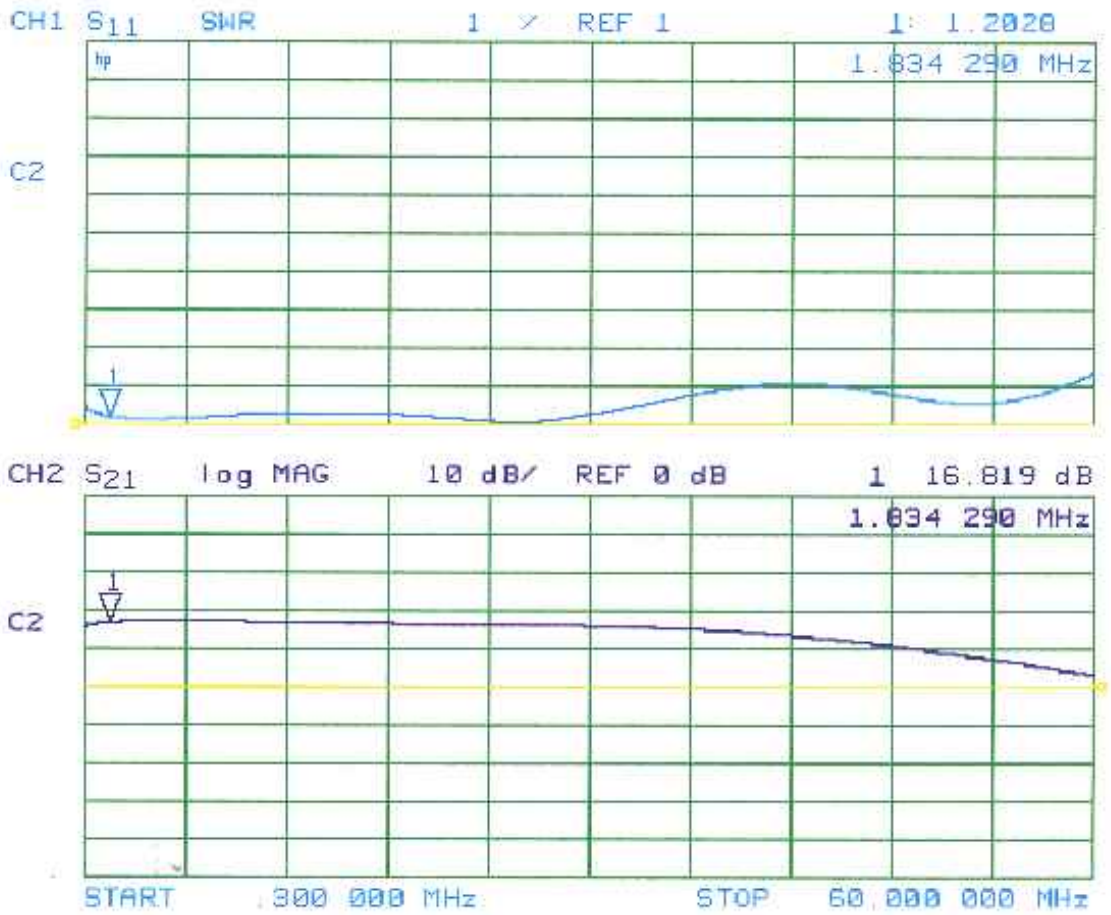
Preamp Noise Figure

I don't have this data saved to a file yet, but the noise figure of the GAsFET amplifier and the DXE amplifier are about the same. The ARR 1-30 had the highest noise figure, about 5.5dB. All of these amplifiers are acceptable for HF receiving in most applications so far as noise figure is concerned.

Input Impedance and Gain

So far, the DXE pre-amplifier has the closest match to 50-ohms over the range of 300kHz to 30 MHz. Gain is also reasonably flat in the DXE amplifier.

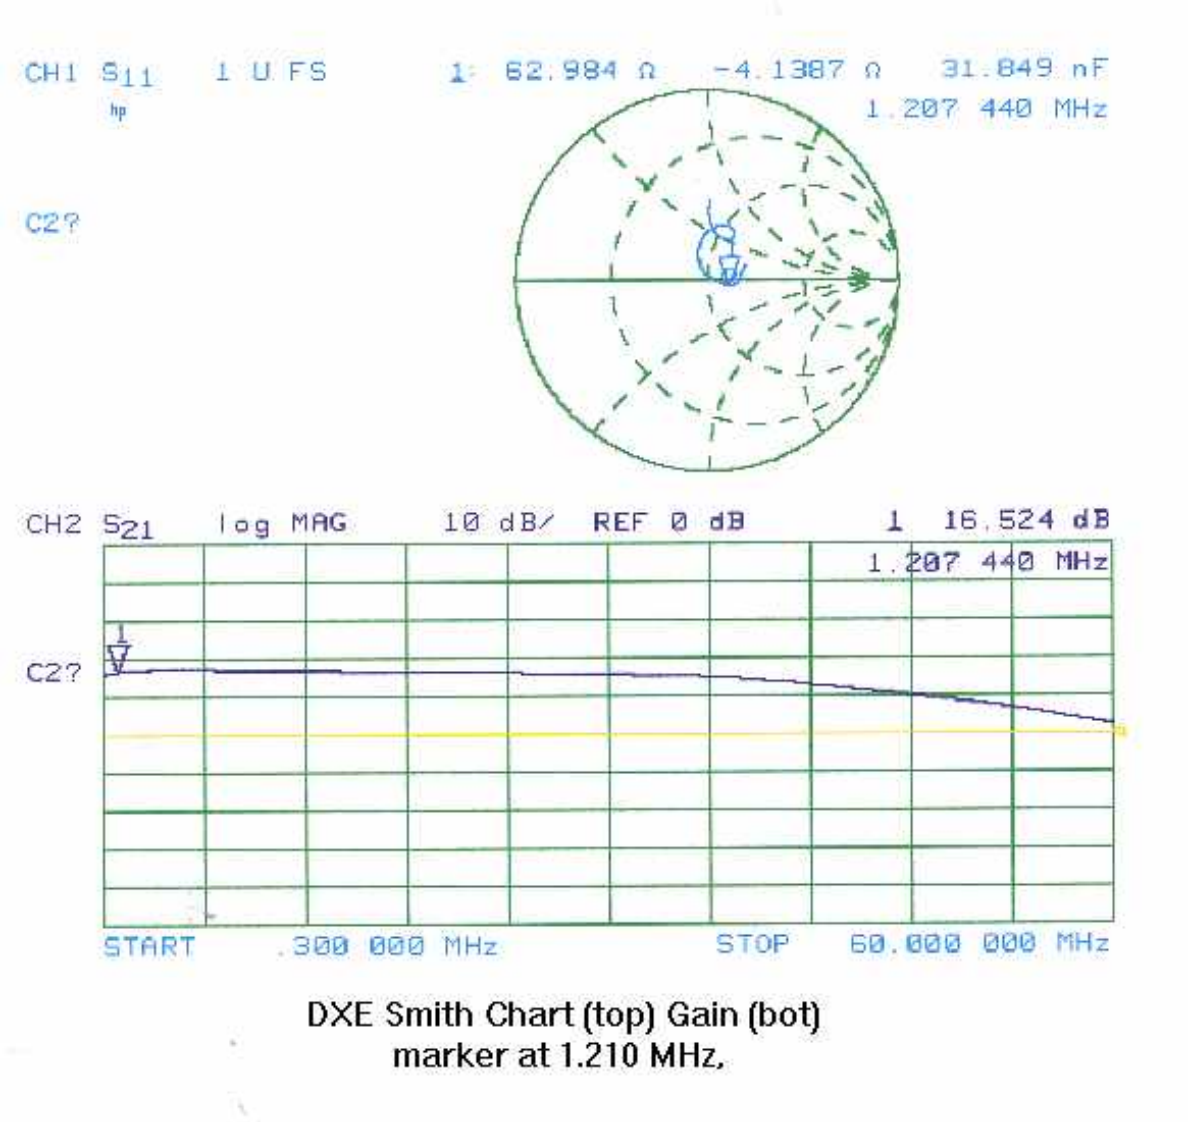
DX Engineering Preamp



DXE preamplifier SWR (top) and gain vs. frequency (bot)

The display above shows input SWR of the amplifier on the top graph, and gain on the lower graph. The marker is at 1.834290 MHz. The vertical graph lines are frequency at about 6 MHz per division. Gain at marker frequency is indicated as 16.819dB, SWR is 1.2028:1.

It is also possible to display input impedance on a Smith Chart:

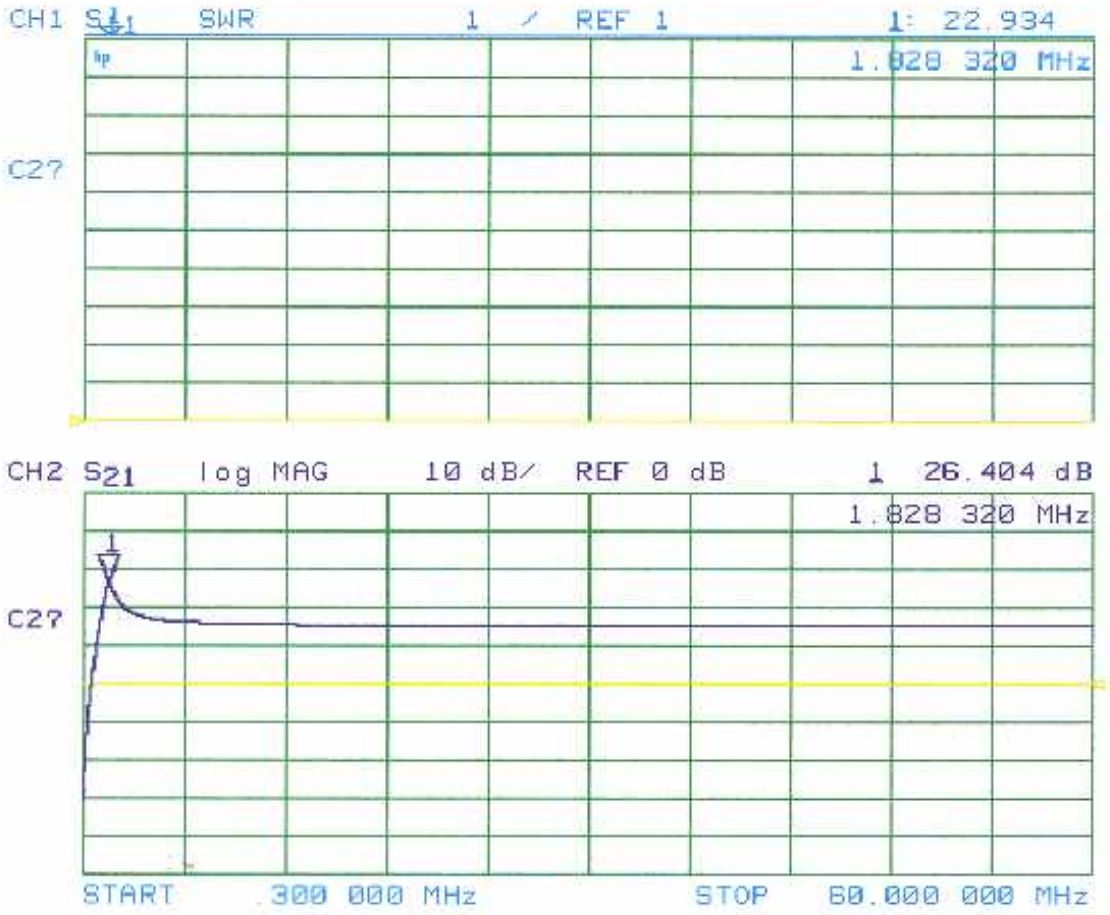


DXE Smith Chart (top) Gain (bot)
marker at 1.210 MHz.

This is the gain and input impedance at 1.207440 MHz.

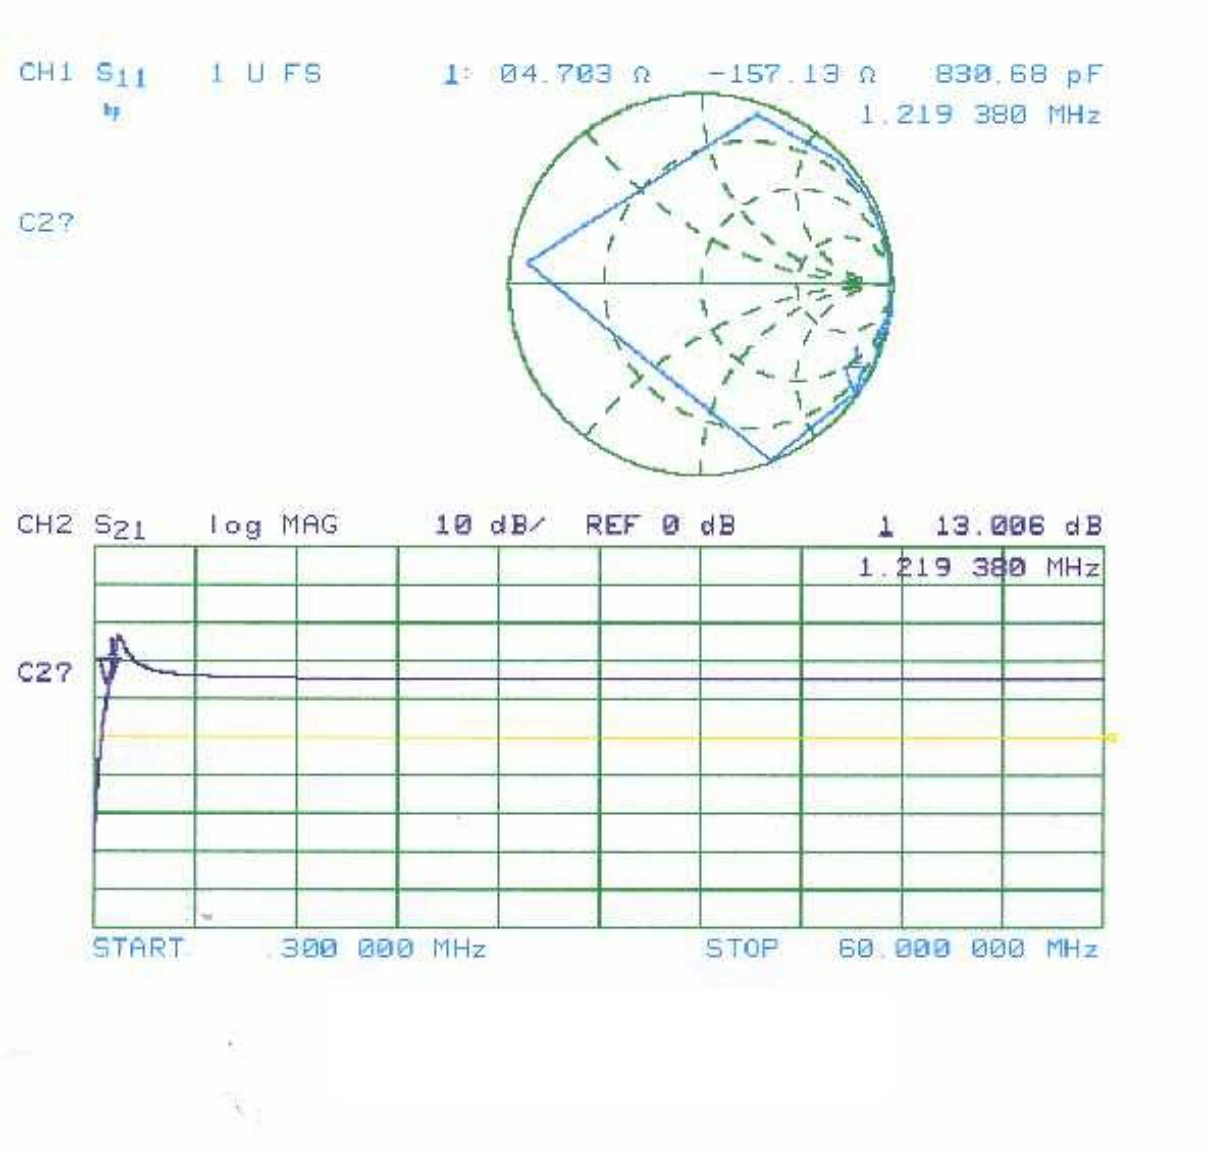
ARR GAsFET PreAmplifier

This amplifier is intended to be a 160-meter only amplifier. It has high gain despite of the very poor match on any frequency. It also has substantial gain on all frequencies swept, but a strong peak on 1.8 MHz.



ARR GAsFET SWR (top) Gain
(bot) marker at 1.828 MHz,

Input SWR is 23:1, gain is 26.4dB. Unfortunately noise figure is not that good for a GAsFET, probably because of the very large input



mismatch.

The above data is a Smith Chart display of the ARR GAsFET at 1.22 MHz. Gain is still 13dB, input impedance is 5 ohms and very reactive (this measurement is in the BCB). Despite being a "160-only" amplifier this amp has substantial gain (~15dB) at 60MHz.

Other Data

If you have a commercial amplifier or ***commonly available*** homebrew amplifier design you would like tested, please contact me. I'd be happy to measure your amplifier (time permitting) and post the results here.

See (soon to be added) summary page for text comparisons.

Bandswitch Failures

[Home] [Up] [Failures_in_antenna_systems] [Loading_amplifier] [Relay Timing]
[Switch Installation]

Bandswitch Failures

Bandswitch failures are caused by:

1.) Improper installation or wiring of switch

a.) Improper Wiring Techniques

b.) Improper contact Alignment

c.) Contamination-of or damage-to switch

2.) Improper relay timing or defective antenna relay

a.) Transmit contact closes ***after*** input contact closes

b.) Transmit contact opens ***before*** input contact opens

3.) Failures in antenna systems

a.) Intermittent arc, open, or short in a tuner

b.) Intermittent arc, open, or short in an antenna

c.) Intermittent arc, open, or short in external lightning protection devices

d.) Intermittent arc, open, or short in a feedline or connector

e.) Sudden large change in either SWR or antenna impedance

4.) Improper loading of amplifier

a.) Loading control set too far meshed (loading too light)

b.) SWR or antenna impedance beyond matching range of amplifier

5.) Excessive drive or drive power transients

a.) Exciter has transients or leading edge overshoot

b.) Operation power peaks higher than tuning peaks

6.) Excessive current

a.) Improper loading (loading too light)

b.) Improper connections

c.) Improper switch ratings

Failures_in_antenna_systems

[Home] [Up]

Any of the problems below can result in destruction of a bandswitch or other amplifier components.

Tuners

Antenna tuners are a common problem. Many tuners are over-advertised, and will not handle the power claimed. Some models also have poor or unreliable connections in inductors. Many tuners have poorly designed power meters with peak meters that don't indicate true peak power. If you look at the antenna tuner review in the February 2003 issue of QST, you will see power rating problems exist with many tuners.

User adjustments also greatly control tuner power ratings. People adjusting "T" network tuners often forget to use the maximum possible capacitance required to match the load. Using less than maximum capacitance will reduce tuner power handling capability.

A very brief arc or open circuit in a tuner can cause a momentary very large change in antenna tuner input impedance. This large impedance change reflects back into the amplifier, and if the tank is momentarily unloaded a catastrophic bandswitch or capacitor arc will occur.

The worse possible change is one that results in a condition of high impedance at the amplifier tank input, in which cases tank voltages can reach many times the normal operating values.

Always be sure your tuner has reliable internal connections, and is tuned correctly (maximum capacitance that allows matching the load). Be sure the tuner can handle the peak transient power from your exciter-amplifier combination.

At one point, I owned an ICOM 775DSP radio. The peak transient power from that radio, even when set to 50 watts, was over 300 watts! While that pulse would not show on a normal power meter, it clearly showed on peak storage meters. My Bird digital storage, a special Coaxial Dynamics peak meter for medical applications, When I drove an 8877 amplifier with that radio, the few milliseconds of peak driving pulse would trip the very fast grid-current-fault protection system in my amplifier.

When I advanced the loading to prevent the grid trip from activating, the transient peak amplifier out was over 5kW. This would cause my antenna tuner, a large old KW Johnson Matchbox, to momentarily flash-over! When the tuner would arc, the amplifier tank would arc.

The entire system would have to be able to handle the exciter's 300-350 watt peak transient (amplified through the PA gain) in order to not have reliability problems!

Antenna and Feedline Failures

Antennas can have arcing problems from bad connections or other defects. If an antenna fails to accept power or changes impedance intermittently, even if for a few milliseconds, it can trigger an arc elsewhere in the system. That point may even be in an amplifier tank system.

Traps can arc, as can other components like gamma capacitors or matching networks. Be sure antenna wires are not able to brush up against other objects in the wind.

Be sure all connectors and hardware are tight, and connections are dry and well-insulated. Normal UHF connectors, even though rated less, handle much more power than type N connectors. UHF connectors are much less likely to develop intermittent connections, and actually have LESS loss below 50MHz. The only potential drawback for HF use is UHF connectors are less water resistant than properly installed N connectors, but that can be cured with proper waterproofing.

Antenna problems will show if you use a peak-storage meter, or a meter with a long hang-time. The only amateur radio products I'm aware of that have enough response time and hang time are the Ameritron meters used in the AWM-30 meter and ATR-30 and 20 tuners. Any momentary faults in my antennas immediately show on the reflected power of those meters, when they are in the peak mode.

Loading_amplifier

Improper Loading of Amplifier

As far as tank voltages are concerned, there really isn't any difference between excessive drive, load faults, or improper adjustment of loading. Improper tank adjustment and excessive drive are equally harmful to component life, and either can create splatter (and in extreme cases cause clicks) on adjacent frequencies.

Most Common Tuning Error

The most common tuning error is adjusting the amplifier at low power, rather than tuning at maximum obtainable drive.

The last few steps in tuning should be:

- Load the amplifier to maximum obtainable output at full exciter drive
- After that, advance the loading control slightly beyond (towards less capacitance).

ALWAYS load your amplifier for maximum obtainable power, and reduce drive to rated or desired power levels! This ensures minimum voltage and current in the tank, and maximum possible linearity for the best signal quality. High grid current is a good indicator of excessively light loading in grounded grid amplifiers.

Exciter Transients or Power Overshoot

Maximum available carrier drive might not result in sufficient drive when an exciter has transients or power overshoot. Transients or overshoot only appears when going from zero power towards full operating power levels, a condition met at the leading edge of speech or CW transmissions. Once the ALC comes up, transients and/or overshoot will generally disappear. With transients or overshoot, it is impossible to tune your amplifier properly with either a carrier, tuning-pulser, or speech waveform. We can not just tune for maximum output and expect the amplifier to be properly loaded when the exciter has transients!

Transients and overshoot, being of short duration and infrequently occurring, make it impossible to tune correctly at maximum drive.

Let's assume your exciter is rated to deliver 100 watts, but has momentary peaks or transients of 160 watts while the ALC or power control loop "takes hold". Power surges of 160 watts, too short to register on normal power meters, occur at the start of ever transmission. Of course, if you don't run the exciter wide open, and reduce power to 50 watts, this problem is rally aggravated!

In this case, the maximum power setting of the exciter should be used while tuning. If you suspect or know the exciter has transient problems, the loading control should be advanced a reasonable amount beyond (further open) the maximum output power setting. This will allow the amplifier tank system to handle transients without arcing or component failure.

Easy-Drive Linear Amplifiers

Some people and manufacturers tout low drive as an advantage, claiming it offers "cleaner signals". Nothing is further from the truth.

Exciters almost always provide the best IM performance when operated at an average peak power a reasonable amount below full output, rather than very low levels. At low levels, exciter performance is dominated by cross-over distortion caused by low-level operation of stages optimized for higher power levels. ALC also bias back early stages, often increasing distortion in those stages. At very high levels, gain compression or bias shift becomes an issue. Exciters typically do best when operated in the area of 60-80% of rated power.

Worse yet, low drive amplifiers are especially susceptible to damage from exciter overshoot or transient problems. Transients and overshoot remains almost the same level regardless of exciter power control settings. As exciter power levels are reduced, the percent of power overshoot becomes worse.

The most undesirable situation is one where exciter power greatly exceeds an amplifier's normal drive power limit. Not only does this reduce system IM performance, amplifier drive transients are aggravated. Amplifiers should be designed or selected to match the exciter's maximum power output, or an external attenuator used to bring the amplifier's drive requirement up to the exciter's full power level.

Demonstration

[Home] [Up]

A Practical Demonstration

This test circuit is easy to duplicate, and demonstrates the extreme voltages that appear in an amplifier when the load is improper for the amount of drive power applied.

Years ago, almost every amplifier had a output transformer. The transformer was similar to tanks circuits in RF PA's, in that it transformed or matched impedances. Even though Q was very low, the transformer could still store and release energy.

Experienced people knew if the volume was turned up too high in a transformer-coupled output stage, and if the load was absent, voltage across the transformer would soar to many times the normal operating voltage. No load or grossly mismatched loads often resulted in damaged transformers, blown output devices, or other output circuit component failures.

Failures induced by load or matching faults would occur in conservative amplifier designs, where components would last years in continuous ***proper*** operation. An audiophile would NEVER think of operating his expensive tube-type amplifier at anywhere near full volume into an open load, let alone a load where grossly improper impedances are selected in amplifier output-transformer taps.

Blame was never placed on stability. Everyone knew and understood conservatively designed well-constructed amplifiers with energy storage systems of any type, even very low Q systems, would still produce over-voltage failures when grossly overdriven or misterminated.

TV manufacturers used this well-known effect to advantage in horizontal output sections, where a flyback transformer with moderately low Q would produce many times the actual turns ratio in peak voltage, because of energy storage. Even modern switching supplies and our automobiles depend on energy storage to produce entirely new voltages, far above supply voltage, without requiring parasitics or high Q.

RF Systems

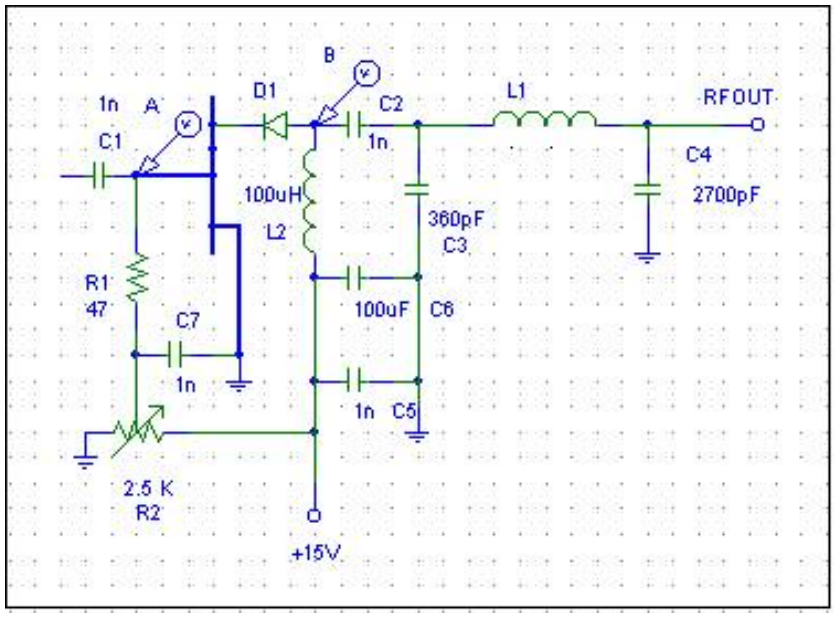
RF systems are certainly no more immune to mismatch than audio amplifiers, they very often are much worse. RF circuits are generally single-ended, and tube-type amplifiers have moderately high-Q (efficient) energy storage tank systems. Single-ended amplifiers with conduction angles under 360-degrees almost always contain intentionally designed “fly-back” systems, where tank circuit Q re-creates the missing portion of a sine wave from the half-cycle (or less) tug of the single-ended output device.

Somehow we have forgotten all this, and allowed ourselves to be misled into believing it takes a circuit or design flaw producing an oscillation to cause an arc or component failure.

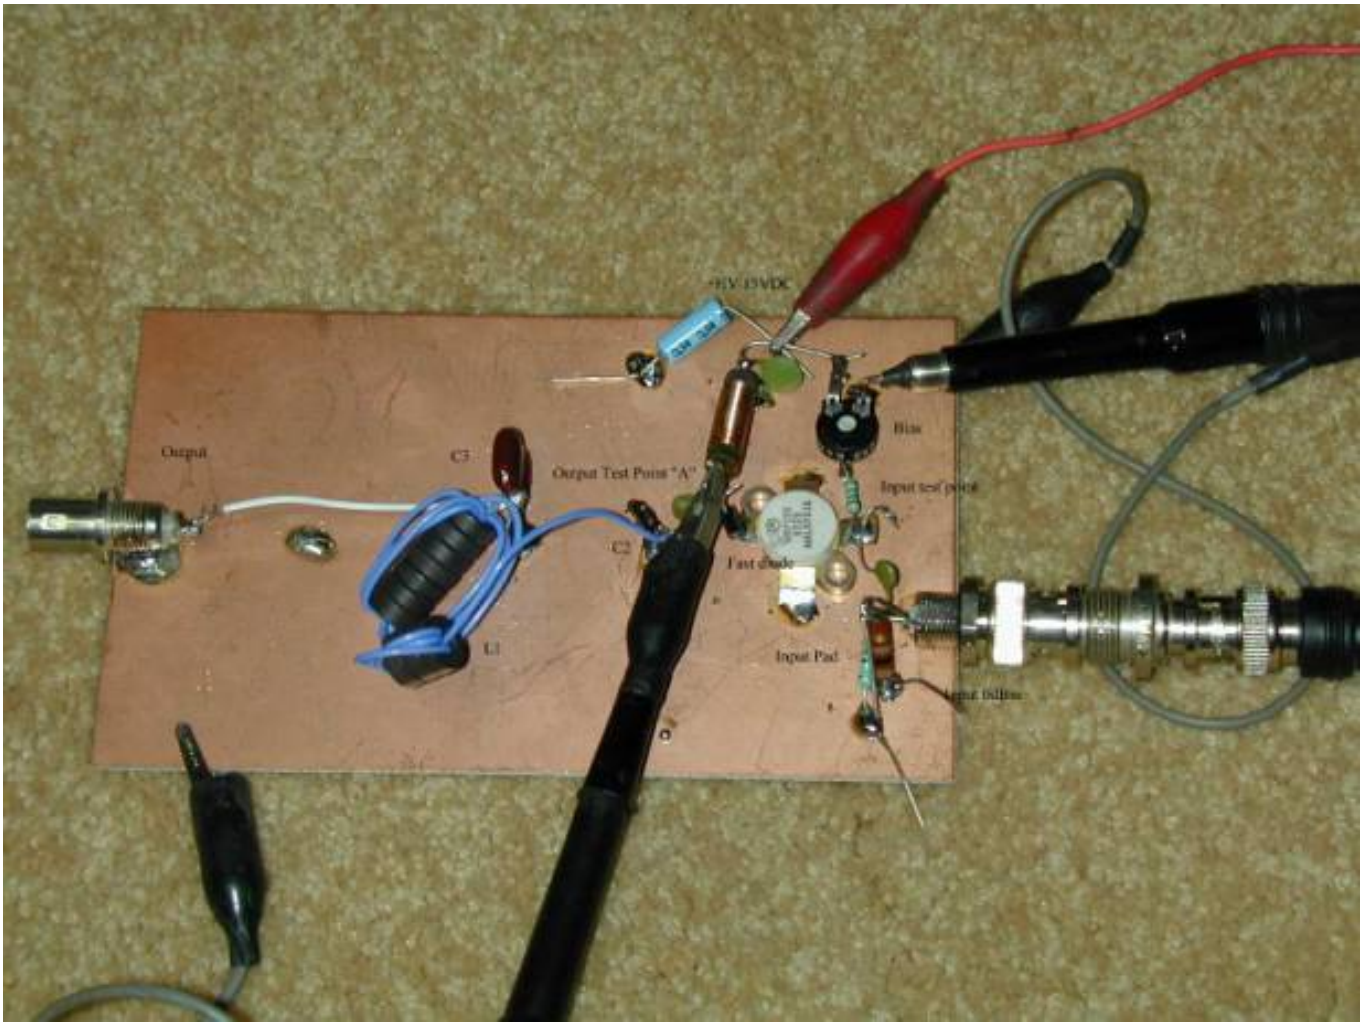
This article demonstrates how easy it is to produce very high voltages from normal perfectly stable PA's with normal tank systems.

Demonstration Circuit

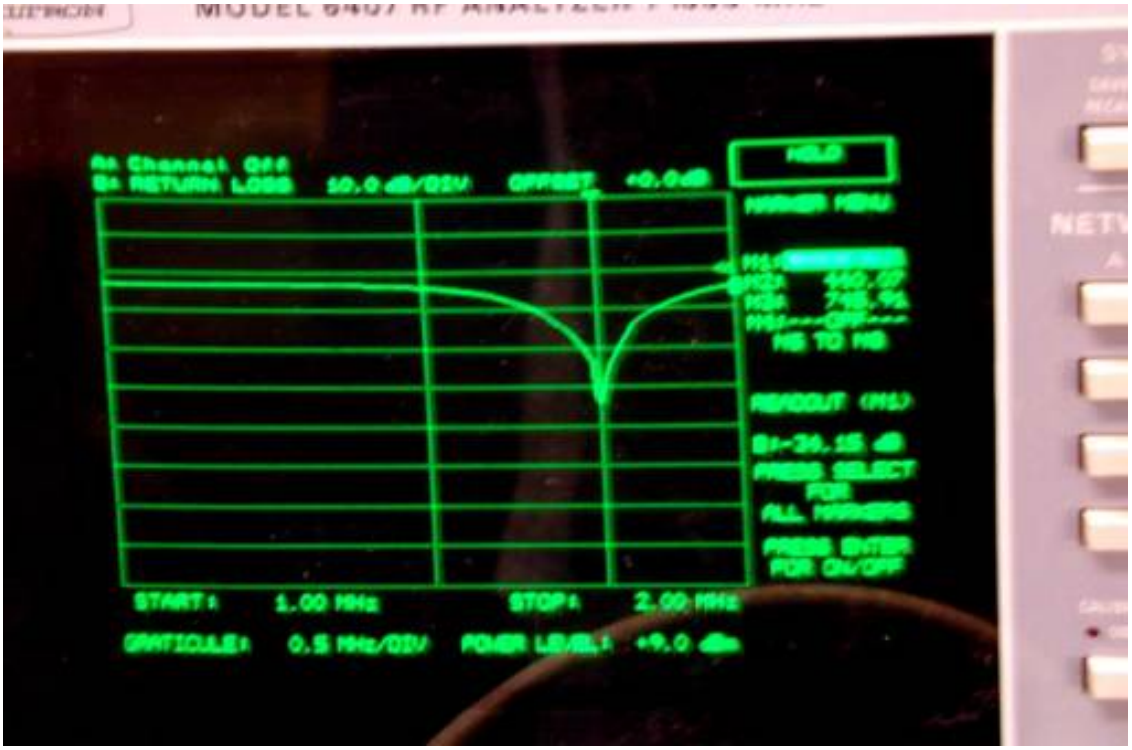
It isn’t safe to poke around in a high-power vacuum tube amplifier while looking at voltages, but a simple demonstration circuit can be constructed.



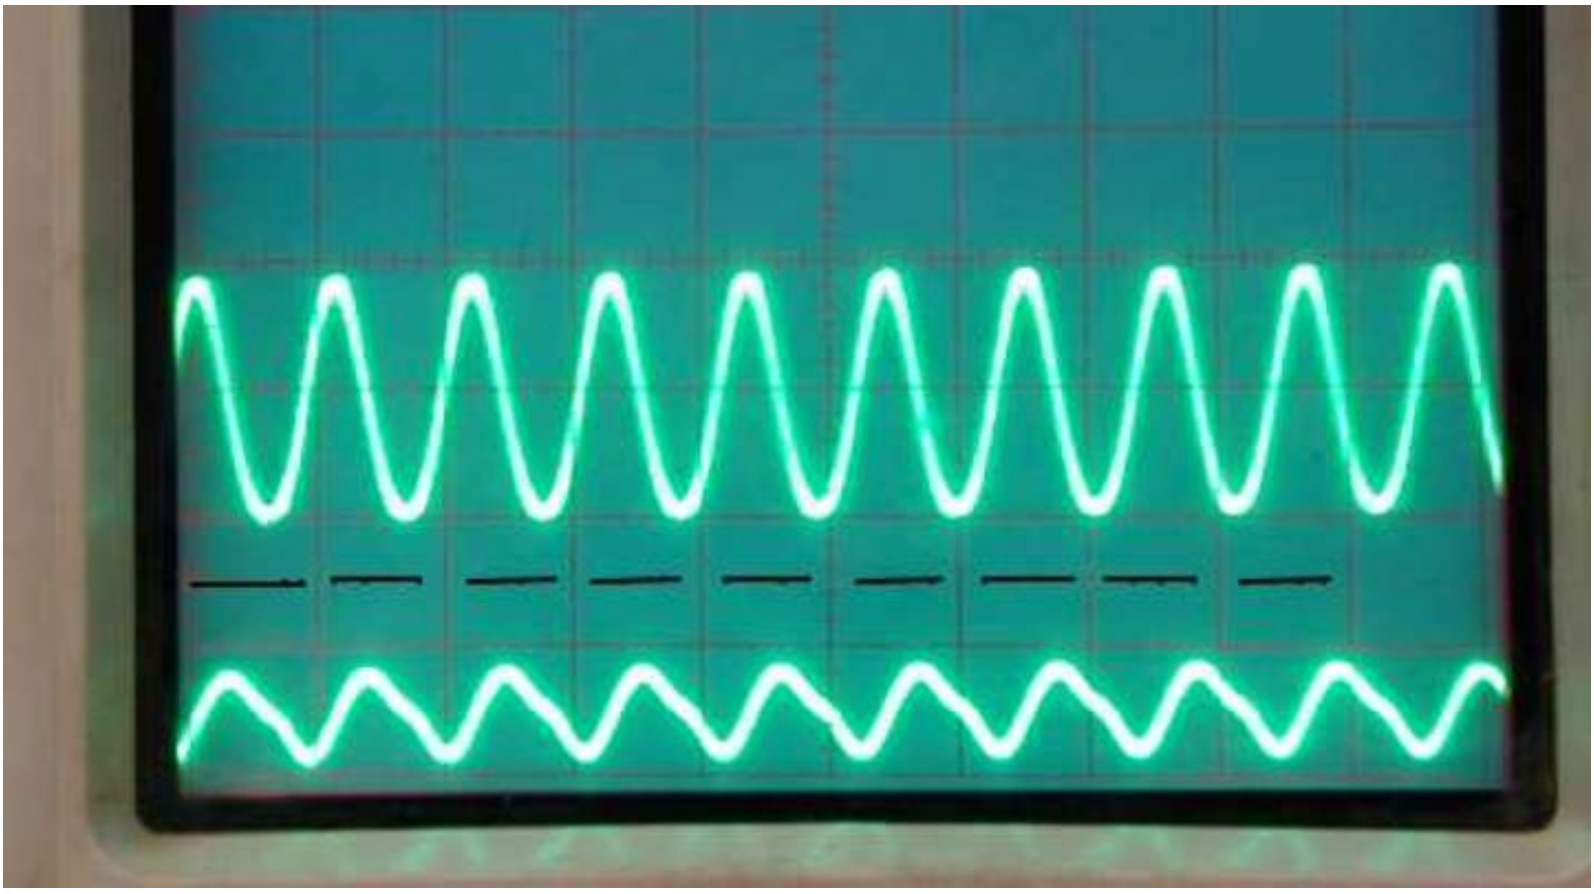
C1 is driven with a signal generator, L1 is selected to match the FET output to a 50-ohm load. The FET is operated at low current and has a series fast-switching diode, to simulate a one-way conducting vacuum tube.



This system was matched at 1.8MHz using the return-loss function of a network analyzer.



0dBm drive was applied with a signal generator, and the resulting waveforms appeared:

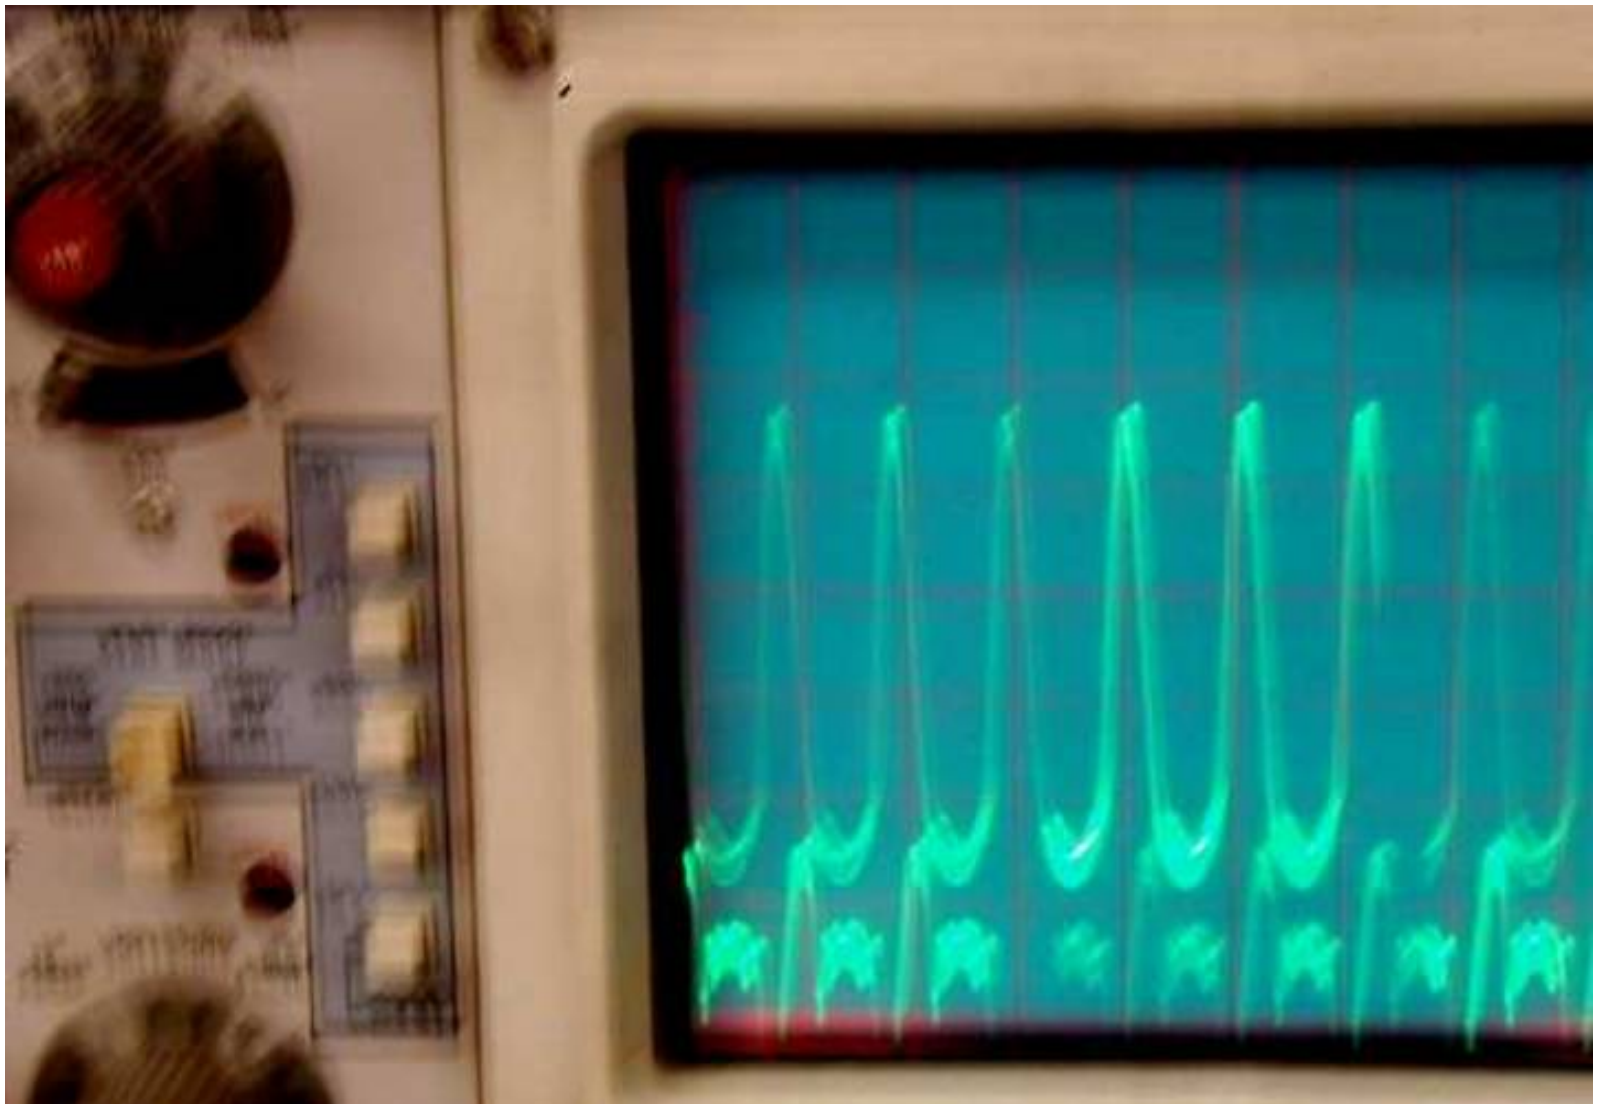


The upper trace is the output at D1 anode (point “B”). The black-dashed line was set at zero-volts. The scale is 10v/div.

The lower trace is drive voltage (point “A”). The scale is .1volt per division.

From this we see peak drain voltage swings approximately 20 volts, from around 5 volts to around 25 volts. This would be normal operation of a PA stage.

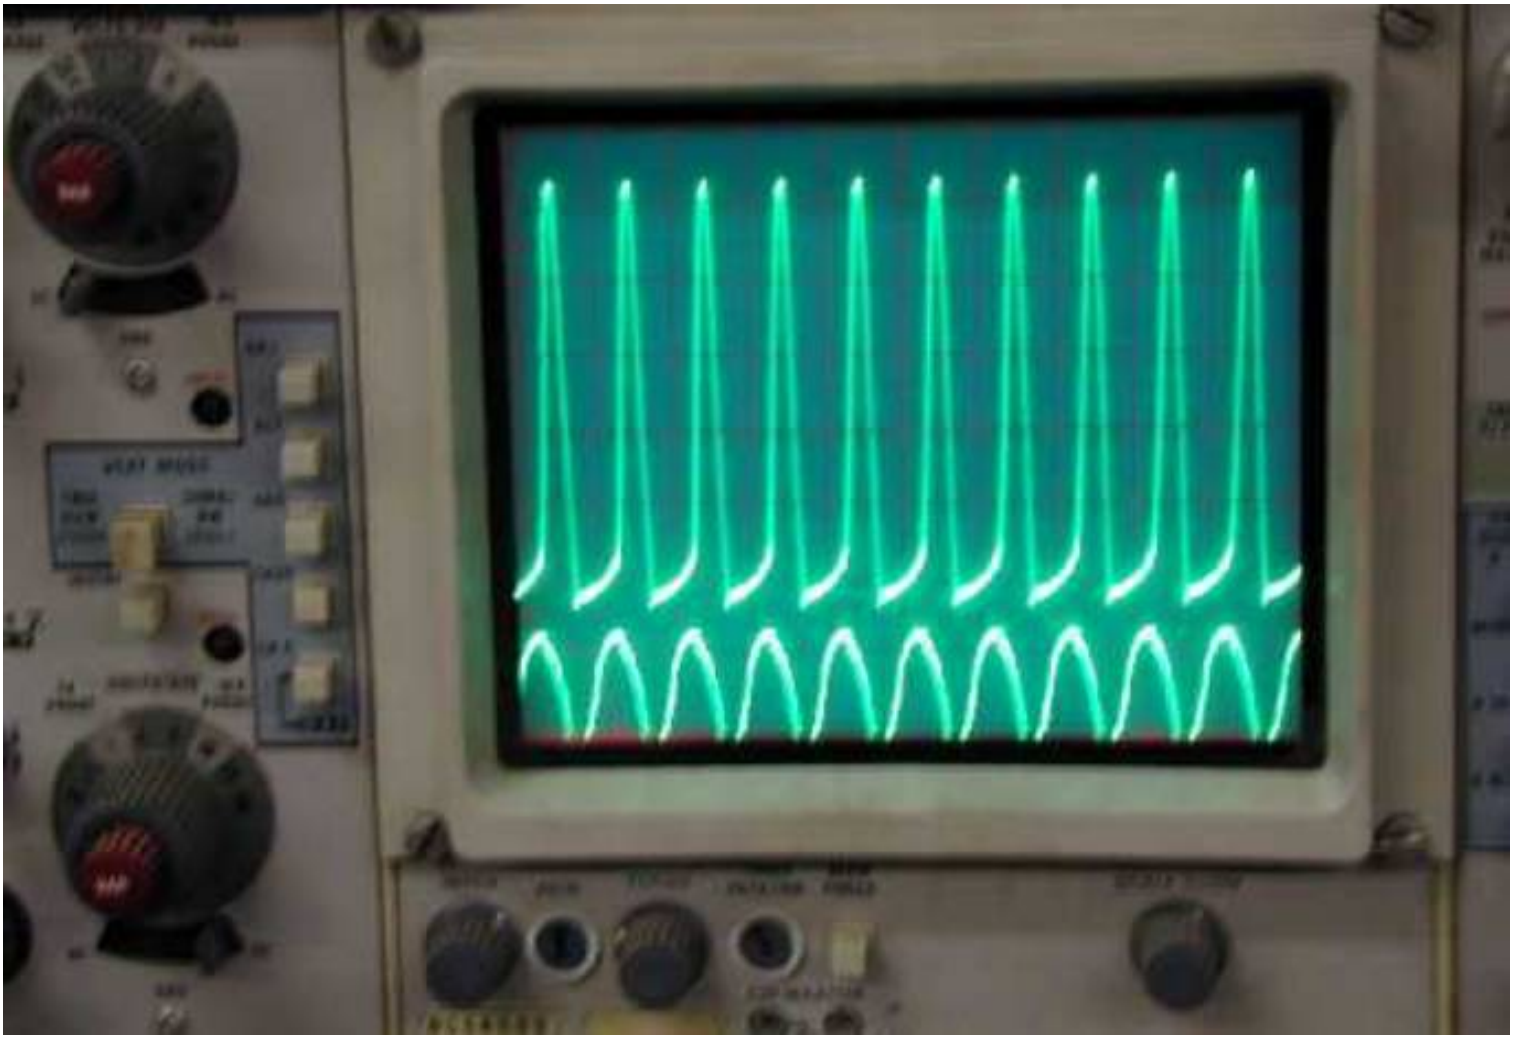
If we increase drive power and overdrive the PA, we get the following voltages:



We now see the peak drain voltage is almost 50-volts from a 15Vdc supply! In a 3000V PA stage, this would be 10,000V peak! It should make sense that amplifiers arc from grossly excessive drive power.

The next question would be what makes a normally driven amplifier arc. Often is when the load is inadvertently disconnected, either through poor relay timing, a bad cable or connection, or perhaps a failure in a component between the antenna and the amplifier.

Here is a scope picture with normal drive, but the load disconnected:



The drive has increased slightly because of feedback through the FET, now that the drain is swinging wildly almost 70 volts, all from a 15-volt supply. This would be the electrical equivalent of 14kV on the anode of a 3-500Z operating from 3000Vdc!

Conclusion

It’s easy to see why perfectly stable HF amplifiers, if overdriven or operated at moderate drive levels under conditions of a load fault, can be damaged by severe arcing.

Virtually all PA arcs (other than those caused by component failures or reduced voltage breakdown from dust or contaminates) occur when the load is interrupted or mismatched, and the PA no longer transfers energy to a proper load.

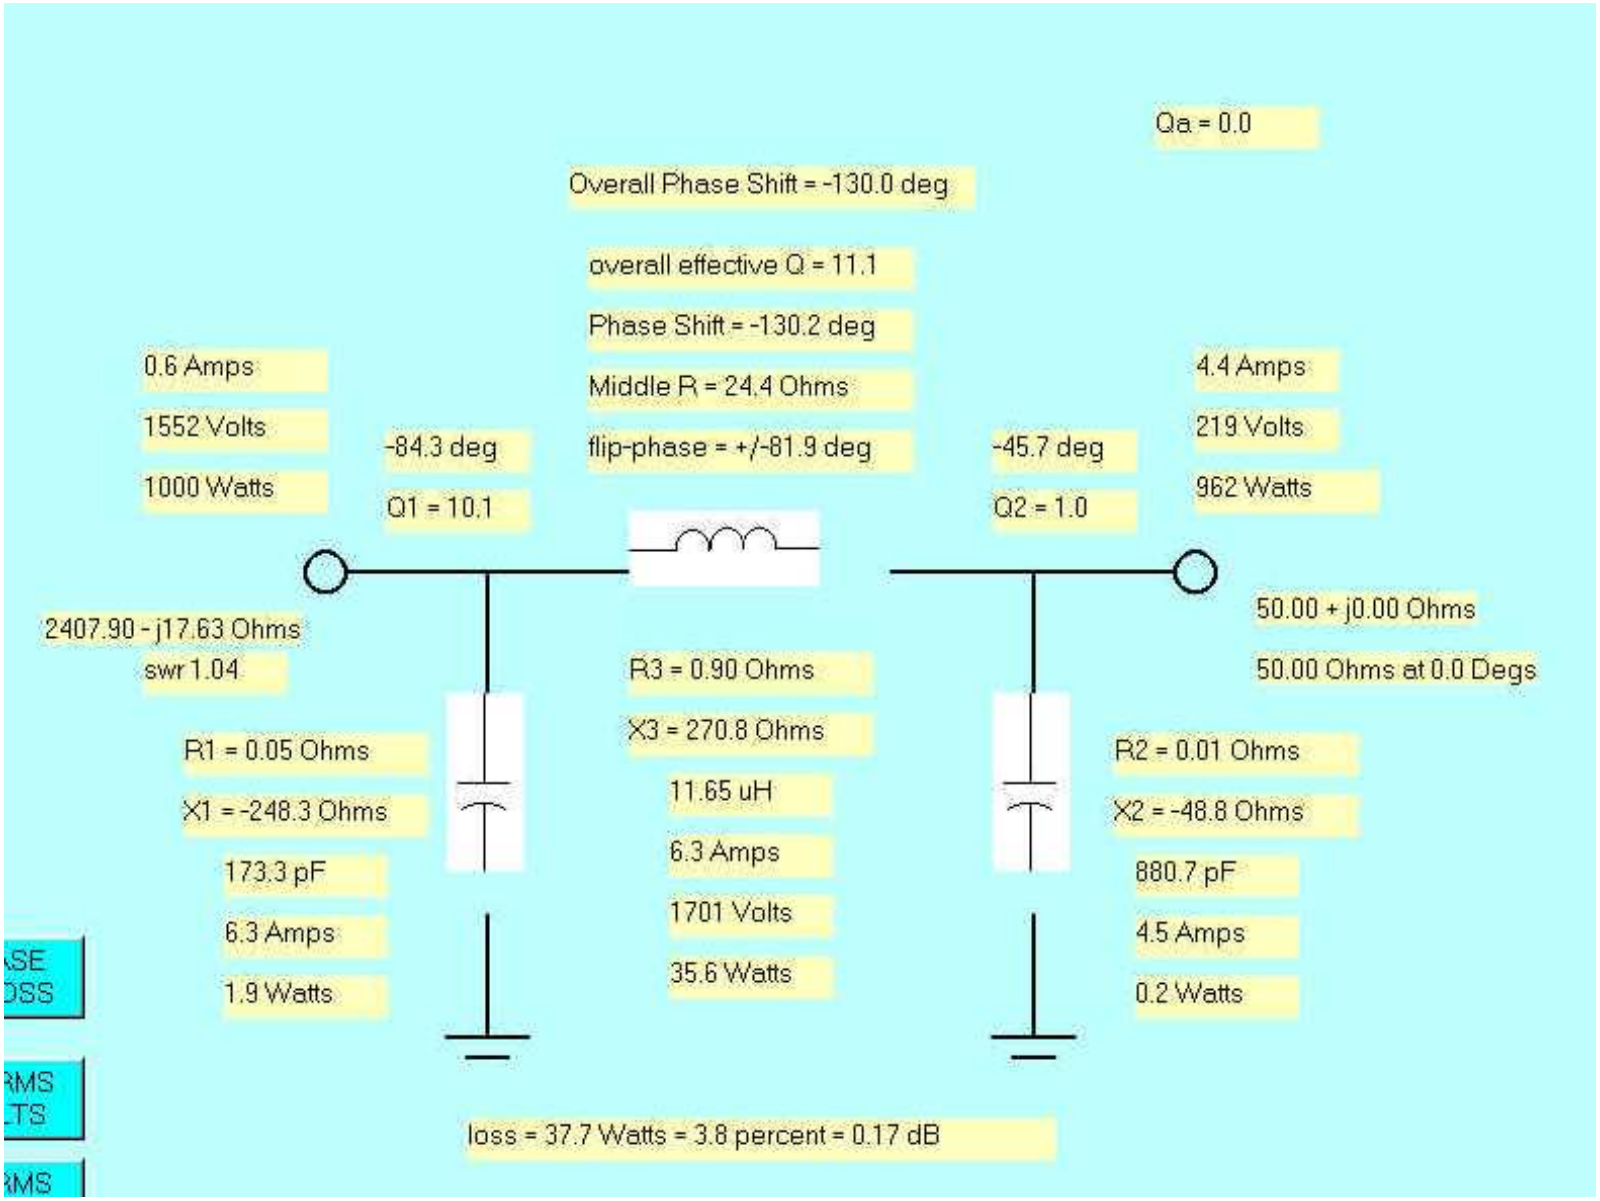
The vast majority of PA failures are caused by improper operation or defective components, not by "strange events" that are unpredictable and non-measurable.

Tank Circuit

[Home] [Up]

Amplifier tank circuit

The following is a model of an amplifier tank circuit with all parameters shown:



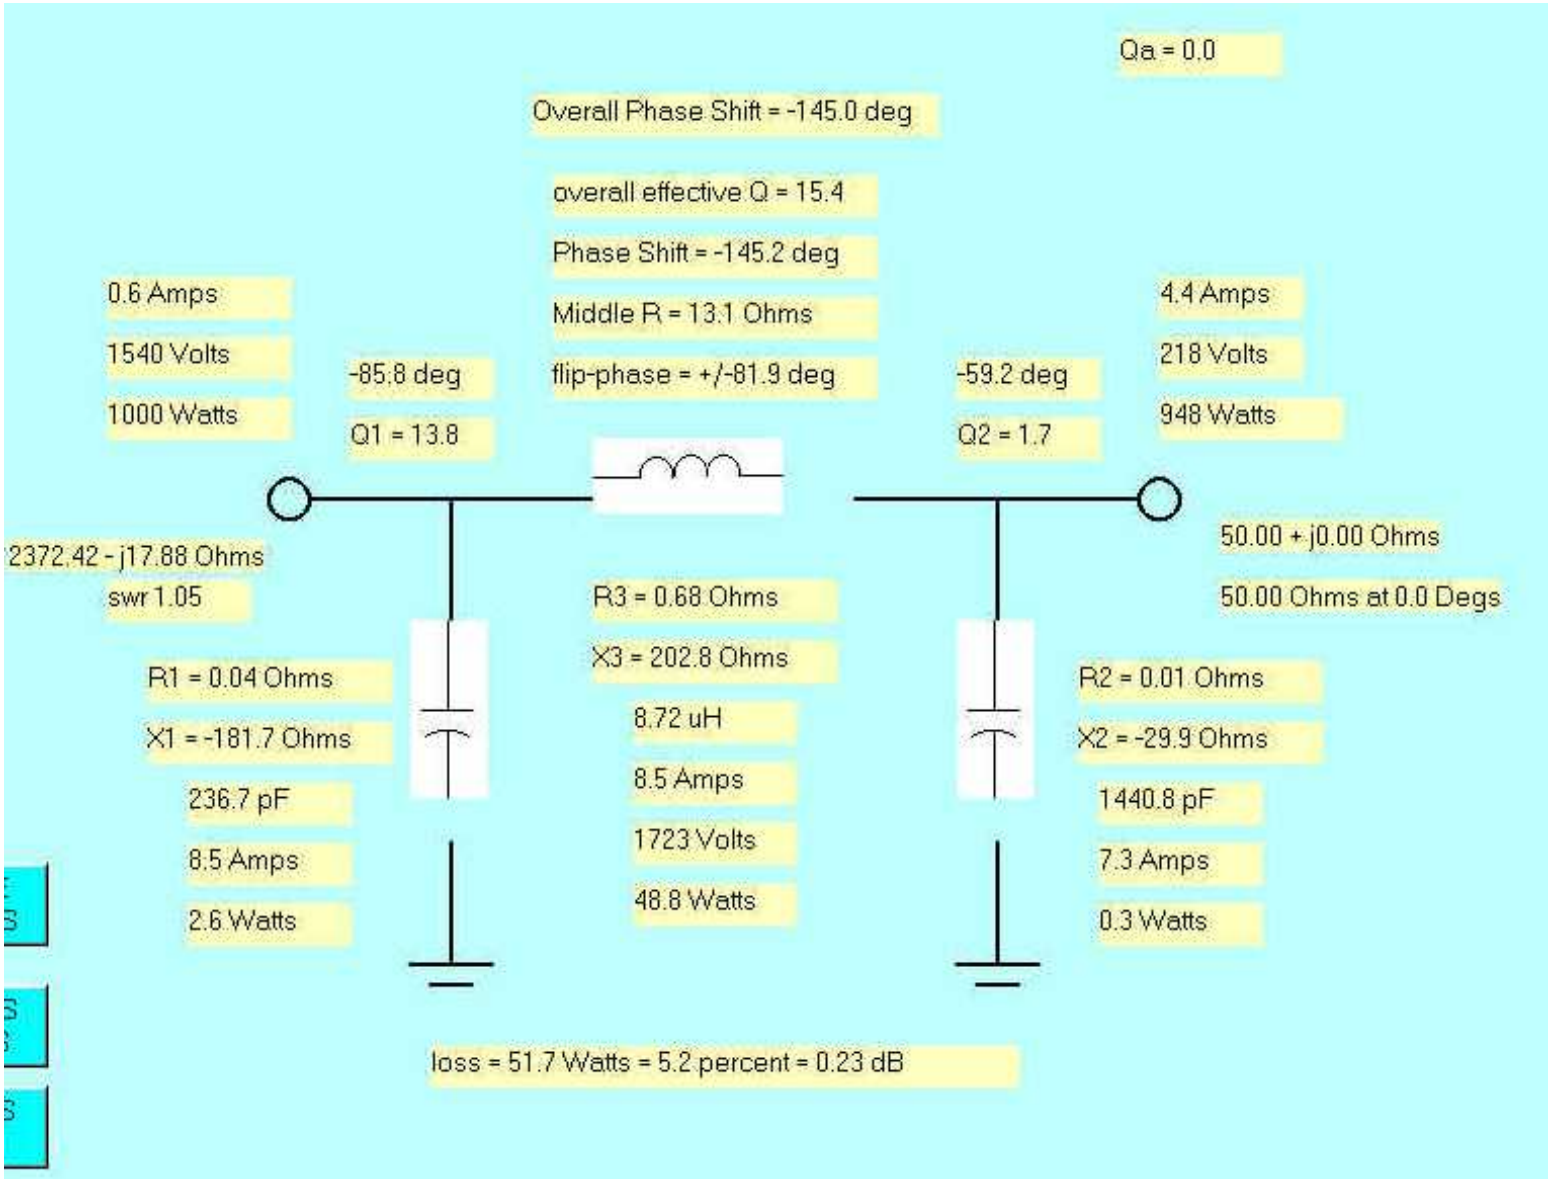
Notice the following:

Voltage across the tank coil exceeds input voltage

Current in capacitors exceeds input current

Phase shift across the inductor is -130 degrees

Increasing the loaded Q from ~11 to ~15 results in:



Notice the following:

1. Voltage across the inductor increases
2. Currents increase
3. Loss increases
4. Phase shift increases

Conclusions

(In all cases Q refers to loaded or operating Q)

1. Voltage across the inductor is always more than tank input voltage
2. Voltage increases with increasing Q
3. Phase shift increases with increasing Q
4. Currents increase with increasing Q

Voltages across a bandswitch contact can exceed tank input voltage, if the contact is near the input of the network. This, coupled with the high energy storage, can result in seemingly conservative components failing when the amplifier is lightly loaded for two reasons:

1. Tank circuit operating Q is higher when the tank is lightly loaded
2. The output device pumps the tank, and all of the energy may not be removed. This allows voltages at the input to greatly increase. See practical demonstration

Relay Timing

[Home] [Up]

Related page at **Relay Timing**

The text below covers electronic circuit to sequence and speed separate relays (like dual vacuum relays) and describes how to sequence mechanically ganged contacts like those in open frame relays.

Relay Timing and Sequencing

All amplifiers must be operated with a load on the output any time drive is applied to the input. Without this, the amplifier can be damaged by arcs or excessive internal voltages or currents. After all, all that power in the PA has to go somewhere! If there is no antenna connected, the energy builds up in the tank circuit or other energy storage system in the amplifier until something absorbs the excess energy that would have made it to the antenna.

In cases of unstable amplifiers, such as those using non-neutralized tubes with high internal feed-through capacitance (i.e. 572B's or 811A's), the output relay must be closed before any idling current is applied. (See stability)

The normal process of engagement sequencing is:

- The operator "keys" the radio (zero time)
- Amplifier output contact fully transfers (time "a" 1-10mS)
- The amplifier input contact fully or partially transfers (time "a" plus 1-3mS=time "b")
- Amplifier operating bias or cathode return path contact closes, applying normal operating bias (time "b" plus 0-2mS=time "c")
- Radio output delay, RF appears at the output of the amplifier (time "c" plus 0-10mS)

This entire sequence can take up to 15mS with large open-frame relays.

The release sequence must be:

- Transmitter ceases output of RF
- Bias drops
- Input relay drops
- Output relay drops

If this process is not followed the bandswitch, capacitors, or other tank components can be damaged from intermittent arcing!

Even though all radios should have a transmitter inhibit delay, many radio designs do not include such delays. The radio output delay primarily prevents shutting down of the radio during leading edges while relays transfer, and annoying broadband clicks or spits at the start of VOX closure or each transmitting cycle.

Some radios have incorporated delays, but incorrectly applied the delays. For example, some early Kenwood radios actually delayed the turn-on and turn-off of amplifier relays, forcing amplifiers to "hot-switch". Such radios are often disastrous to amplifier component life.

Increasing Relay Speed with proper sequencing/ Dual Relay System

Relays can be made faster by operating them from a higher-than-normal supply voltage, and using external current limiting to provide a constant current at the relay's rating. For a single relay, omit everything associated with RL2. R3 becomes a jumper.

A two-relay circuit would look like this:

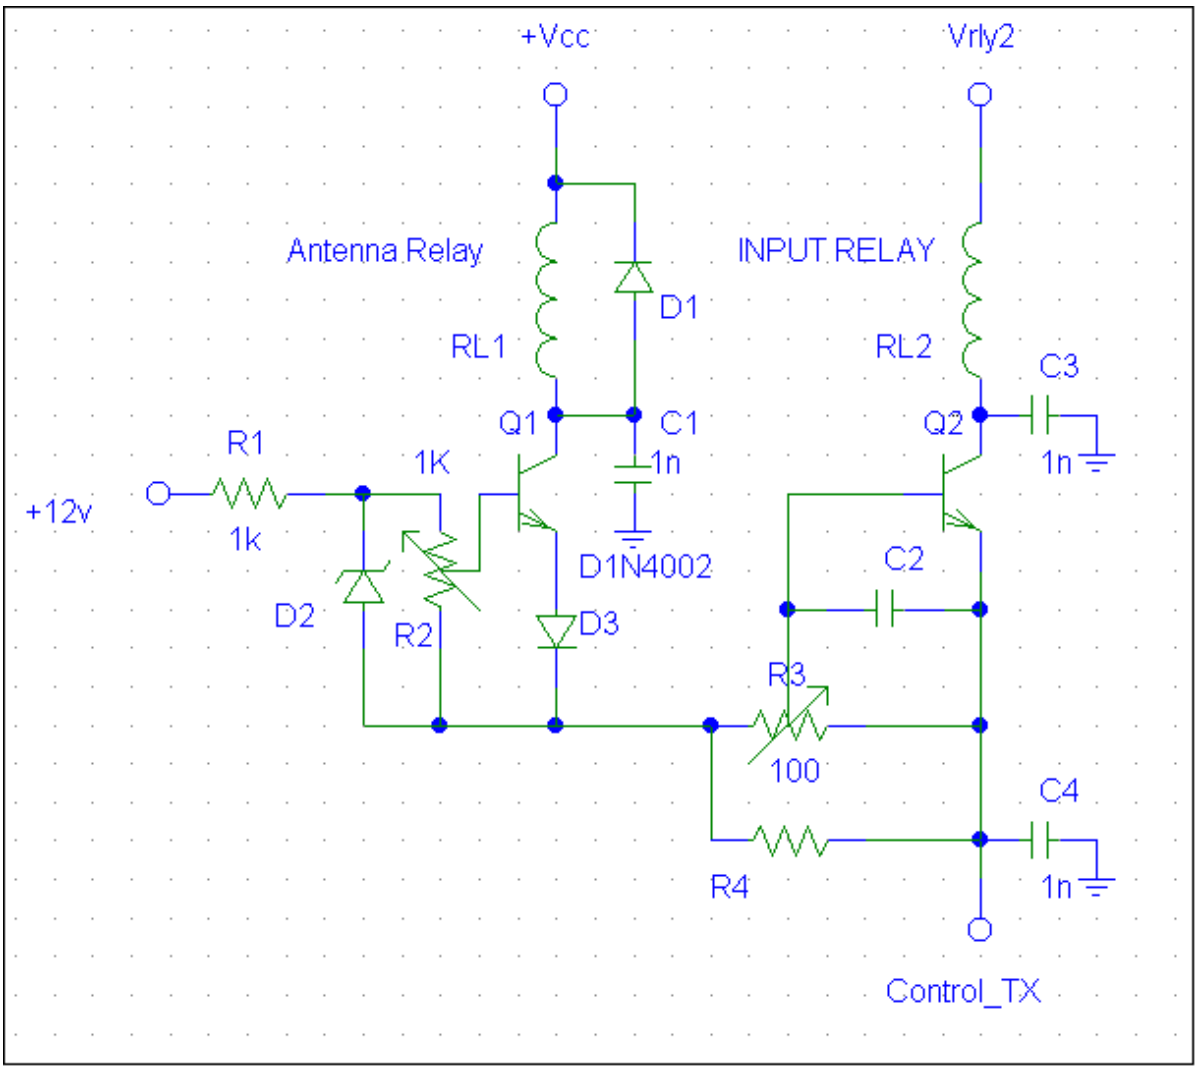


figure 1

R1 1k 1-watt

R2 1k 1/4-watt

R3 100-ohm 1/4-watt

R4 found by the following, where Irl1 is the antenna relay current:

$$R := \frac{.7}{\left(\frac{Irl1}{4}\right)}$$

For example:

$Irl1 := .25$

$$R := \frac{.7}{\left(\frac{Irl1}{4}\right)}$$

$R = 11.2$

Power rating of R4 is:

$P := I^2 \cdot R$ where I is RL1 current and R is R4 resistance.

C2 input time delay cap, normally 10-50uFd 10v

D1 1N4001-1N4007

D2 3-4V small zener (.25w-1w)

Q1,Q2 NPN power transistor. Vceo rating must exceed Vcc supply voltage, plus safety margin. Imax must exceed relay current ten times or more. Watch dissipation! Use hfe above 40 for best current stability.

Power Source:

- Vcc supply must exceed RL1 relay voltage by 2-3 times.
- Vrly2 supply should approximately equal RL2 rated voltage. This voltage must be obtained from a reasonably stable supply voltage +-20% regulation no load to full load. Do not use a large dropping resistor, or you will unintentionally speed up the input relay RL2.

R2 sets current through RL1 (antenna relay). The adjustment range of R2 is from zero current to a maximum where only RL1 resistance limits relay current. R2 must be adjusted for rated current through RL1.

R3 should be set for proper delay of RL2 (input relay).

D1 adds delay to release of RL1 (antenna relay). If release of antenna is too slow, add small value of series resistance until RL1 opens just after RL2 opens.

The above circuit has the following features:

- Control V open circuit will never exceed +12V
- No back-pulse or transient is generated
- Delays are easily tailored to any relay
- Extremely high or dangerous voltages are not present.
- Speed is faster than systems using dropping resistors for speedup
- Relay speed is maximized without exceeding rated relay current

How It Works

Relay pull-in is always slowed by the inductance of the armature coils. Since RL1 is fed by a voltage higher than normal, current will reach pull-in strength much sooner than with normal supply voltages. Q1 is a constant current source, adjusted by R2. This circuit prevents RL1 from being overheated, or having excessive steady-state operating current. Q1 also limits the voltage appearing at Control_TX.

After RL1 (antenna relay) current reaches a value that allows contact transfer, Q2 will conduct. This applies current to RL2, the input relay. It pulls in last, time delay is set by R4, R3, and C2.

Upon release of Control_TX, RL2 releases with only internal relay delays. RL1 is held on by the current loop through D1 as the field tries to

collapse. This causes RL1 to have a longer release time than RL2, so the antenna remains connected longer.

No back-pulse voltages make it to the exciter, because of the circuit configuration.

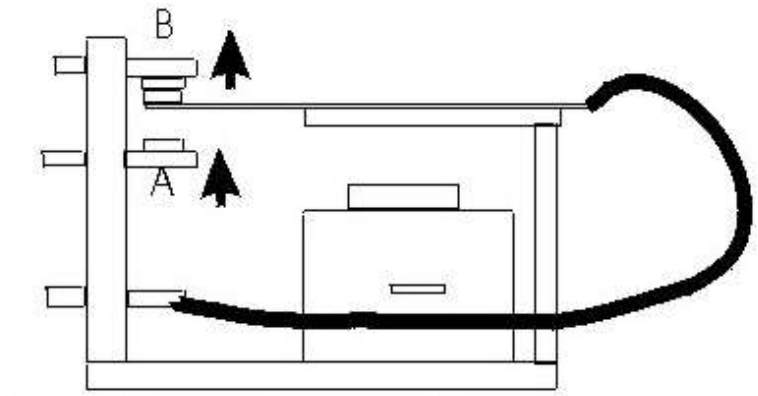
This is a simple, safe, adjustable relay system.

Mechanically Ganged Relay Contacts

Large multiple-contact open-frame relays using a common armature can be mechanically sequenced by slightly bending each contact carrier, the associated normally open contact, or both.

By carefully pushing on the armature center:

- The output contact should very obviously close first
- The input contact should close second
- The cathode or bias contact should close last, but nearly at the same time as the input contact



Relay Sequencing open frame relay

1.) Reference the pictorial above, use needle nose pliers to bend the unused normally OPEN contact at the amplifier tank circuit connection UPWARDS. Do this by positioning one jaw on the top of the bakelite frame and the other under the outer tip of "A" and squeezing until "A" is just slightly bent upwards towards the moving contact. ***DO THIS ONLY ON THE OUTPUT CONTACT!*** This will force the TANK CIRCUIT of the amplifier to connect to the antenna ***BEFORE*** the input circuit connects. **This change prevents arcs in tank components caused by improper relay timing.**

2.) Locate the unused normally closed contact for bias switching. Using the same technique above, bend "B" (the normally closed contact) upwards until B no longer contacts the moving contact. **This change puts 1/3 more contact pressure on the amplifier bypass contacts, and decreases receiver dropout when the amplifier is on bypass.**

When properly modified, you should see the ***output contact*** make slightly before any other contact on the relay when the armature is manually closed. You should see the UNUSED bias or cathode switching normally closed contact have a slight gap when the relay is NOT energized.

Separate Relays

Separate relays offer a unique problem. First, some relays can actually be dangerous to use.

NEVER USE REED RELAYS, UNLESS YOU ARE ABSOLUTELY SURE EACH RELAY HAS A SINGLE REED THAT MOVES BETWEEN THE NORMALLY OPEN AND CLOSED STATIONARY CONTACTS. MANY REED RELAYS HAVE A NO and NC REED IN A SINGLE COIL. THEY WILL RUIN EXPENSIVE RADIOS IF A REED WELDS SHUT!

NEVER USE COMBINATIONS OF SINGLE THROW RELAYS TO MAKE A DOUBLE THROW RELAY!!

DUAL REED RELAYS OR SEPARATE SINGLE-THROW RELAYS (like a SP NO and SP NC combined to make a SPDT section) CAN CAUSE SEVERE DAMAGE TO YOUR AMPLIFIER OR RADIO.

Relays must have an absolutely fail-proof positive transfer between open and closed poles. The normally closed poles should also be series-connected so the path is through both normally-closed contacts. This will prevent any possibility of accidental connection between amplifier output and input in the event of a relay or component failure.

Amplifier and Radio Relay Sequencing

[Home]

Related Page on Relay Timing

One problem on SSB and CW is relay time delay, especially when multiple devices are connected. Some radios have inherent RF output to external relay control timing issues. The result of improper timing is often a very wide leading edge "pop" or "click". The pop or click repeats at every relay closure. Slow VOX or semi-break in causes less frequent pops than QSK or fast VOX operation.

Required Sequence

The required sequence is:

1. Key closure or voice start
2. Unwanted delays in keying, VOX, and radio circuits
3. Amplifier relay or accessory (like front-end saver) signal activation
4. Desired RF hold off delay that is slightly greater than longest possible relay pull in delay for all switched devices
5. RF Appears
6. Keying or voice stops
7. RF stops (must include fall time of RF envelope)
8. Desired delay for complete signal fall before relay release

Time Delays

Most small to medium relays for amplifier switching are 5-15 milliseconds, with small enclosed and vacuum relays running around 5mS. Typical open-frame relays are in the 10-20mS range.

- **Relay closing time delay increases greatly as voltage across the coil is reduced. Decrease in speed can be as much as 300% as minimum operating voltage is approached.**
- **Relay opening time is delayed by excessively high relay holding current and back-pulse canceling diodes. The slowing can typically be as much as 200%. If you work QSK, use a design that eliminates back-pulse canceling diodes.**

PIN Diode switches can close and open in a few milliseconds or less.

Some very small reed relays rival PIN diodes in time. There are some low power reed relays that operate in less than 1mS!

Common Errors

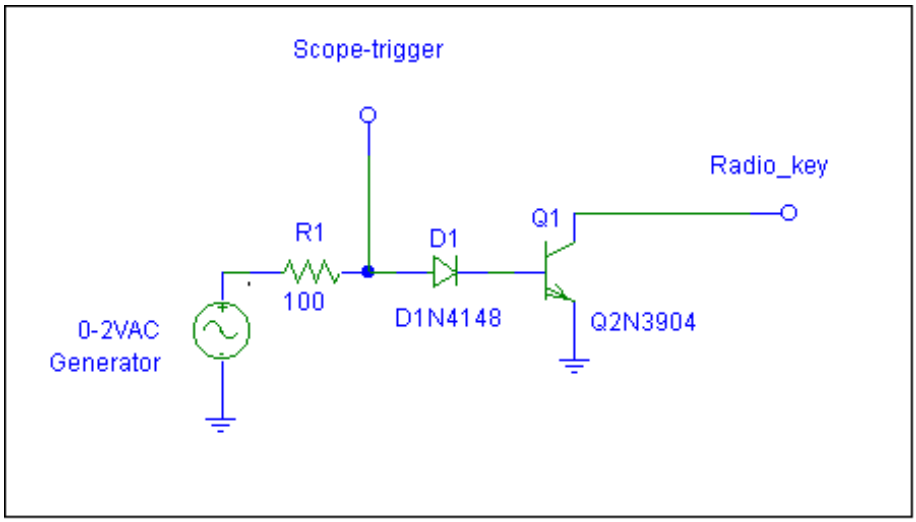
The most common errors are:

- **Lack of high operating voltage across the relay coil on pull-in. This is caused by excessive voltage drop in switching components or low relay supply voltage.**
- **Use of relays to buffer or isolate amplifiers**
- **Use of accessories that add time delay to relay lines**

Measuring Time Delays

Measurement of time delay requires a dual channel oscilloscope with separate trigger input, and a low frequency signal generator.

I normally use this keying test setup:



- The level of the generator controls weight or duty cycle (ratio of on-to-off time).
- The trigger is to the scope external trigger. The level threshold of trigger sets scope sweep starting time.
- The scope probes can be moved to any points to compare timing or sequence delays.

What to Watch

The radio must have enough RF output delay AFTER the radio low-amplifier control signal appears so the amplifier relay does not truncate

leading edge of RF

The radio or amplifier must hold the relay long enough so the falling edge is not truncated.

Problem Areas

- **Any device added between the control line output of the radio and the amplifier**
- **Any device that switches on the output of the radio**
- **Front end savers and amplifier relay buffers are a particular problem, often causing excessive control line delay times**

W8JI Control Line Interface

Some systems have multiple control lines from different devices that must be "keyed" in parallel. With direct parallel connections, one device can load the system and stop other devices from operating properly. This usually happens when a device is off but still connected. Simple isolation diodes work to prevent that, but the voltage and current at the radio is the highest voltage of any device and current is the sum of all the device currents. Even worse, the radio output control has to discharge the RF bypass capacitors of each connected device.

My 160 station consists of a solid-state homebrew amplifier with 16 MRF-150's, an AL1200, an 8877 amplifier and either an FT1000D or an Orion. I almost never listen through the FT1000 or Orion when working CW, so I also have at least two outboard receivers that must be muted.

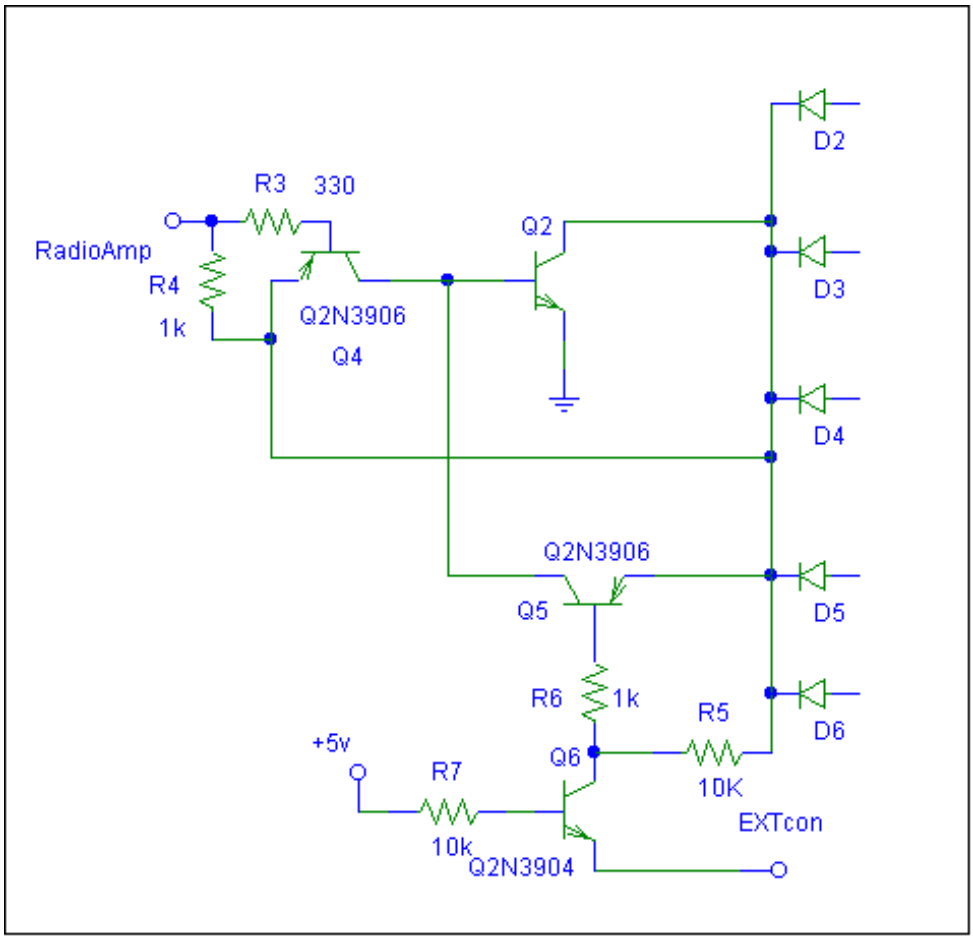
My homebrew 8877 amplifier uses a high-voltage relay system, the solid state amplifier has 5-volt TTL level switching, the TX antenna sampling line uses a 28-volt vacuum relay, and the receivers have 5 volt muting lines that mute when pulled to ground. The Ten-Tec Orion requires an isolation relay on the receive antenna port, and I occasionally switch other devices when transmitting.

All of this is driven by a microprocessor controlled antenna switching system that prevents changing antenna directions or antenna while transmitting.

Any attempt to directly parallel devices would be a disaster!

The circuit below interfaces my radio to multiple amplifiers, receivers, and antenna control systems. Multiple devices can be connected in parallel, such as 28 volt relay control lines and 5 volt control lines, as long as they are all positive voltage. This system pulls within 1 volt of ground.

It is necessary to be careful with some radios. There is no standard interface voltage. TenTec, for example, uses interface systems that have a threshold around 1 volt. TenTec's handshake lines require buffering with a small very fast reed relay, many transistors and IC's will not pull low enough to activate the TT handshake line. If you need relays of any type between the amplifier keying system and the radio, always be sure you test the entire system for proper relay sequencing.



RadioAmp goes to radio's amplifier keying control output.

EXTcon goes to computer or other keying device that only handles low-voltage low-current.

D2-D6 go to devices that require control.

+5V sets the threshold of EXTcon trigger. EXTcon open circuit voltage is also limited to less than 5 volts.

The radio is exposed to the highest voltage from the keyed loads, but the current is limited to roughly V/500 where V is highest voltage device. A 28 volt amplifier would require the radio to key about 14mA peak current during relay transition, although average current would be lower. The exact current depends on beta of Q2 and Q4, and if EXTcon is used. A device like Q6 can be added to the radio line to limit radio voltage to 5 volts or less regardless of amplifier relay voltages.

HF Stability

[Home] [Up]

HF instability, or instability at the operating frequency of the amplifier, is the most damaging type of problem. This is because the primary energy storage system, the tank circuit, is resonant with high Q at or near the operating frequency.

If you look at network analyzer swept measurements of a tank circuit, you'll see the maximum voltage distributed through the tank occurs at or near the operating frequency.

Some amplifiers have designed-in HF stability problems. The Yaesu FL2100 is one example of an amplifier with poor RF design. Un-neutralized amplifiers using tubes with high feedthrough capacitance are another source of problems. Any amplifier with high feedthrough (or feedback) capacitance is a candidate for HF instability if the load is removed while the amplifier tube or tubes are drawing quiescent current. Dentron amplifiers with four 811A and four 572B tubes, as well as the Collins 30L1 with four 811A's, are examples of relatively unstable amplifiers (along with the FL2100).

The cure is to remove intentional undesired feedback or to neutralize the PA!

SB-221

[Home] [Up]

SB221 Tank Circuit Voltage Distribution Vs. Frequency

Arcs in the bandswitch, tuning capacitor, and other tank components are often blamed on parasitics. No one ever can catch the amplifier in such a state of oscillation, so we are just left with conjecture and speculation that the arc was caused by a VHF parasitic.

It should be easy to prove if a VHF oscillation, or oscillation or drive on any frequency, could cause an arc. All we need to do is excite the anode of the PA tube with RF, and measure the voltage distribution in the tank with a very high impedance detector probe. This would then tell us at what frequencies the highest voltages occur.

While every amplifier manufactured is claimed to suffer from parasitics, I have limited time to measure and document the results. It would be impossible to test every PA, so I picked a PA that is commonly rumored to have parasitics.

The purpose of the series of measurements below is to see if it is possible for resonances in the tank to INCREASE anode voltage to the point where an arc will occur, or if it just an imagined problem or a problem "invented" to sell a specific cure.

Test Method

It is not practical to drive an HF PA from frequencies between 1 and 300MHz, so we have to excite the tank another way. The best method is to use a constant voltage source injected at a tube anode, and measure the voltage throughout the tank without disturbing anything. This can only be accomplished with a high input impedance detector probe, and a voltage-leveled source. Fortunately I have both available.

In order to be accurate, the tank must be adjusted normally. I did this by tuning the PA with a 100 watt exciter and a 50 ohm load. After tuning, the amplifier is disconnected from power mains and from the exciter.

The tube is purported to be the source of unwanted VHF oscillation energy. By injecting the anode with a known voltage, and sweeping the tank slowly over a wide frequency range, we can determine voltage distribution at any point in the tank system. By looking at the relationship to anode voltage, we can determine if it is even possible to arc a tank at frequencies far removed from the operating frequency.

Of course this would not prove an arc would occur, it would simply prove if it is possible for an arc to occur and at what frequency. The higher the voltage at a given frequency, the more likely an arc would occur. If the voltage is much lower, and arc at that frequency would be impossible.

The Measurements

The anode is excited with a swept power-leveled source feeding a bridging pad and the anode. The sweep is from 1 MHz to 300 MHz. The small coaxial cable and multicolored wire are from the high impedance J-FET source follower probe used to feed the second RF port of an Agilent network analyzer. In this condition the network analyzer acts like a sweep generator with a voltage detector.

- HP Network Analyzer source connected to tune anode at tube. Constant power source leveled at 10dBm at injection point load.
- 100k-ohm 3pF active voltage detector probe
- Transmission loss calibrated at zero dBm for mid-scale into the 100k probe as detector, across 2700-ohm resistor.
- All displays 10dB/div voltage, sweep is 1MHz to 300MHz.
- 1600 data points, 5 second sweep time.

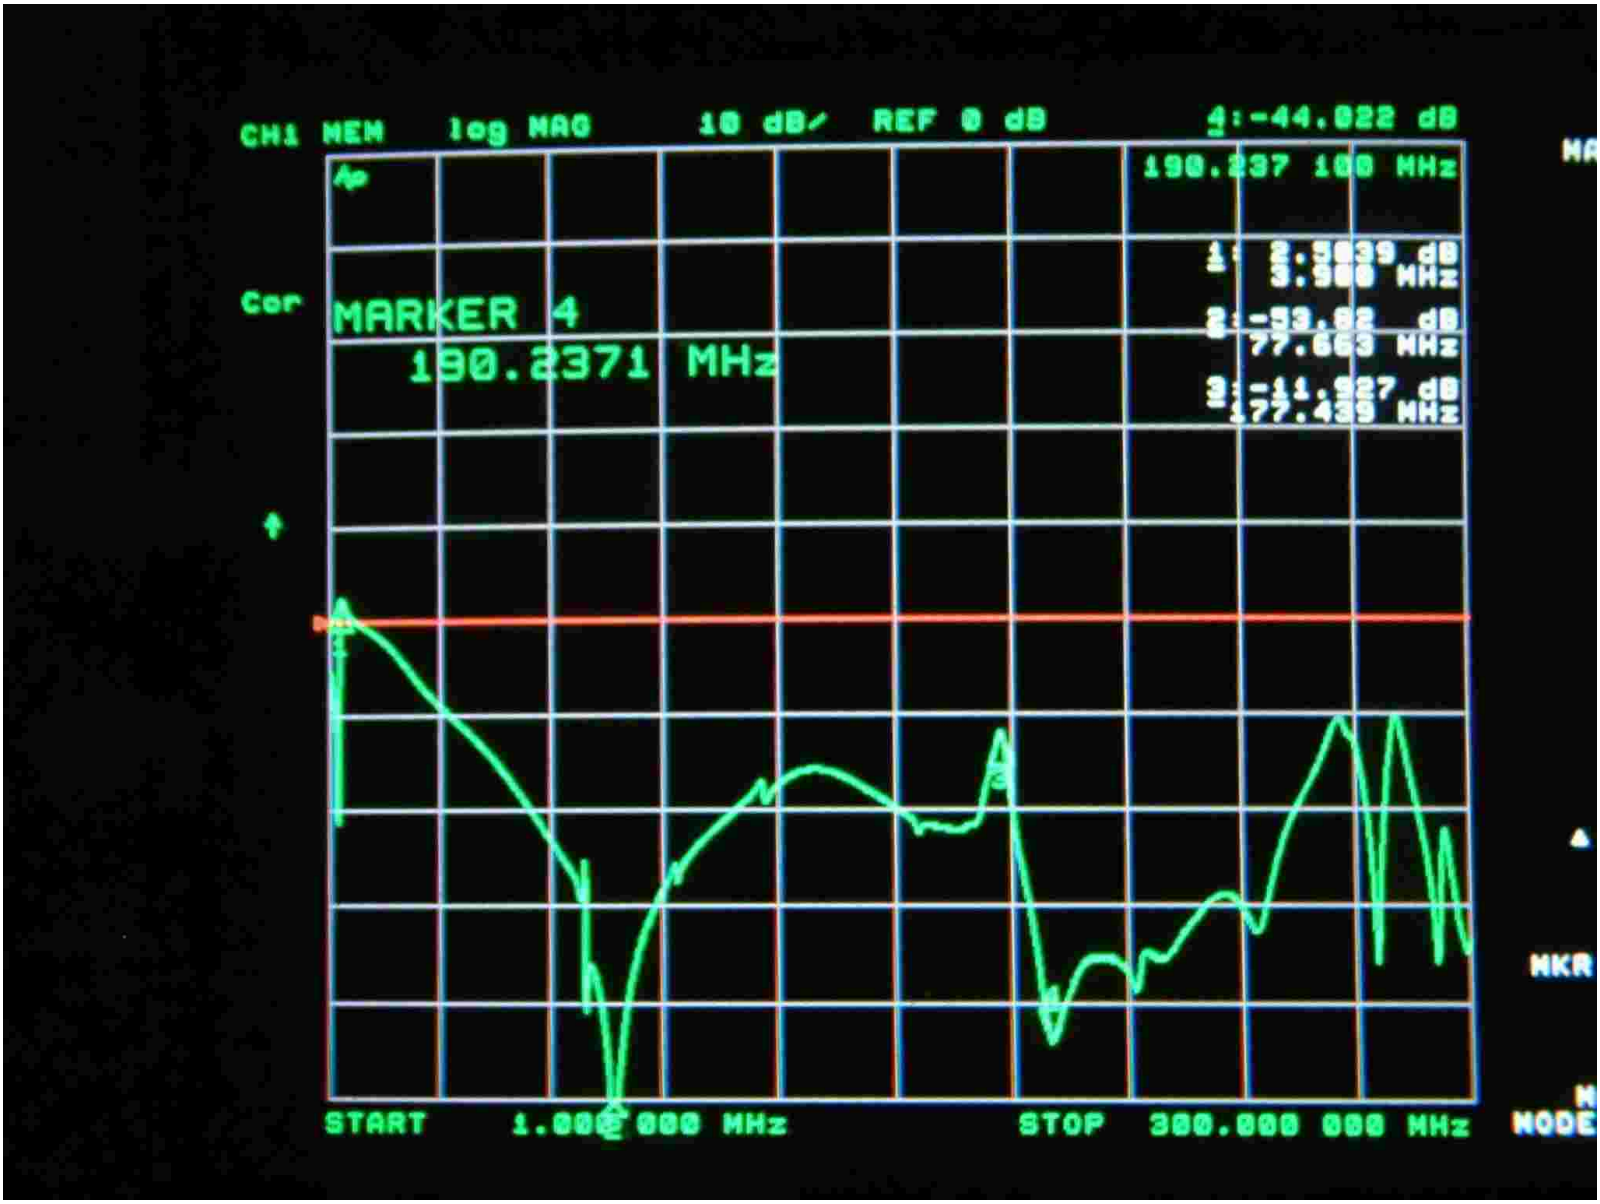


Figure 1. Tank adjusted for normal operation at 3.8MHz. The above sweep is voltage across the tuning capacitor, which is +2.5dB at plate tune capacitor. +2.5dB becomes reference for comparing HF voltages to parasitic voltages. With the anode at 3000 volts peak swing at 1300 watts on 80 meters, the reference level would be 2.5dB. A 1300-watt parasitic would develop the same starting voltage swing and it would be attenuated through the tank by the same amount as the displays indicate.

In this case at the tuning capacitor, a 180MHz parasitic would be 14.4dB down in level (marker 3) compared to the HF voltage (marker 1). This is 19% of the HF voltage level, or 570 volts peak with 3000 volts of anode voltage swing. A VHF arc at 180MHz would be impossible. As a matter of fact, there isn't any frequency very far from the operating frequency where an arc could occur!

A grid dip meter would show a strong dip at 180MHz, because it would be loaded by the tank. This is why a grid dip meter can not locate a "problem frequency", it might actually be locating a good frequency!

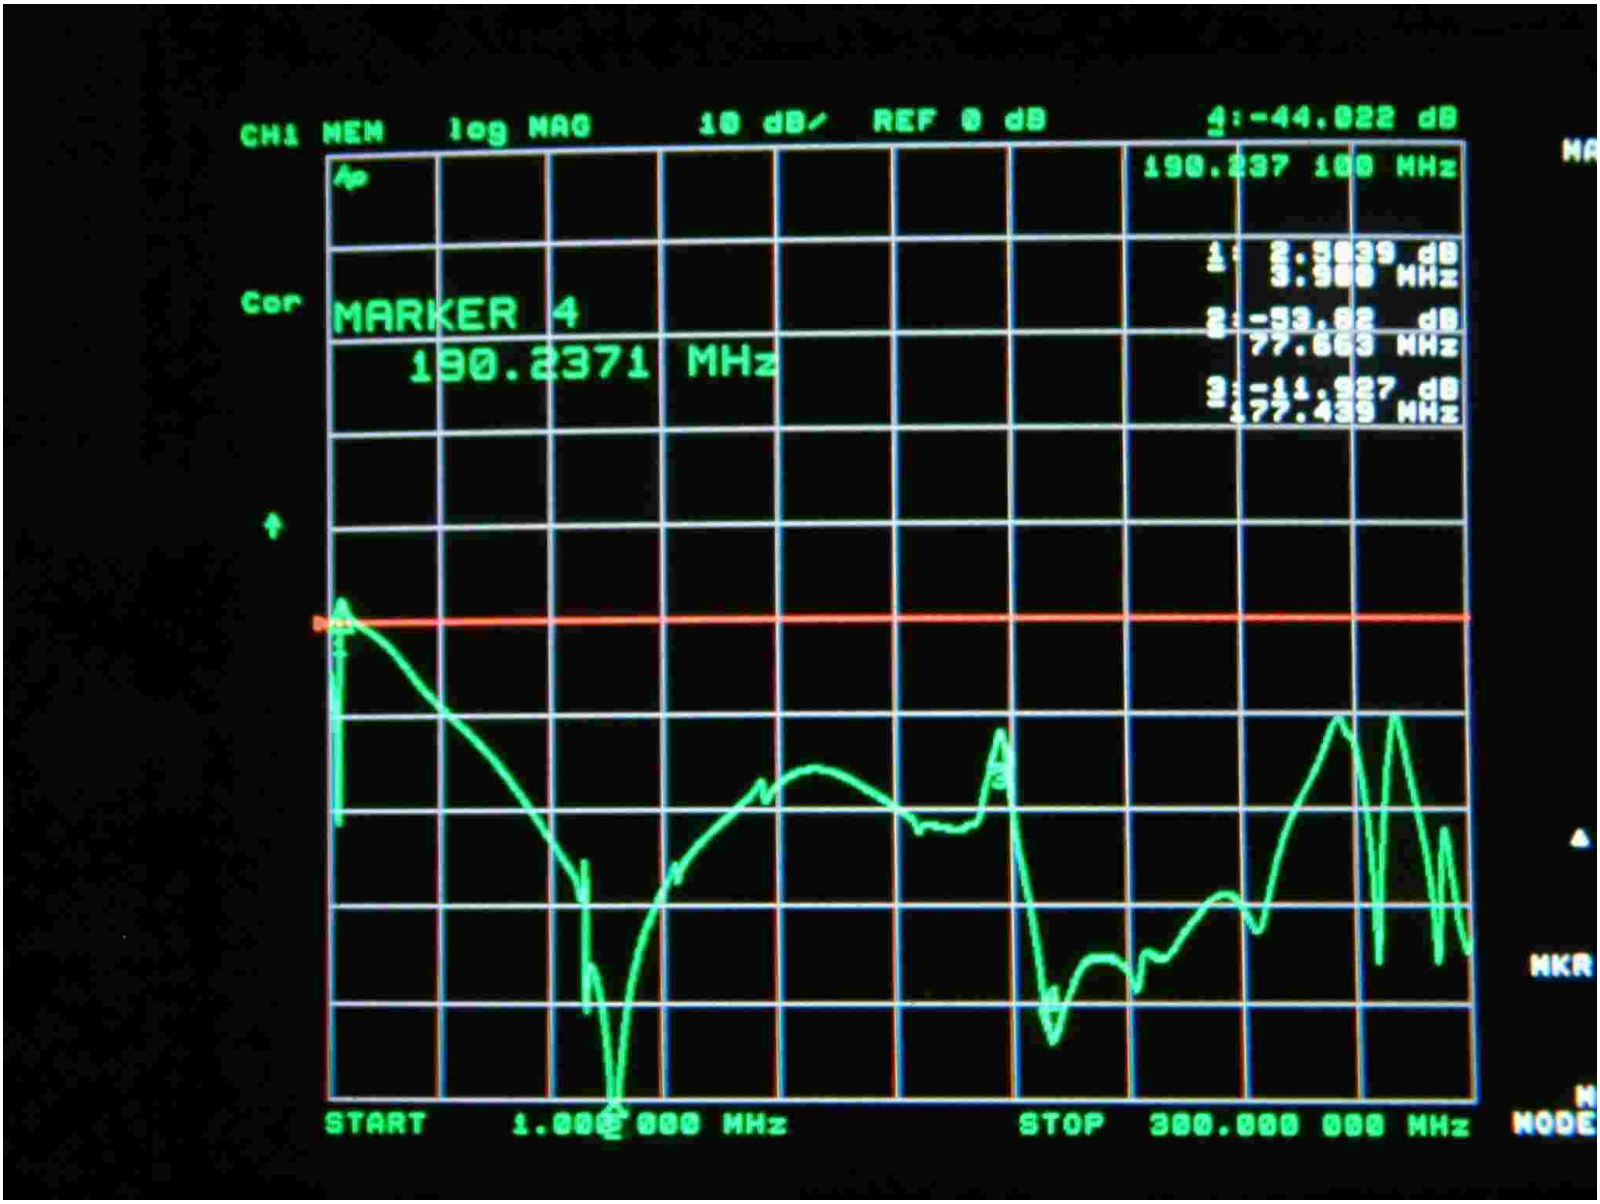

Figure 2. 80m position. The above graph indicates voltage at the 15 meter tap to closest arc point on switch. Highest voltage at frequency marker 3 is -12dB at 177 MHz. This is -14.5dB anode voltage, or 19% of anode voltage! 19% of 3000 would be only 570 volts, making it impossible to arc the 15M tap at VHF frequencies. After all, that tap survives constant exposure to over 3000v at the fundamental frequency when operating 80 meters!

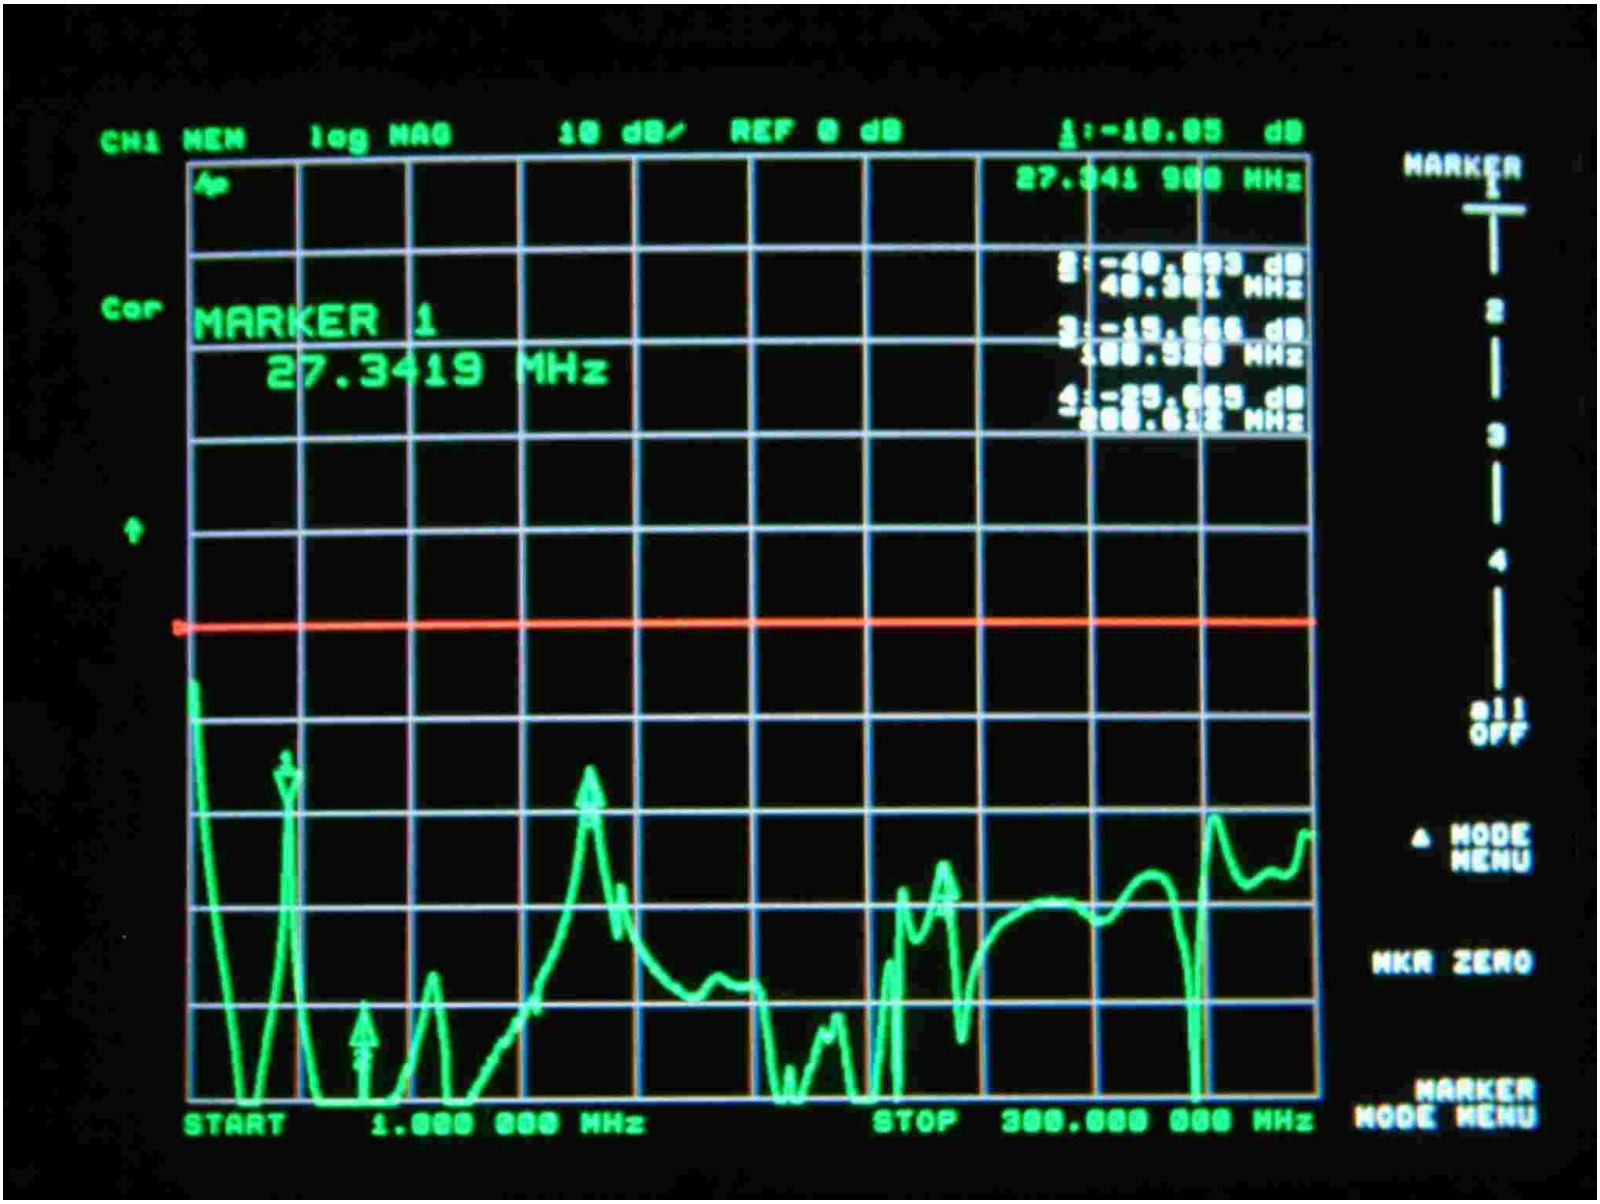

Figure 3. 80m position. Voltage across loading capacitor. All spurious response voltages are at least 20dB down from the anode voltage. No VHF arcs possible here either.

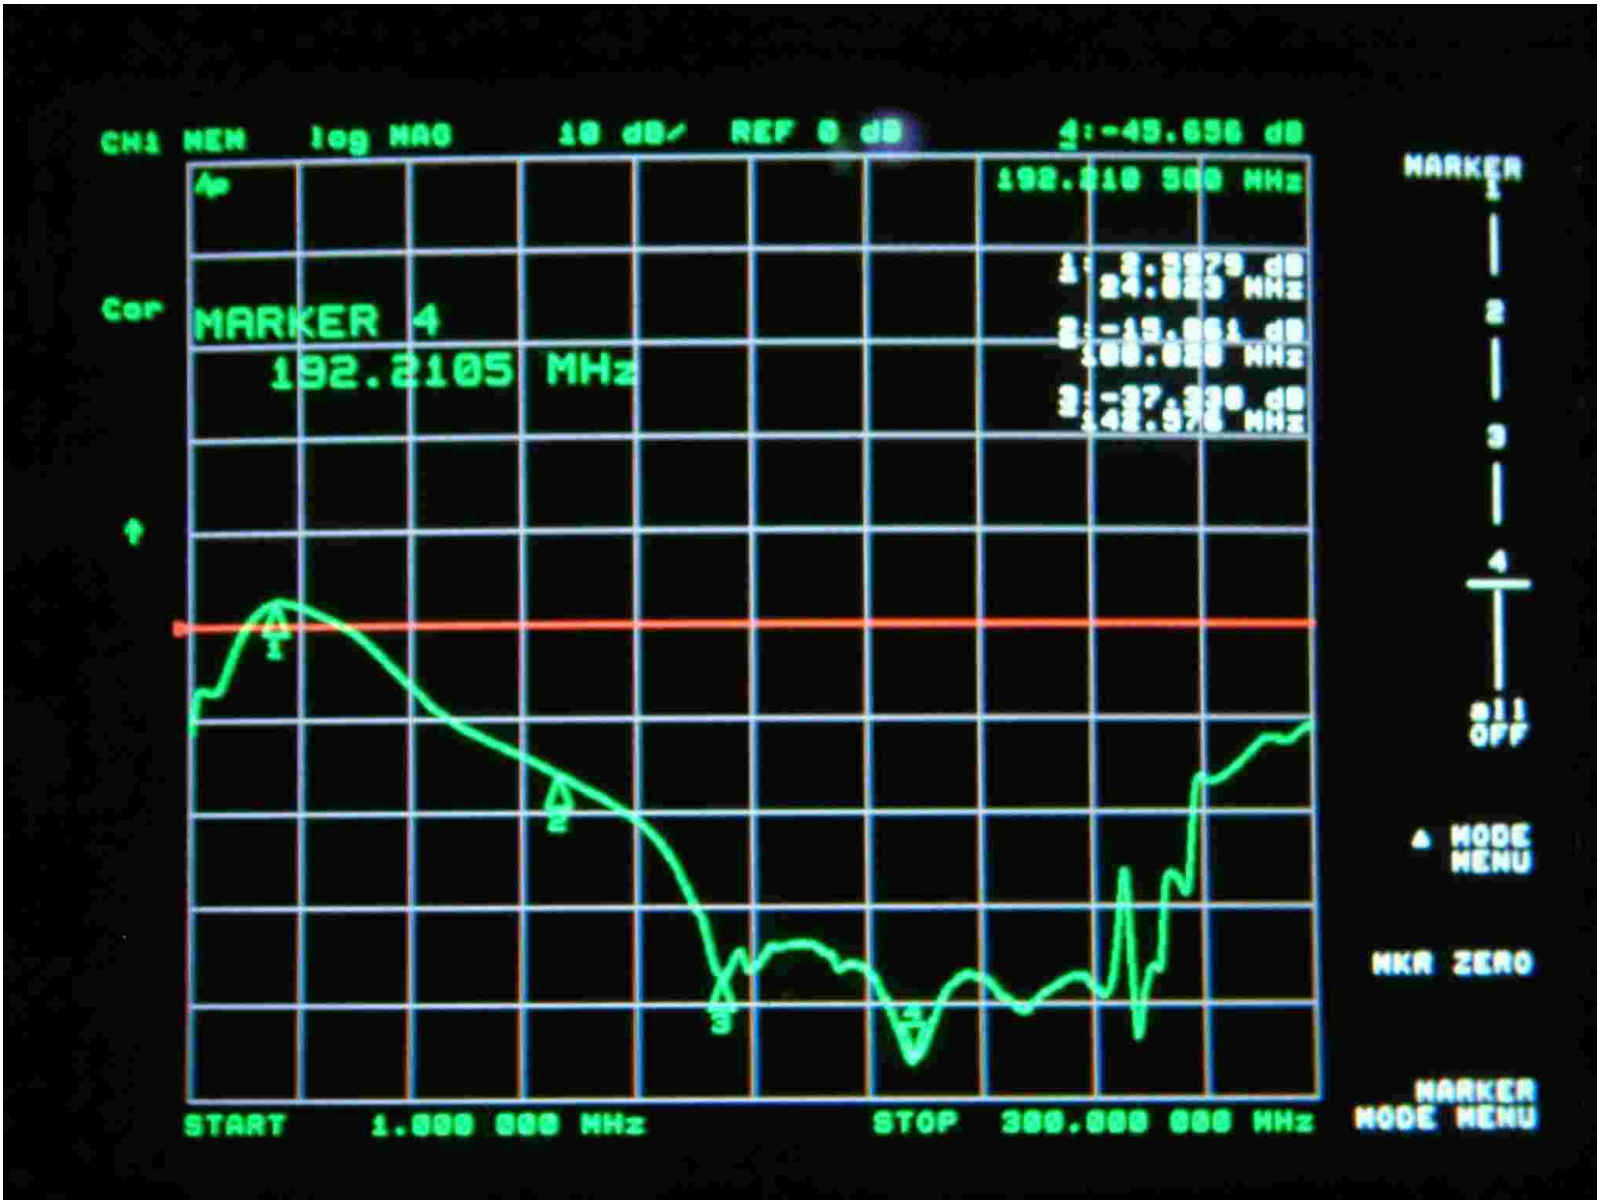

Figure 4. Tank normally loaded on 15-meters. Voltage across tuning capacitor. Anode injection voltage reference at +2.6 dB.

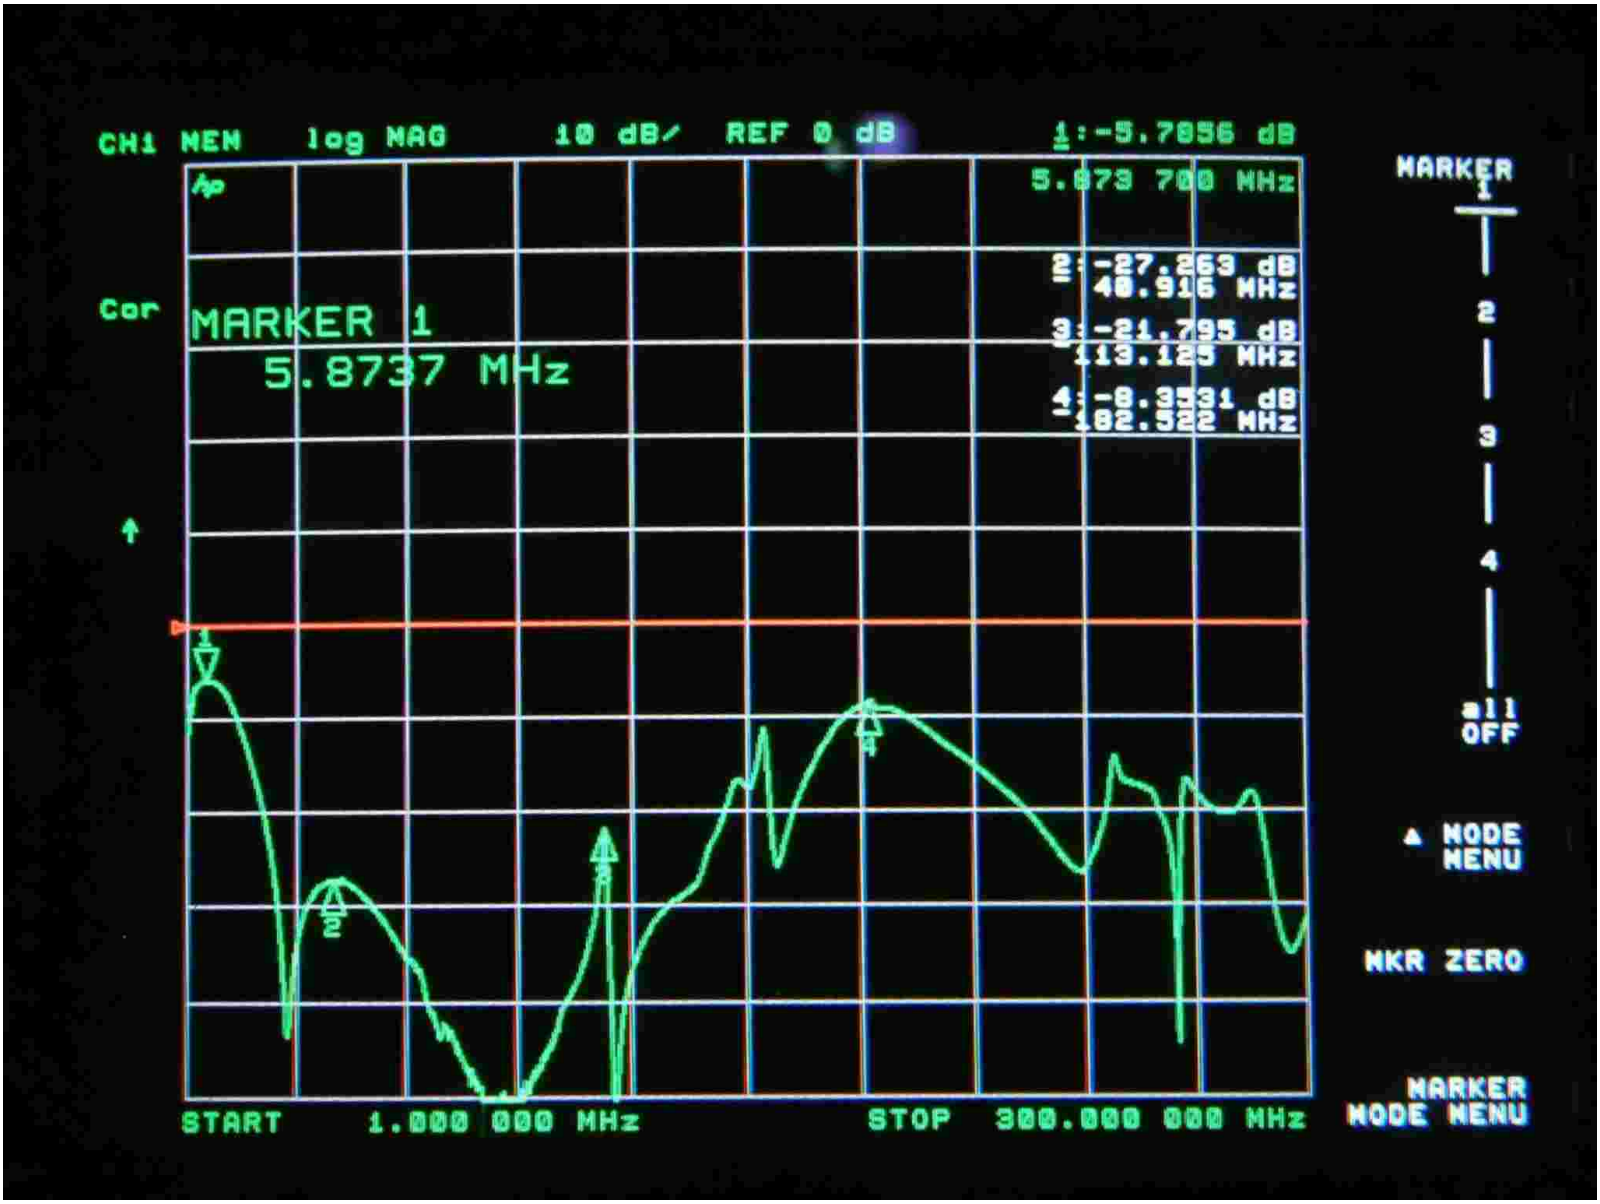

Figure 5. 15m operation. Voltage at highest VHF voltage point in system past the parasitic suppressors. This voltage was at plate blocking capacitor on plate choke side. Point 4 is 11 dB down, or 27% of anode voltage.

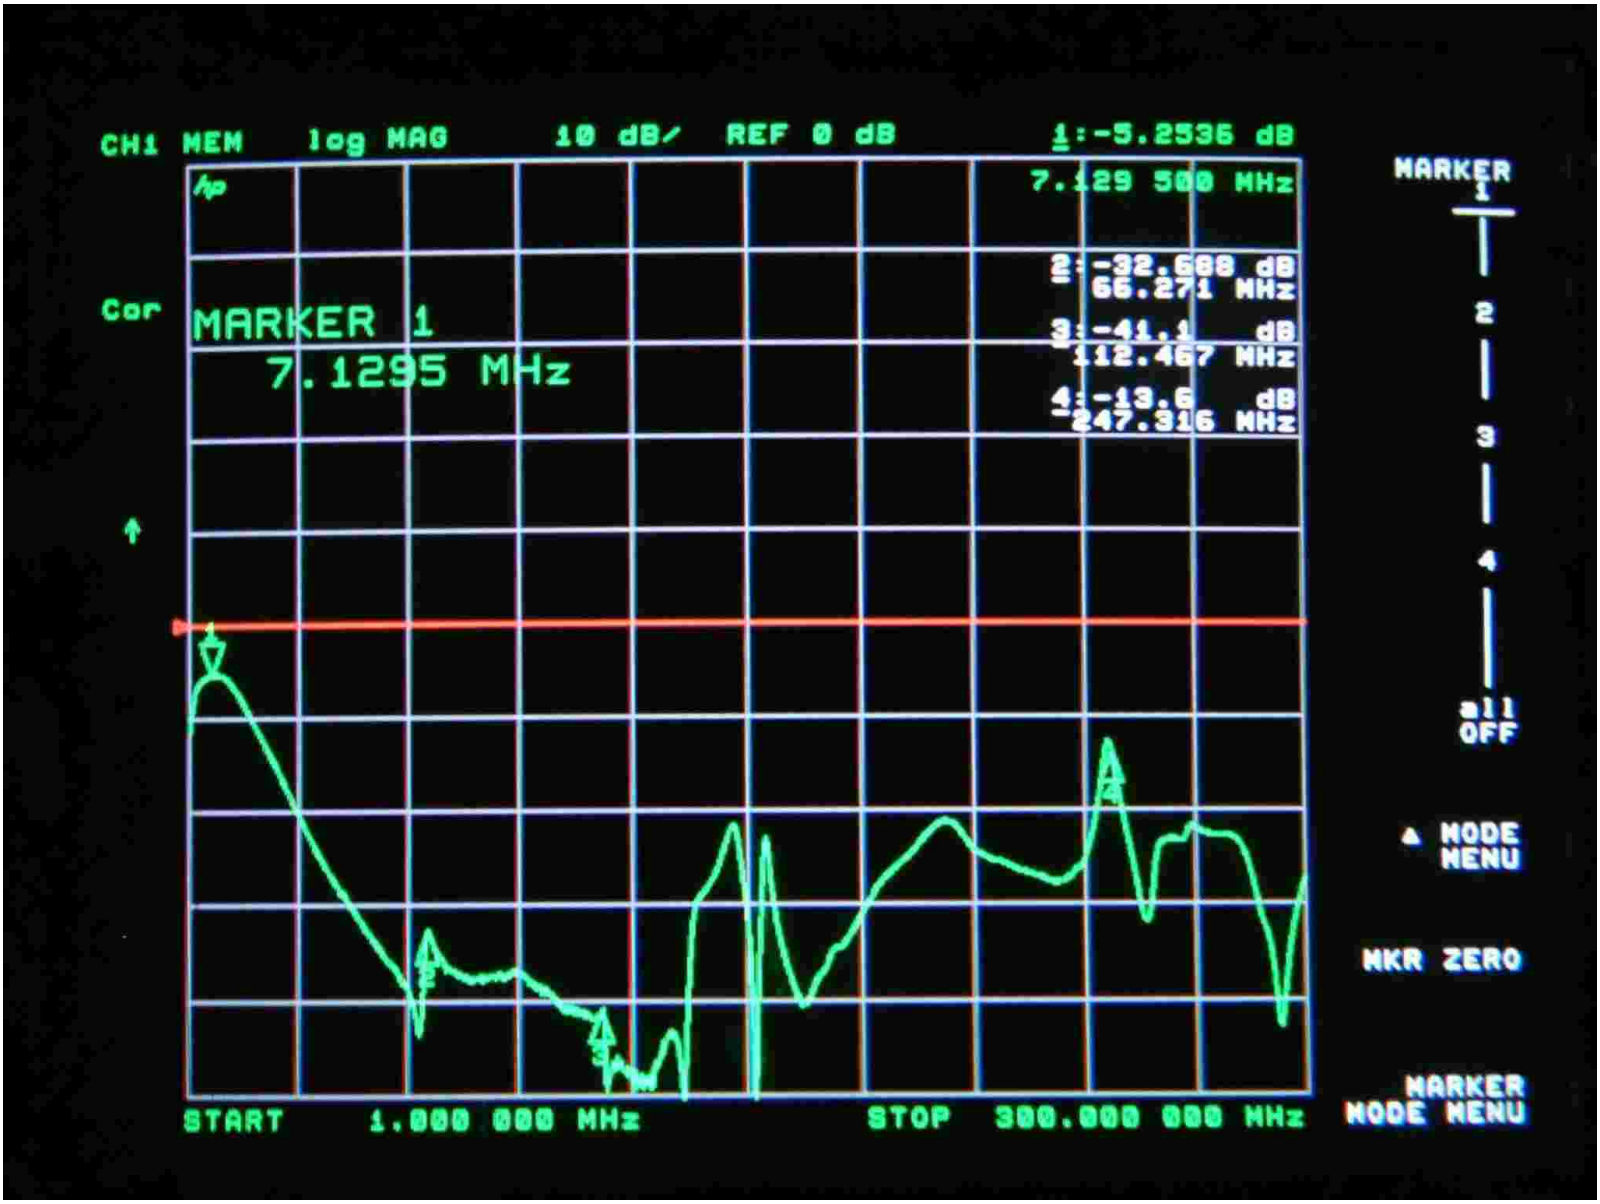

Figure 6. Voltage across loading capacitor at tank-end stud to chassis. Peak at 247MHz is -16dB, or 16% of anode voltage (480v at this point with 3000v at anode). This peak is caused by layout, and the loading cap coupling directly to tubes through stray capacitance from anode system. Impossible to have a VHF arc here, but it could aggravate TVI at USA channel 13.

Conclusion

From the above swept data, we can see VHF voltage would always be much less than HF voltage. The only likely candidate for arcing is improper operation at or near the operating frequency.

What causes arcs? Click here.

More SB221 will be added at a later date. Including performance improvement modifications.

FL2100 Problems

[Home] [Up]

The reason Svetlana tubes oscillate in the FL2100 is two-fold:

1. Bias is inadequate for Svetlana tubes. Svetlana tubes have LOWER mu (not higher as some people claim) and draw more current for a given amount of bias.
2. The FL2100 has a very poor attempt at neutralization or feedback. It also has a poor bias system.

Bias Error

The FL2100 only applies ~15 volts negative bias to the 572B grids for cutoff. This in not adequate for some brands of 572B tubes, especially those with slightly lower mu.

Feedback Error

The FL2100 design uses a capacitor from the OUTPUT of the pi network back to the input. One should NEVER do that, because the pi transforms phase along with load impedance and feedback voltage depending on control settings and load impedance!

A good design would never neutralize or add feedback from the OUTPUT of a tank circuit with a varying load back to the input.

What the design errors do in the Yaesu FL2100

When the antenna relay open, the LOAD is removed from the pi network. This INCREASES the amount of feedback by several times. The tubes, having less mu and requiring more bias, are no longer in cutoff with the relay open and draw current. This allows the tubes to amplify, and the greatly increased feedback causes the FL2100 to oscillate on whatever frequency the tank is tuned to. With no load, the voltage soars to many kV until the bandswitch arcs.

Changing tube brands in even a reasonably design amplifier is no problem at all. Changing tube brands (especially when a brand does not have the same characteristics) in an amplifier with multiple major design errors can be a big problem.

The Svetlana "fix" of increasing FL2100 bias is really not a " fix".

Corrections

Feedback

The most important "fix" would involve removing the capacitor from the output of the tank back to the tube input. This would disable the very poor feedback system.

If the amp is unstable at upper HF, a neutralization system similar to that used in the AL-811H Ameritron should be used.

Bias

The FL2100 bias system should be rewired so the relay opens the filament CT return. Normal operating bias should be left on the grids. This would FULLY cut-off any tube brand.

Switch Installation

[Home] [Up]

Switch Installation Problems

Wiring

Wiring must not have sharp points or protrusions. Solder connections should be smooth and rounded, the solder should generally for a small rounded ball that coves all sharp edges. The last motion in switch wiring to each contact should be soldering, not clipping! Clipping of protruding wires results in sharp edges. Sharp edges concentrate the electric field in a small area. This greatly decreases voltage breakdown. The difference in voltage breakdown can be profound, more than 50% reduction in voltage breakdown may result from changing a rounded connection to a sharp point.

In some cases, and intentional anti-corona ring is added near the highest-voltage contacts. Any large smooth rounded metallic object connected to the contact will disperse the electric field and reduce voltage gradient between that contact and other nearby connection or hardware. This will greatly increase switch voltage hold-off.

Contact Alignment

Switches normally have a detent located at the front of the switch. The detent causes the switch to "snap" into each band position, keeping the contacts centered.

The detent may consist of one or more balls held with spring pressure against a ball-race with recesses or dimples, or a spring-loaded cam follower that presses against a notched wheel attached to the shaft.

When the mounting nuts of supports are loosened, clearance in wafer holes and mounting brackets allows wafers to rotate a few degrees. This allows the contacts of each wafer rotor to be centered in the mating wafer stator contact. Pick-up-and-hold contacts are normally adjusted so they do not extend beyond the edge of the leading-edge stator contact.

Contact alignment is normally performed in the middle of rotation, checking by rotating in from each direction. The center position is selected, and the wafer mounting screws loosened. Each switch wafer contact group is centered or aligned, and the mounting screws retightened. After

adjustment, each position of rotation should be checked for contact centering or alignment.

Contamination

Dirt and dust are deleterious to voltage breakdown of components. They are most harmful under high humidity, when moisture and salts in the contaminant may increase conductivity. Contaminants mainly reduce voltage breakdown because they fill air gaps with slightly conductive particles.

Well-designed switches normally have much closer contact spacing than dielectric paths, because contact angles move the ends near the rotor close together. Even so, contamination of the (normally) ceramic dielectric can be an issue in conditions of severe dust buildup.

Never use contact cleaners or other lubricants on high-voltage high-current switches or relays. Many contact cleaners have carbon-based chemicals that will speed the formation of carbon tracks when corona or arcing forms. Other lubricants are very poor RF dielectrics, reducing voltage ratings.

Cleaners should be pure light hydrocarbons that fully evaporate, leaving no residual contaminants.

Preamp Summary

[Home] [Up]

When comparing low-band preamplifiers the important parameter is almost always output TOI.

Output third order intercept is a measurement standard of how well the amplifier stands up to strong signals with creating new "phantom" signals through unwanted mixing.

Type	Advertised range	NF	Gain peak	OUTPUT TOI (third order intercept)	1dB gain compression (output)
ARR 1-30	1-30MHz	5.43dB	20.4dB@13MHz	30.38dBm	21.5dBm
ARR GAsFET	single band	3.2dB	26.4dB	11.39dBm	8.1dBm
DXE RPA-1	200kHz-40MHz	3.4dB	17.3@5MHz	43.04 dBm	26dBm
ICE 124A		4.2dB		14.05 dBm	
KD9SV	160M/80M	4.9dB		14.02@full gain 0.14 dBm@12dB below full gain	

Note: *These are measurements of a single new random sample that appear to be working properly, with no noticeable defects in components or wiring.*

Vacuum Tubes

[Home] [Up]

Power Grid Tubes

Power-grid vacuum tubes cover a wide range of applications, and a wide variety of styles have evolved over the years. Every design is a compromise of some type, designed to better fit a few specific applications. For example, there are dozens of grid and cathode (electron emitter) designs. There is a wide variety of anode styles and types. Even the heaters or filaments have multitudes of shapes, materials, and physical dimensions.

The big enemy of old vacuum tubes or tubes that have sat a long time is gas. The big enemy of high gain power grid tubes (or valves) using metal oxide cathodes is grid current and excessive cathode current. Many common problems are discussed below.

Numbering System

While manufacturers use a variety of numbering systems, most Eimac tubes use an easily decoded system.

First number = number of active elements in the tube

- 2=diode 3=triode 4=tetrode 5=pentode

First letter = envelope type

- nothing or - = glass
- C = ceramic

Second letter = anode type

- nothing or - = internal
- X = external
- W = water

- V = vapor

Number group = anode dissipation (actual dissipation is much higher than number is some tubes, so check the books)

Last letter = Base or connection type

- Blank = pins or tabs
- A or Z = coaxial or pins
- F = flying leads

Last number = mu, where 1 = lowest mu through 7 = highest mu

- 1 through 5 are best suited for grid driven applications
- 7's are best for cathode driven

From this we see a 3CX3000F7 is a triode with ceramic envelope and external anode, has approximately 3000 watts dissipation (in fact it is 4000w), has flying leads, and highest mu (most suitable for grounded grid).

In addition, some tubes have additional letters inserted in the type number. Examples are the 4PR1000 or 3CPX800A7. The P generally signifies pulse rating, and the R more rugged construction.

Electron Emitters

Power-grid vacuum tubes operate by a thermionic emission process. In a vacuum tube, we commonly call the electron emitter a "cathode". The cathode can be directly heated or a filament-cathode. Another type is the indirectly heated, or heater-cathode type of electron emitter.

The cathode, regardless of sub-category, uses a material easily able to "give-up" electrons with heat. The cathode is heated in a nearly perfect vacuum to temperatures above 1000K (we would see that as a red glow) to as 2600K (a yellowish-white glow). This heat supplies energy to loosely bound electrons at the cathodes surface, causing some electrons to escape the material. These electrons form a cloud suspended around the cathode.

Commonly Used Cathode Materials

Material	Operating Temp Range K	Emission mA/watt	Emission mA per cm^2	Special Features

Pure Tungsten	2400-2600	2-10	100-1000	Immune to positive ions, can be operated at highest anode voltages. Instant on.
Thoriated Tungsten	1800-2000	50-100	700-3000	Much higher emission, but less immune to positive ions. Can be operated at reduced filament voltage or operated with peak currents over emission limits with little effect on life. Instant on.
Oxide-filaments	1000-1100	200-1000	400-3000	Very high emission per watt of filament power, but extremely sensitive to positive ions. Emission failures occur from low temperature operation if electron cloud is depleted. Must be thoroughly warmed up before any current is drawn, but warm-up time is short.
Oxide-cathodes	1000-1100	10-200	1000-3000	High emission in small cathode. Long warm-up time. High peak emission for pulse applications.

Positive ions are formed through ionization of residual gasses. High anode voltages speed formation of positive ions. The space charge (electron cloud) surrounding the cathode repels positive ions, and keeps the ions from poisoning the cathode. When positive ions contaminate the cathode, electron emission is reduced.

Tungsten has the highest melting temperature of any metal, above 3600K. Tungsten has the ability to operate at high temperatures for many hours without evaporation of materials becoming a major problem. Tungsten is one of the few materials able to withstand total depletion of the electron cloud in a vacuum tube. Tungsten emitters are not damaged by stripping away of electron clouds, and the resulting cathode bombardment by positive ions. This immunity to damage means emission life is

not shortened by excessive current, operation before full temperature is reached, or low filament voltage.

If a cathode material sensitive to positive ions is operated with excessive HV, or has excessive cathode current for the cathode operating temperature, it will suffer emission failure. This is why indirectly-heated tubes or oxide-cathode tubes must have long controlled warm-up times before any cathode current is drawn. We must ***NEVER*** operate the 3CX1500A7/ 8877, 3CX800A7, or other oxide-cathode tubes at reduced heater voltage! This would allow the cathode's protective electron cloud to be depleted, and nothing would prevent positive ions from striking and poisoning the cathode.

Anodes

The anode is operated with a positive potential. This creates a strong electric field that attracts electrons from the cathode. The electrons are accelerated (or impeded) as the pass through the opening in the grids, and eventually strike the anode at reasonably high velocity. Since the electrons have mass and speed, they have kinetic energy. This energy produces heat, as well as dislodging other electrons from the anode. The amount of heat is proportional to the velocity and number of electrons. The power converted to heat is the anode voltage times anode current, at any instant of time.

The actual plate dissipation is the time-integrated amount of anode current and voltage. In an amplifier with steady current, anode dissipation is found quite easily by multiplying the accelerating voltage (anode-cathode potential) times anode current. In an amplifier system, dissipation is a complex function of the constantly changing anode voltage and current. In such systems, a very close approximation of anode dissipation is given by multiplying average anode current by average anode voltage, and deducting the useful power extracted by the load.

Internal Anodes

Many lower power tubes use internal anodes. Internal anode tubes can use any electron emitter or grid configuration, although the most common large transmitting types use thoriated-tungsten filament/cathodes. Internal anode tubes are cooled by infrared radiation, by direct thermal conduction to the envelope, and through external connections via leads exiting the envelope.

The anode often serves three very important functions in a transmitting tube:

- The anode collects most of the electron current from the electron emitter in the tube (cathode)
- The anode must dissipate heat produced from kinetic energy of electrons that strike the anode

- The anode often degasses the tube

The material used in the anode varies with tube type and manufacturer. Most transmitting tubes use molybdenum, tantalum, graphite (carbon), or other high temperature materials in the anode. The material must be mechanically and electrically stable, even while operating with very high temperatures.

In transmitting tubes, virtually all anode heating comes from the kinetic energy of electrons striking the anode. The actual resistance of materials in the anode (and other elements in the tube) is very low, and the relatively small amount of $I^2 \cdot R$ heating is dwarfed by the hat caused by electrons impacting the surface of materials in the tube.

Higher power internal anode tubes almost always have a gettering material coated directly on the anode. The getter acts as a sponge, soaking up any gas molecules inside the tube. This is necessary because any gas creates positive ions, reducing tube life. Not only that, even the slightest amount of gas greatly reduces breakdown voltage through a vacuum.

Note: Peak anode voltage in a properly tuned and properly driven amplifier approaches two times the dc anode potential, and under conditions of mistuning, load faults, or excessive drive anode voltage can be several times the dc anode potential. It is important that any tube have an anode breakdown voltage at least four or more times the expected highest dc anode potential, or occasional anode to grid (and cathode) arcing may occur.

The most common gettering material is zirconium. For example, zirconium is used on the outside of graphite or molybdenum anodes in 3-500Z and other tubes. It is the dull gray powdery or grainy texture coating you see on the surface of 3-500Z, 811A, and 572B anodes.

Zirconium getters best at about 1000 degrees C, this is why large metal anode transmitting tubes like the 4-400A, 4-1000A, and 3-500Z must be operated with a dull red to red anode color. Zirconium also releases some gasses and absorbs other gasses at various temperatures. The varying temperature across the length of the anode (and as the anode heats and cools) allows the gettering agent to absorb a wide variety of gasses.

The quickest way to ruin a 3-500Z, or other glass power grid tube, is to never show anode color over a prolonged period of time! Storing a 3-500Z for many years without operation almost guarantees a flash-over will occur at the first application of high peak anode voltage.

Gas, either from poor manufacturing processing, out-gassing from elements, or seal leakage is the primary failure mode of glass tubes. Secondary to high-vacuum (gas) arcs are problems like bad welds or grid or cathode materials that fall out of alignment due to thermal or mechanical stresses.

External Anodes

We commonly associate external anodes with expensive tubes having fragile low-dissipation grids, long warm-up time oxide cathodes, and poorer reliability of tubes like the 3CX1500A7/8877, 8874, or 3CPX5000A7.

External anode tubes, just like *internal* anode tubes, can use any type of grid and cathode structure.

3CX1200's, 3CX3000's, and 3CX10,000's are popular tubes using thoriated-tungsten emitters. They have very long life, nearly instant warm-up, and very rugged grids.

External anode construction provides three primary advantages, all of which center around size reduction:

- More dissipation (power) can be handled in a smaller package
- Compact size allows better operation at higher frequencies
- Gain is higher, because electrons are more focused and better controlled by the electrostatic field of grids

Only oxide-cathode tubes enjoy the last two advantages. Oxide cathodes provide a very compact high-current emitter. Normally cathode oxide is deposited in bands or rings, and grid wires are aligned directly over the gaps in oxide bands. The 8877, for example, has fairly large diameter cathode (over 1"). More than 100 concentric bands of oxide are deposited on the cathode, and a grid wire is aligned just outside the area of each emission band.

This construction allows the control grid's electrostatic field to control emission, yet keep grid wires away from the primary cathode-to-anode electron streams. The grid is placed very close to the cathode (thousandth's of an inch), while the anode is much further away.

The result is very low grid current (grid intercept) from wire placement out of the electron stream, and very high gain from the very high ratio of electric fields (from distant anode and very close grid) reaching the cathode electron cloud.

Unfortunately the very same things that create very high gain also cause manufacturing and potential operating problems. The close spacing of cathode and grid increases the chance of grid-cathode shorts. Critical placement of grid wires outside of the many cathode bands makes the grid susceptible to alignment problems. If every grid wire, out of hundreds of wires, is not perfectly aligned outside the electron stream electrons will impact one or more wires and cause gold to migrate off the grid. The mechanism is much like water evaporation, rather than a catastrophic event like boiling or melting. The gold will slowly evaporate and redeposit elsewhere in the tube, either causing arcs, shorts, or poisoning of cathode oxide. This is the most common failure of metal-

oxide cathode tubes.

Ceramic tubes with thoriated tungsten electron emitters have much longer life and higher reliability than any other type of power grid tube, as a general rule. They combine the best of both worlds, having the low seal leakage and low out-gassing typical of ceramic external anode tubes and the rugged wider-spaced high dissipation grids.

The only disadvantage of thoriated-tungsten ceramic tubes is gain and frequency response is generally less than provided by oxide-cathode tubes.

The most common failures in thoriated-tungsten ceramic tubes relate to old age, and loss of emission. Ceramic tubes have very good shelf life, unlike large glass tubes.

Grids

Grid control the movement of electrons inside the tube through electric fields surrounding the grid wires. The electric field extends beyond the many wires making up the grid, almost completely dominating the high electric field created by the anode.

The anode and grid normally operate at cooler temperatures than those where robust thermionic emission of electrons occur. With little or no thermionic emission, the electric potential difference (strong electric field gradient) between the anode and grid(s) results in minimal current flow (electron movement) between anode and grid. Most of the current that does flow between anode and grid occurs because of stay gas molecules creating ions or electrons dislodged from the anode by kinetic energy of cathode-to-anode electron flow as electrons impact the anode.

Elevated grid temperatures, primarily caused by kinetic energy of cathode electrons striking the grid, may eventually reach magnitudes where the grid actually starts to show thermionic emission. Many people assume the grid dissipate rating of a tube is a value set by grid failure, but that is incorrect. The dissipation rating is actually a power related value, indicating the power required to heat the grid enough to start thermionic emission.

Eimac determines rated grid dissipation of a tube by increasing long-term grid dissipation while periodically checking at very short intervals for thermionic emission from the grid.

In actuality, tungsten grids in tubes like 3-500Z's can be operated at temperatures where they show color without permanent damage. While tube operation at such temperatures is compromised, the grid and tube often suffers no permanent damage.

The same is not true for gold-plated grids, like those in metal-oxide cathode tubes. Grids plated with soft poorly-bound materials like gold suffer gradual long-term deterioration even with

moderately low levels of grid current. Heat the grid of a metal-oxide cathode tube to temperatures even well below incandescence, and the result is instant irreversible failure.

This is why ALL metal-oxide cathode tubes should have a fast-acting electronic grid protection systems, and why fuses and worse yet resistors intended as fuses offer no protection at all to grids in metal-oxide cathode amplifiers.

Just as anode dissipation can not be determined by simply multiplying Ip times Ep in a working amplifier, control grid dissipation can not be determined by simply multiplying voltage by current in a sub-class 2 amplifier (i.e. AB2). Beware of any article or author who tells you RF grid voltage can simply be multiplied by average grid current to determine grid dissipation.

Grid dissipation, like anode dissipation, is a time-integrated function of instantaneous dissipation throughout the RF cycle. Computer models have made the difficult task of calculating grid current simple and accurate. Short of that you need to do an actual complex analysis of the grid system, such as in a Chaffee analysis.

In grid driven stages, assuming total power applied at the grid is accurately known, grid dissipation is determined by deducting bias power from RF grid power. This is very similar to the short-form determination of anode dissipation from anode power and RF power output. This does not easily work in cathode-driven PA's, because drive power is mixed with output power.

Grids are normally supported only at one or two places, and use very small wires. Normally the base material forming the grid is selected to be very hard, and to have minimal movement over wide temperature changes. The normal base metal in high power tubes is tungsten, just as used in filaments. Metal-oxide tubes require a gold overlay, to prevent contamination of materials.

Grid failures occur from four primary causes:

- Poor alignment of the grid causes some areas to "hot spot" without overall current being high
- Excessive grid current in metal-oxide tubes causes gold to migrate
- Gold plating is not always bonded properly, resulting in sputtering or flaking of gold
- Poor welds or material problems result in grids warping or moving into the cathode

Non tube-manufacturer related grid failures, like anode failures, are generally the result of a series of somewhat lengthy abuse spread over long periods of time.

Using Old Tubes

Tubes that have "set up" for a while often collect gas. This gas either comes from slow leakage through tube seals or outgassing of tube elements. This is the number one problem with old vacuum

tubes. The section below describes how to remove gas in old tubes.

Gettering and Arcing

Gettering is very important, since even miniscule amounts of gas will cause a low-resistance arc from anode to grid or cathode. The normal results of such arcs are blown grid chokes, collapsed anode chokes, damaged meter shunts, and other problems cause by high fault currents. While a few people blame high fault currents on parasitics, it is actually impossible for a parasitic to create such arcs. All the anode and grid can do is deplete the electron cloud from the area of the cathode, and the available current even with a parasitic is limited by the available emission. Uncontrolled arcs are always the result of gas or element alignment in the tube, rather than excessive current from oscillations.

Anode systems should have series-resistance to limit peak current in the event of a tube arc or failure. That series resistance should always be in the anode lead between the filter capacitors and RF choke. A diode clamp should be installed to protect meters, especially the grid meter since the grid is in the normal path of any internal tube arc.

Ceramic tubes, because of low anode operating temperatures, have the gettering agent applied to the cathode or filament assembly. This is the only area inside the tube that heats enough to activate most common gettering materials. **Ceramic tubes without internal flaws or broken seals can generally be gettered by running the filament at rated voltage for an extended period of time before application of any high voltage. The normal time for gettering is between one hour and one full day. If the tube does not getter within a day it is most likely never going to be restored to a operational relatively pure vacuum.**

Glass internal anode tubes generally have the gettering material coated on anodes, which must be operated a high temperatures to activate the getter. Glass tubes have a propensity for seal leakage and element out-gassing, both of which lead to a short self life for large tubes.

Under some conditions a glass tube can be restored to operation by running low anode voltages and positive bias on the grid. This will sometimes allow full operating anode temperatures to be reached, and the tube can be "cooked" for several hours. I've had about a 50% success rate restoring old 3-500Z's that have sat for years without use, and that arced when started at full voltage, by cooking them this way.

Most important, an arc by itself will break down and getter gas inside the tube. This is why an amplifier with a gassy tube will sometimes operate without problem after a sudden tube arc.

Intentional arcing and overheating, while pumping down a tube, are often a normal part of tube manufacturing processes.

Filaments

Filament life in vacuum tubes, like filament life in light bulbs is a complex function of operating hours, hot and cold cycles (thermal shock), mechanical shock, and temperature.

Other than avoiding physical shocks to the tube, or cycling the filament off and on needlessly, temperature is the only variable we can control. We should be sure the filament is operated at or below the maximum recommended voltage.

In amateur service, filaments and heaters rarely (if ever) are operated enough hours to have operating-time related failures. Most failures are mechanical failures, more related to constant on-and-off cycling of the tube rather than wear.

Mechanical issues such as material or assembly defects can combine with close element spacings inside the tube, and cause failures. With spacings in thousands of inches, even the slightest change in physical shape or positioning filaments or cathodes can create a grid-to-filament (or cathode) shorts. Material quality and manufacturing techniques by tube manufacturers are critical to tube life, and sometimes mistakes are made.

Some claims are made that oscillations can cause filaments to bend, but there isn't anything that even remotely supports such claims.

For example, the normal peak filament current of a sine-wave powered 3-500Z filament is about 1.414 times 15-amperes, or 21 amperes. The total force on the filament helice is 11 grams distributed over a 7 cm area for this 21-ampere current in the typical helical structural dimensions of the filament.

The small additional force of a fully saturated emission condition (which requires around 1000 volts of positive grid voltage) results in only 30% increase in total bending force, hardly significant in any filament robust enough to last years in normal operation. Not only can the peak current not reach fatal levels though any type of emission, the grid-cathode potential is not able to reach levels required to saturate filaments.

Why Does The Tube Go Bang?

In order for any tube under any condition to draw more than the peak saturated current, operating potential has to exceed the breakdown voltage of the tube.

There are two reasons excessive current might flow between elements in a tube:

- The peak anode supply voltage exceeds the hold-off voltage of the tube, causing a good tube

to arc
- The tube may be defective either through gas or an incorrectly located anode or grid

Either of these conditions would allow an internal arc, with fault current limited mostly by external circuit resistances. Oscillations, like normal drive power, can only take a healthy tube up to the saturated emission limits. Even then it would take hundreds or thousands of grid-cathode volts to saturate the emission, an impossible condition unless someone drives a 3-500Z mistakenly with a 4CX5000 or some other large PA!

There is a special condition where tubes can fail, and that is where excessively high voltage components are used in tank systems. Under load fault conditions, when nothing absorbs energy supplied to the tank and tank components do not saturate or breakdown, the tube peak anode voltage can reach levels where an arc occurs in a healthy tube. See the load faults and tuning section, and the practical demonstration areas of this website.

Summary

Tubes are relatively robust components, but they are one of the primary points of failure in any electronic device that uses tubes. While many of us would like to believe we can make small circuit changes to prolong tube life, the fact is most tube failures are related to material or construction problems within the tube. In amateur service, most failures relate to manufacturing problems in the tube.

Out-gassing and seal leakage are particularly troublesome in glass tubes, since porous anodes and imperfect glass-to-metal seals allow miniscule amounts of gas to enter the vacuum.

To insure maximum life in Amateur Service using thoriated tungsten tubes:

- Keep seals below rated temperature
- Avoid long periods of excessive anode or grid dissipation
- Avoid extended periods of non-operation
- Avoid filament voltage OVER the manufacturer's rating
- Do not excessively cycle the filament
- Do not subject the tube to shock or vibration
- Use some form of reliable fault-current limiting in the anode

To insure maximum life in Amateur Service using metal-oxide cathode tubes:

- Keep seals below rated temperature
- Avoid long periods of excessive anode dissipation
- Avoid even very short periods of excessive grid dissipation by including a fast electronic

grid-trip circuit

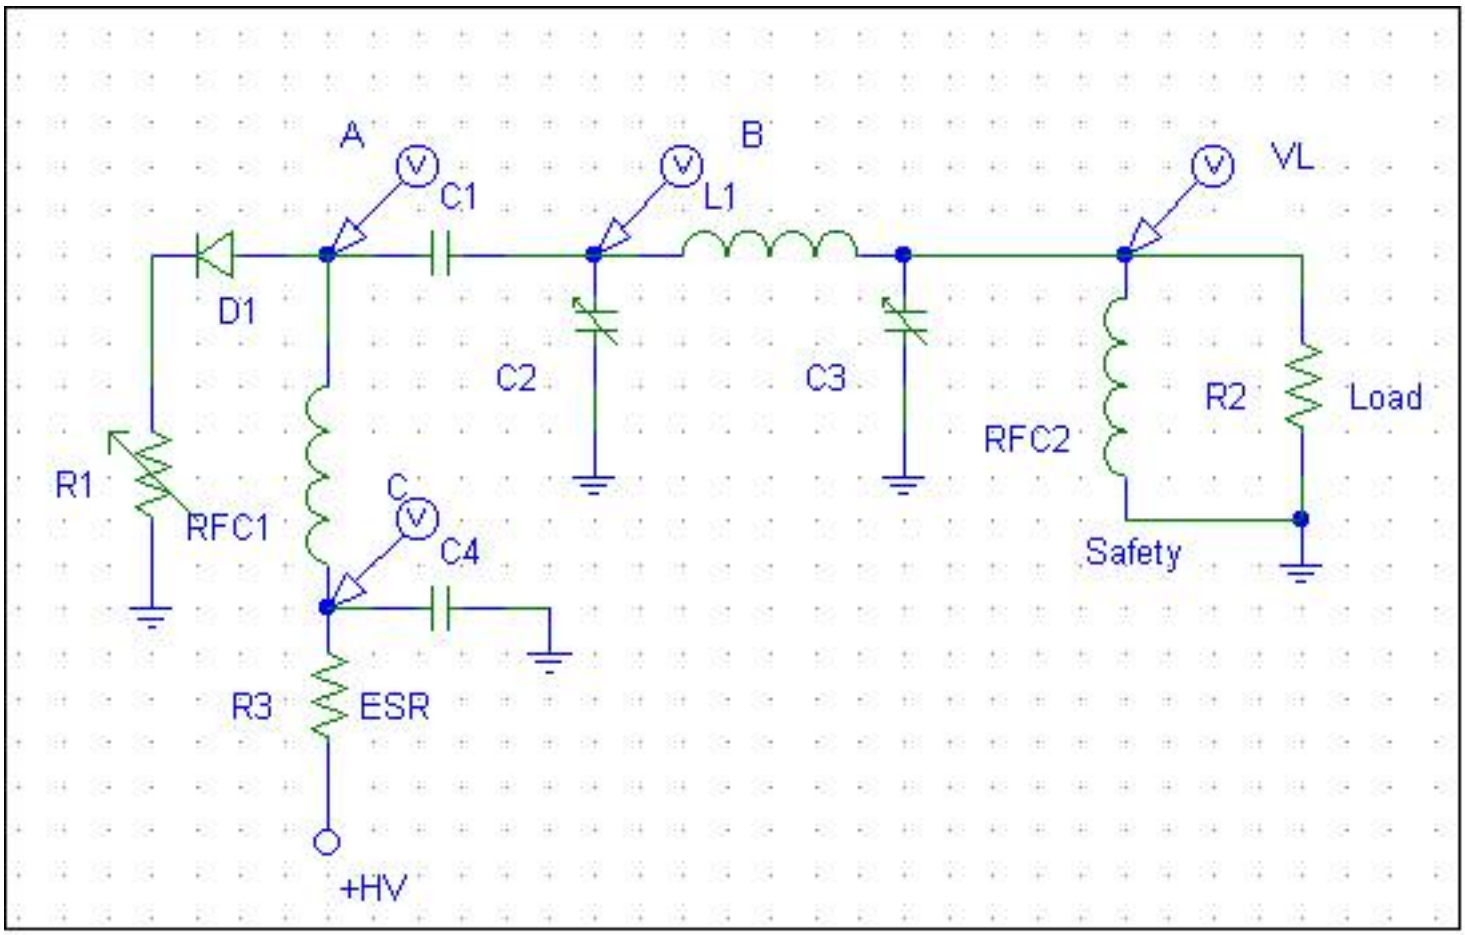
- Avoid filament voltage OVER or UNDER the manufacturer's rating
- Do not excessively cycle the filament
- Always allow full warm-up before allowing any cathode current to flow
- Never apply excessive high voltage, as it may strip or poison the cathode
- Do not subject the tube to shock or vibration
- Use some form of reliable fault-current limiting in the anode

Vacuum Tube Amplifiers

[Home] [Up]

How the Tube Converts DC to RF Power

A typical vacuum tube radio-frequency amplifier has a high voltage power source. This power source supplies the energy for the RF output power. The vacuum tube acts like a non-linear variable resistance in series with a diode. The electrical equivalent of the anode and output system is:

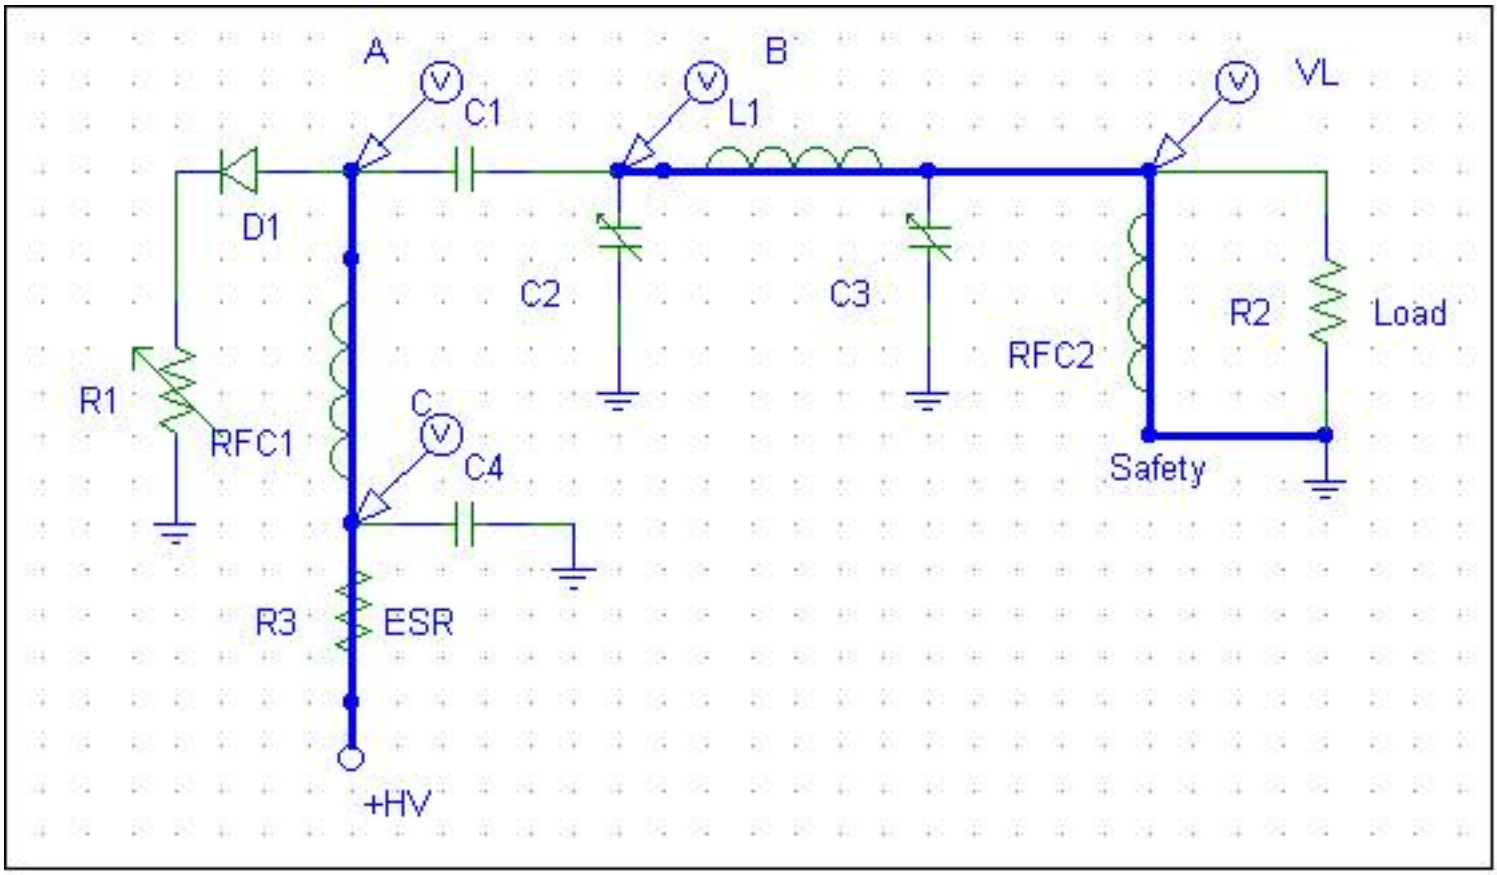


R1 represents the time-varying anode to cathode resistance, as grid-cathode and anode-cathode voltage changes, R1's value changes.

D1 represents the directional characteristics of the tube anode-to-cathode path. It is always “on” when the voltage at “A” is more positive than ground. D1 would also behave as a current limiter, the limit being somewhat less than the saturated emission current of the cathode.

Let’s examine how this circuit converts DC to RF power. We will assume +HV is 3000 volts.

In the initial state, C1 has been charged through the following DC path:



Hopefully the designer was smart enough to include RFC2, to prevent charging or discharging C1 into the load, which might be a sensitive piece of gear or the operator!

The voltage across C1 is the anode-to-ground voltage at A. Everything past A, at B and VL, is zero

volts in the resting state because of the low-dc resistance of RFC2 and the nearly infinite resistance of C1. RFC1 establishes a fixed magnetic field that is set by the quiescent current through R1.

As a positive-going grid-to-cathode voltage perturbs R1, the magnetic flux in RFC1 tries to hold supply current steady. RFC1 does this by increasing the voltage across its terminals. Energy stored in the electric field of C1 tries to hold the voltage steady, and it sources any additional current the tube (R1) requires.

The anode, in effect, “tugs” or pulls point A towards ground. The initial peak current can be quite high, because C1 has a low-reactance path to ground through C2. L1 also builds up a magnetic field, as C2 develops voltage from the current flowing through C2 and C1 back to the tube. On the initial RF cycle, the voltages hardly change before the grid is moving back negative.

At a time interval equal to 1/(4F) (where F is the RF frequency), the positive grid voltage has peaked. The grid begins to swing negative (or less positive) with respect to the cathode. Anode-cathode resistance (R1) decreases.

The collapsing field in L1 (and to a much lesser extent RFC1) tries to hold current the same, and in doing so the collapsing fields supply a small amount of additional anode voltage. Since there is no forced upward swing (the tube cannot source anything), the tank components are left to pull the small voltage change back up to the original anode voltage and slightly beyond. L1 (and to a lesser extent RFC1) actually pull the anode voltage higher by an amount nearly equal to the amount the than the tube pulled the voltage down. ***The actual amount the tank pulls this voltage higher than +HV depends on the amount of energy transferred to the load compared to energy stored in the tank system!*** This is VERY important in understanding where arcs come from!

This cycle repeats over and over, and assuming the tank system at C2, L1, and C3 is resonant, the voltage at point A increases in swing while the peak current through R1 (the tube) is gradually reduced. Eventually***, in a fully loaded amplifier,*** equilibrium is reached. In a ***properly tuned amplifier*** running at maximum available power, equilibrium occurs when point “A” swings up and down an amount just under twice the anode DC voltage.

Consider a class AB 3-500Z using a 3000-volt supply. When the amplifier is tuned into the load properly at full rated power, and driven to full power, anode voltage will swing between 5500 volts maximum and 500 volts minimum at point A. This would be a ***total anode voltage swing of 5000 volts***. Peak anode current in continuous carrier operation would typically be 1.12 amperes, with a minimum R1 value of 446 ohms. This is typical of continuous CW power out of 750 watts with a single 3-500Z tube with a 190-degree conduction angle running at 400mA anode current.

Let’s assume (we actually CAN have this condition, if the amplifier and exciter relays are not sequenced correctly) we have an envelope that rises instantly. At the peak of first positive grid-cathode cycle, the anode resistance would drop to someplace well under 400 ohms (anode

resistance is non-linear with anode voltage, and is lower with higher anode voltages). The saturated anode current would easily reach 7.5 amperes, if tube emission permits.

(Emission in a directly heated thoriated-tungsten tube is typically in the range of 50-100mA per watt of heater power, large transmitting tubes being at the upper end of that range. A full-emission 3-500Z has a saturated emission current of about 7.5 amperes.)

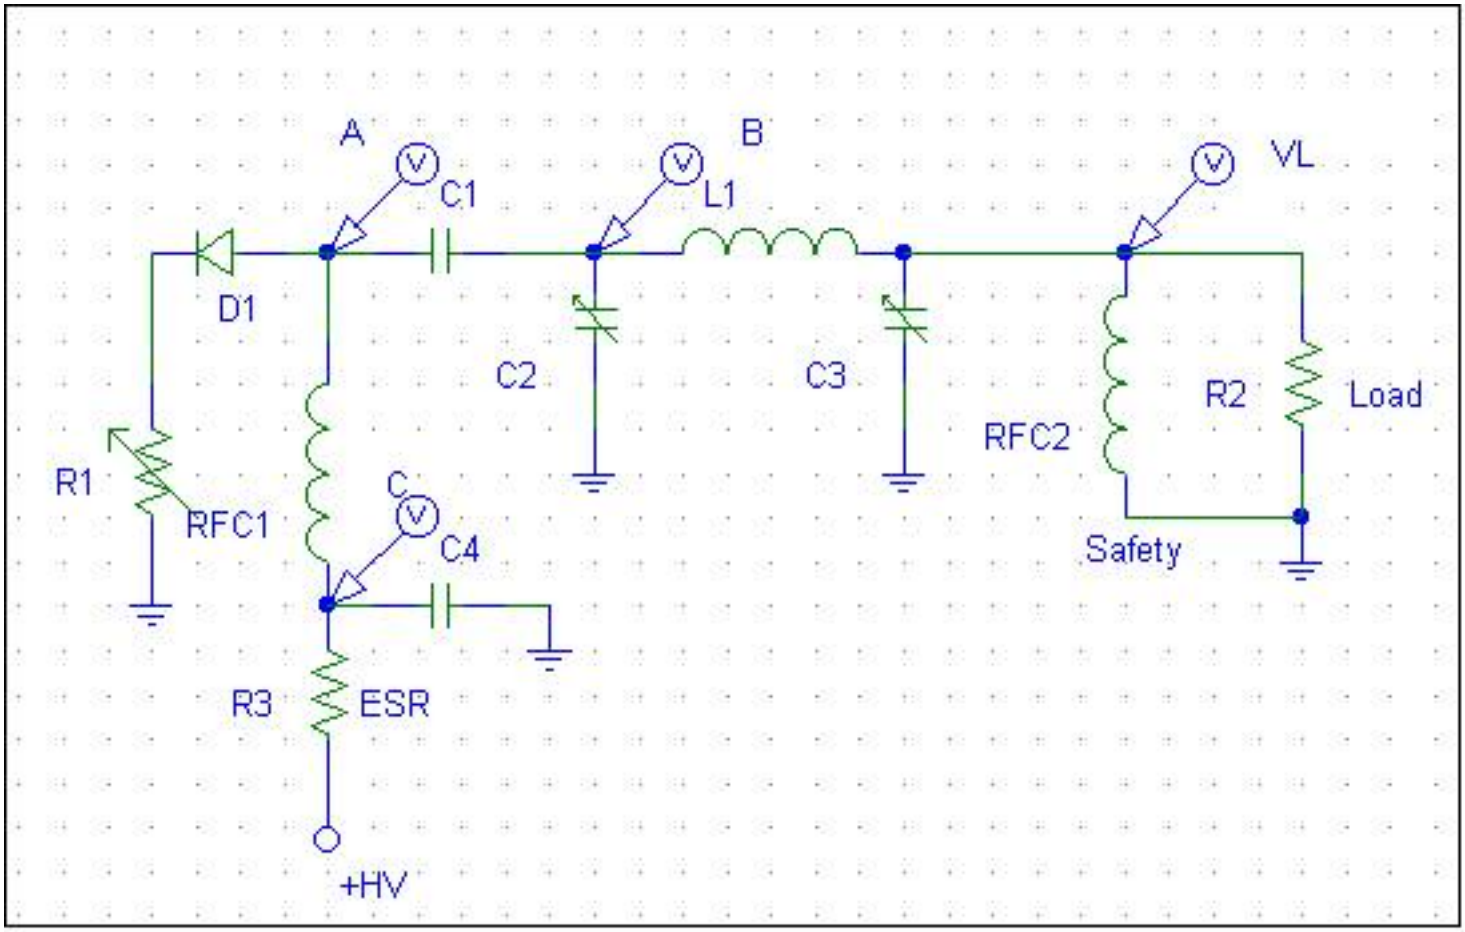
If we have infinitely fast envelope rise and fall times from the exciter, amplifier RF-envelope rise and fall times are determined by the operating Q of the tank system. C2/L1/C3 dominate the high frequency energy storage. RFC1 and C1, being larger values, dominate lower-frequency energy storage, while stored energy in the power supply dominates long-term energy demands. The voltage across C2, upon initial application of RF drive, is a rapidly expanding sine wave. It reaches maximum steady-state swing many dozens or hundreds of RF cycles later than the initial tube excitation (and decaying in a similar fashion).

The peak voltage across C2 is equal to the peak anode voltage swing, and is slightly less than twice the HV supply voltage in NORMAL operation. The voltage across C3 is a function of the load resistance, and power delivered to the load.

Incorrect Loading or Load

We know the tank circuit stores energy. We now understand the conversion process where DC is converted to AC (or RF) power. We also must understand ***energy must be transferred out of the tank at a rate equal to or exceeding the rate at which it is supplied by the downward "pull" of the tube. If we do not remove energy at a sufficient rate, voltages and currents increase until a new point of equilibrium is reached.*** Voltage at point "A" can actually swing well beyond twice +HV on upward excursions, and below zero volts (becoming negative) on downward excursions.

The maximum voltage with a load or drive fault can be tremendously higher than the typical working voltage of the tank system when energy is being removed at the proper rate.



We have the same basic tank system as discussed earlier, but *with light loading compared to drive level* the tank is pulled down very hard by the tube. Minimum Rp is reached early in the cycle, before the tank voltage reaches it's minimum swing. This is easy to do, since the tube only pulls the system down and the tank stores the energy of that downward tug.

As the plate voltage swings below zero (negative) from the tank energy, the tube is already cutting off. Nothing clamps or prevents point A from going negative. D1 effectively takes the tube out of the circuit. By the time the tank reaches it's minimum, the tube's grid-cathode voltage is already on its way positive. The tank free wheels positive, and can overshoot the +HV supply by several times the supply voltage. If loading is light enough and Q is high enough, this continues until the energy stored in the tank reaches equilibrium with energy transferred to the load, or a component fails and the arc dampens the tanks gyrations.

See the practical demonstration page.

VHF Stability

[Home] [Up]

rev PM Feb23/03

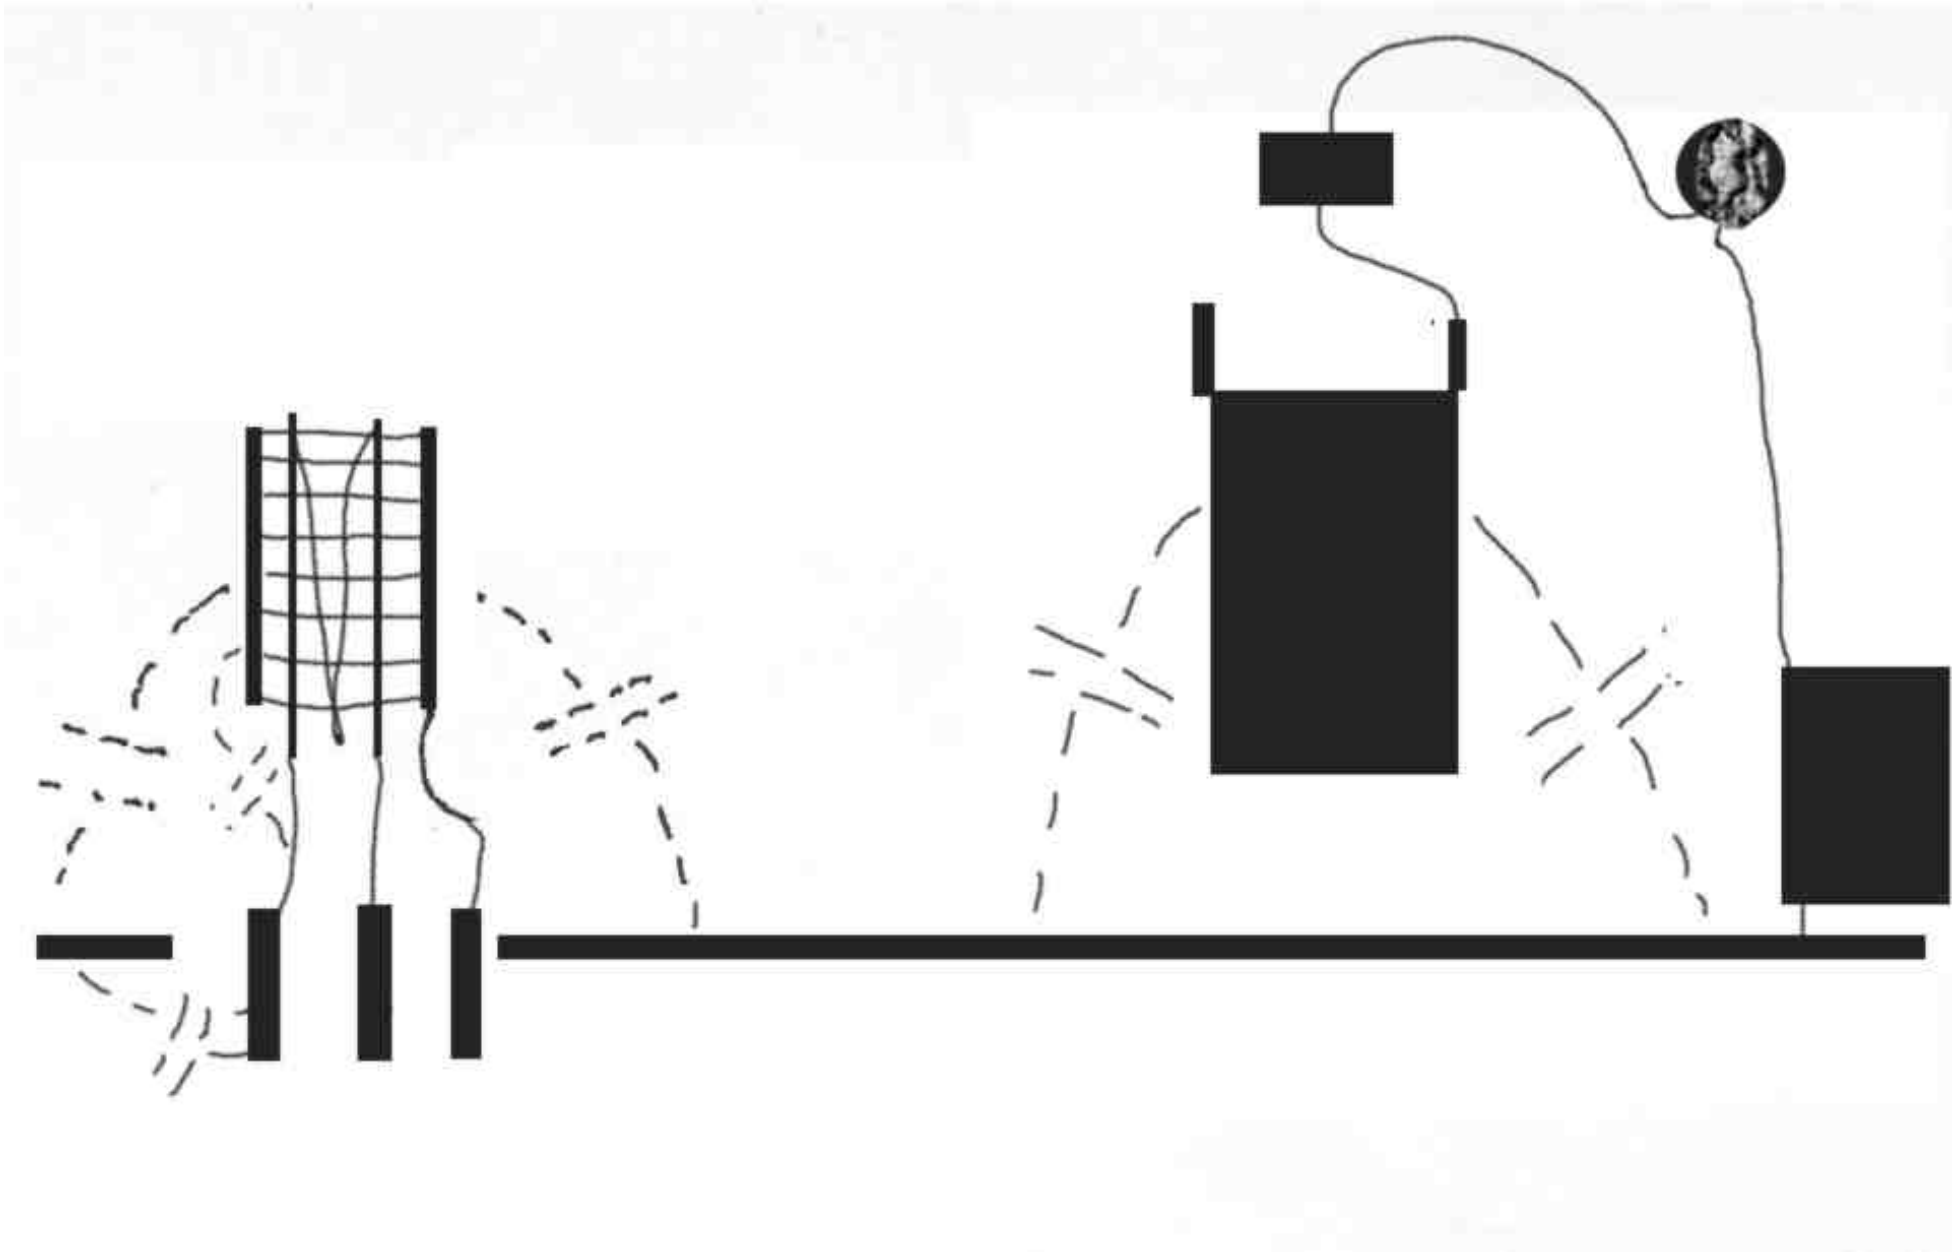
HF Amplifier Stability at VHF

A great deal of empirical engineering surrounds stabilizing amplifiers. While other forms of troubleshooting and engineering follow logical steps, it seems very few builders actually follow planned steps to test for amplifier stability. It is difficult to find detailed information describing suppressors and how they function.

Cause of VHF Oscillations

As in most planned oscillators, the most sensitive control element in the tube generally has the largest influence in determining oscillation frequency. The normal mode of VHF oscillation in HF PA's is at a frequency where the tube becomes a tuned-plate tuned grid oscillator. The control grid to anode path generally has the highest possible gain in the amplifier system, and that is why this part of the system is (by far) the most problematic area of the amplifier system.

The control grid system behaves like it is connected to a parallel tuned circuit. The stray capacitance is primarily between the grid element inside the tube and ground, generally via the filament and other connections. The inductance is via the grid leads inside the tube through the socket to the actual chassis connection. At some frequency, the grid capacitance will parallel-resonate the total inductance in the grid to ground path.



The anode is the second most common problem area. If the anode also has stray capacitance to ground. The path from the anode to chassis has inductance. At some frequency, anode capacitance parallel tunes the path to ground. This resonance greatly increases anode impedance at some very high frequency.

The grid also has capacitance to the anode, and this is the feedback path.

With all of this, the circuit has everything needed to become a tuned-plate tuned-grid oscillator.

If feedback loss (attenuation) from anode-to-grid is less than tube gain at some problem frequency, the tube ***may*** oscillate. The final requirement is the phase of unwanted feedback must be a value that causes regeneration, or positive feedback. These requirements are the same in any oscillator.

Once again, the conditions required for instability are:

- Gain must exceed attenuation in the feedback path
- The grid must have a sufficiently high impedance for the amount of available feedback to cause a stability problem,
- The anode or other element involved in the oscillation process must have a sufficiently high impedance at the same frequency as the grid to cause a stability problem
- Feedback phase must be within the correct range to obtain ***positive*** feedback

If any one of these four requirements are not met, the tube will not oscillate! This is true no matter how high or low Q is in any individual path, or if the tube has suppressors or not.

Claims have been made that tubes will remain stable for years, and a "sudden event" will make the tube break into an uncontrolled oscillation. That absolutely can not happen, unless one or more of the four important system parameters above change. Once one or more parameters change, the tube will oscillate continuously until operating voltages are removed. Quite often, in fact most of the time, oscillations are not damaging. The most common effect of VHF oscillations are creation of spurious signals; ***not*** bangs, pops, or arcing bandswitches. Bangs and pops are caused by gassy tubes or other problems, while arced bandswitches (if caused by an oscillation) are generally caused by oscillations at or near the desired operating frequency!

Location of Suppressor

Suppressors are normally found in anode systems, even though outer locations will work. A VHF suppressor must be located between the tube element and a low-impedance path to ground at VHF. This is because the suppressor must be able to load or "de-Q" one or more portions of the unwanted oscillator circuit. The actual working circuit causing a VHF oscillation is almost always entirely different than what appears on the actual component-based schematic. The cathode, an element commonly involved in low-frequency instability, is rarely involved in VHF oscillations, other than supplying electrons and stray capacitance to ground.

A VHF oscillation, if it happens to occur in an HF PA, is almost always rooted in the system behaving like a "tuned-plate/tuned-grid" oscillator.

Most of our modern PA's are grounded grid (cathode driven). Cathode driven operation requires one or more grids be directly grounded to the chassis (at least for RF) with the lowest impedance possible. *This is necessary to shield the output from the input, and assure operating frequency stability and purity of emissions.*

Using the anode for suppression generally works best because the grid or grids can remain well-grounded for RF, provided the best operating frequency performance.

The Most Unstable Tubes

The most problematic tubes for VHF oscillation have relatively large elements and long thin leads. Tubes of this type have low gain or are unusable at VHF, because elements in the tube (combined with lead inductances) are actually resonant at VHF.

Leads are a particular problem. The longer and thinner the leads, the less stable a tube becomes. Long thin leads move the self-resonance lower in frequency while increasing element impedance. This allows even a tiny amount of anode-to-grid feedback to cause oscillations.

Tubes most troublesome are 811A's, 572B's, 833's, 4-1000A's, 3CX1200A7's and 3CX1200D7's.

Tubes of moderate instability are 3-500Z, 3-1000Z, and 4-400A's.

Tubes having virtually unconditional VHF stability are the 3CX800, 3CX1200Z7, 3CX1500/8877, 3CX3000, and 3CX5000/3CPX5000/YU-156 series.

Looking at the above tubes, it is the tubes with the thinnest and longest leads that are most troublesome. These also are tubes with the poorest VHF performance when used in amplifiers intended to operate at VHF.

The most troublesome tubes above tend to oscillate in the lower-VHF range, between 30 and 100 MHz. The typical instability frequency of an 811A or 572B is around 80-100MHz, assuming all leads are short.

Moderately stable tubes tend to oscillate at 100-200MHz. 3-500Z's, for example, generally are most unstable from 180-200 MHz.

Anode Circuit Layout

Anode circuit layout can contribute to VHF instability. Long thin leads from the tube anode connector to the chassis at VHF are a problem. Problems can occur when thin (and long) plate blocking capacitor leads, thin and/or long wiring, and poor mounting of the plate tuning capacitor are used. Remember, this is a VHF path also, even if the amplifier only *intentionally* operates on HF.

To maximize stability:

- Use wide anode circuit leads from the tube to the tuning capacitor
- Mount the tuning capacitor directly on the chassis, or on a large metallic groundplane area that is thoroughly bonded to the chassis at many points
- Use a low-inductance plate blocking capacitor
- Keep all leads as short as possible, even if it is at the expense of having wiring "look pretty" with all perfectly aligned 90-degree angles
- Use the chassis as a groundplane and an input/output shield, not a front panel

Grid Circuit Layout

The grid circuit layout is probably the single most important area for insuring a stable design. Long thin leads from the tube grid connector to chassis at VHF are a problem. This can be from thin (and long) grid bypass capacitors, thin and/or needlessly long wiring, and failure to ground grids directly to the chassis by mounting ground lugs directly on the chassis near the grid pins.

To maximize stability:

- Use wide low-inductance grid leads from the tube socket directly to the chassis, Connect the ground leads at the closest possible point, using ground lugs right at the grid pins (rather than using socket mounting screws) for grounding
- Use low-pass Pi-network or parallel tuned networks as input matching circuits
- Mount any swamping or load resistors near the tube, with short leads
- Mount the low-pass or bandpass input matching system near the tube, or use exceptionally low-impedance transmission lines to reach the input matching system
- Keep all grid connections as short as possible, even if it is at the expense of having wiring "look pretty" with all perfectly aligned 90-degree angles

A Bad Grid Idea

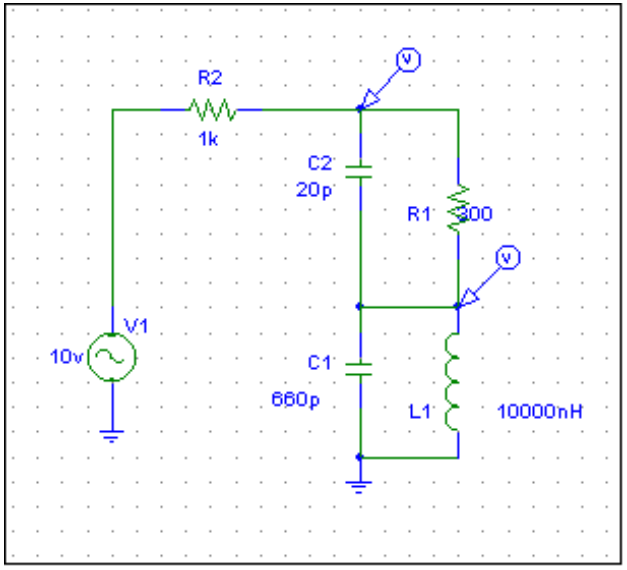
One of the very worse things in modern grounded-grid triode PA's is the inane engineering claiming floating grids on capacitors adds useful negative feedback. This is similar to what Collins did in their 811A amplifier, and Japanese manufacturers copied the bad idea into their power amplifiers. Heathkit was also a victim of this engineering gaff.

When I was designing PA's in the late 70's and early 80's, an employee of Eimac and author of many articles and a handbook put considerable pressure on me to float the grids of 3-500Z PA's through small mica capacitors.

The theory presented was pretty simple. He claimed floating grids through small mica capacitors added negative feedback, making the amplifier "work better". The basic idea was that filament-to-grid capacitance formed one part of a capacitive voltage divider, the grid-to-ground capacitors forming the other half of the divider.

The alleged "idea" was this capacitive divider would float the grid partially up from ground, and reduce grid-to-cathode (grid-to-filament) driving voltage. I quickly concluded that no one ever actually measured or calculated feedback over a wide range of operating frequencies and grid currents. Since this is a C1/C2 divider, the sampled feedback should be constant in both amplitude and phase regardless of frequency, power levels, and tuning.

The basic circuit is:



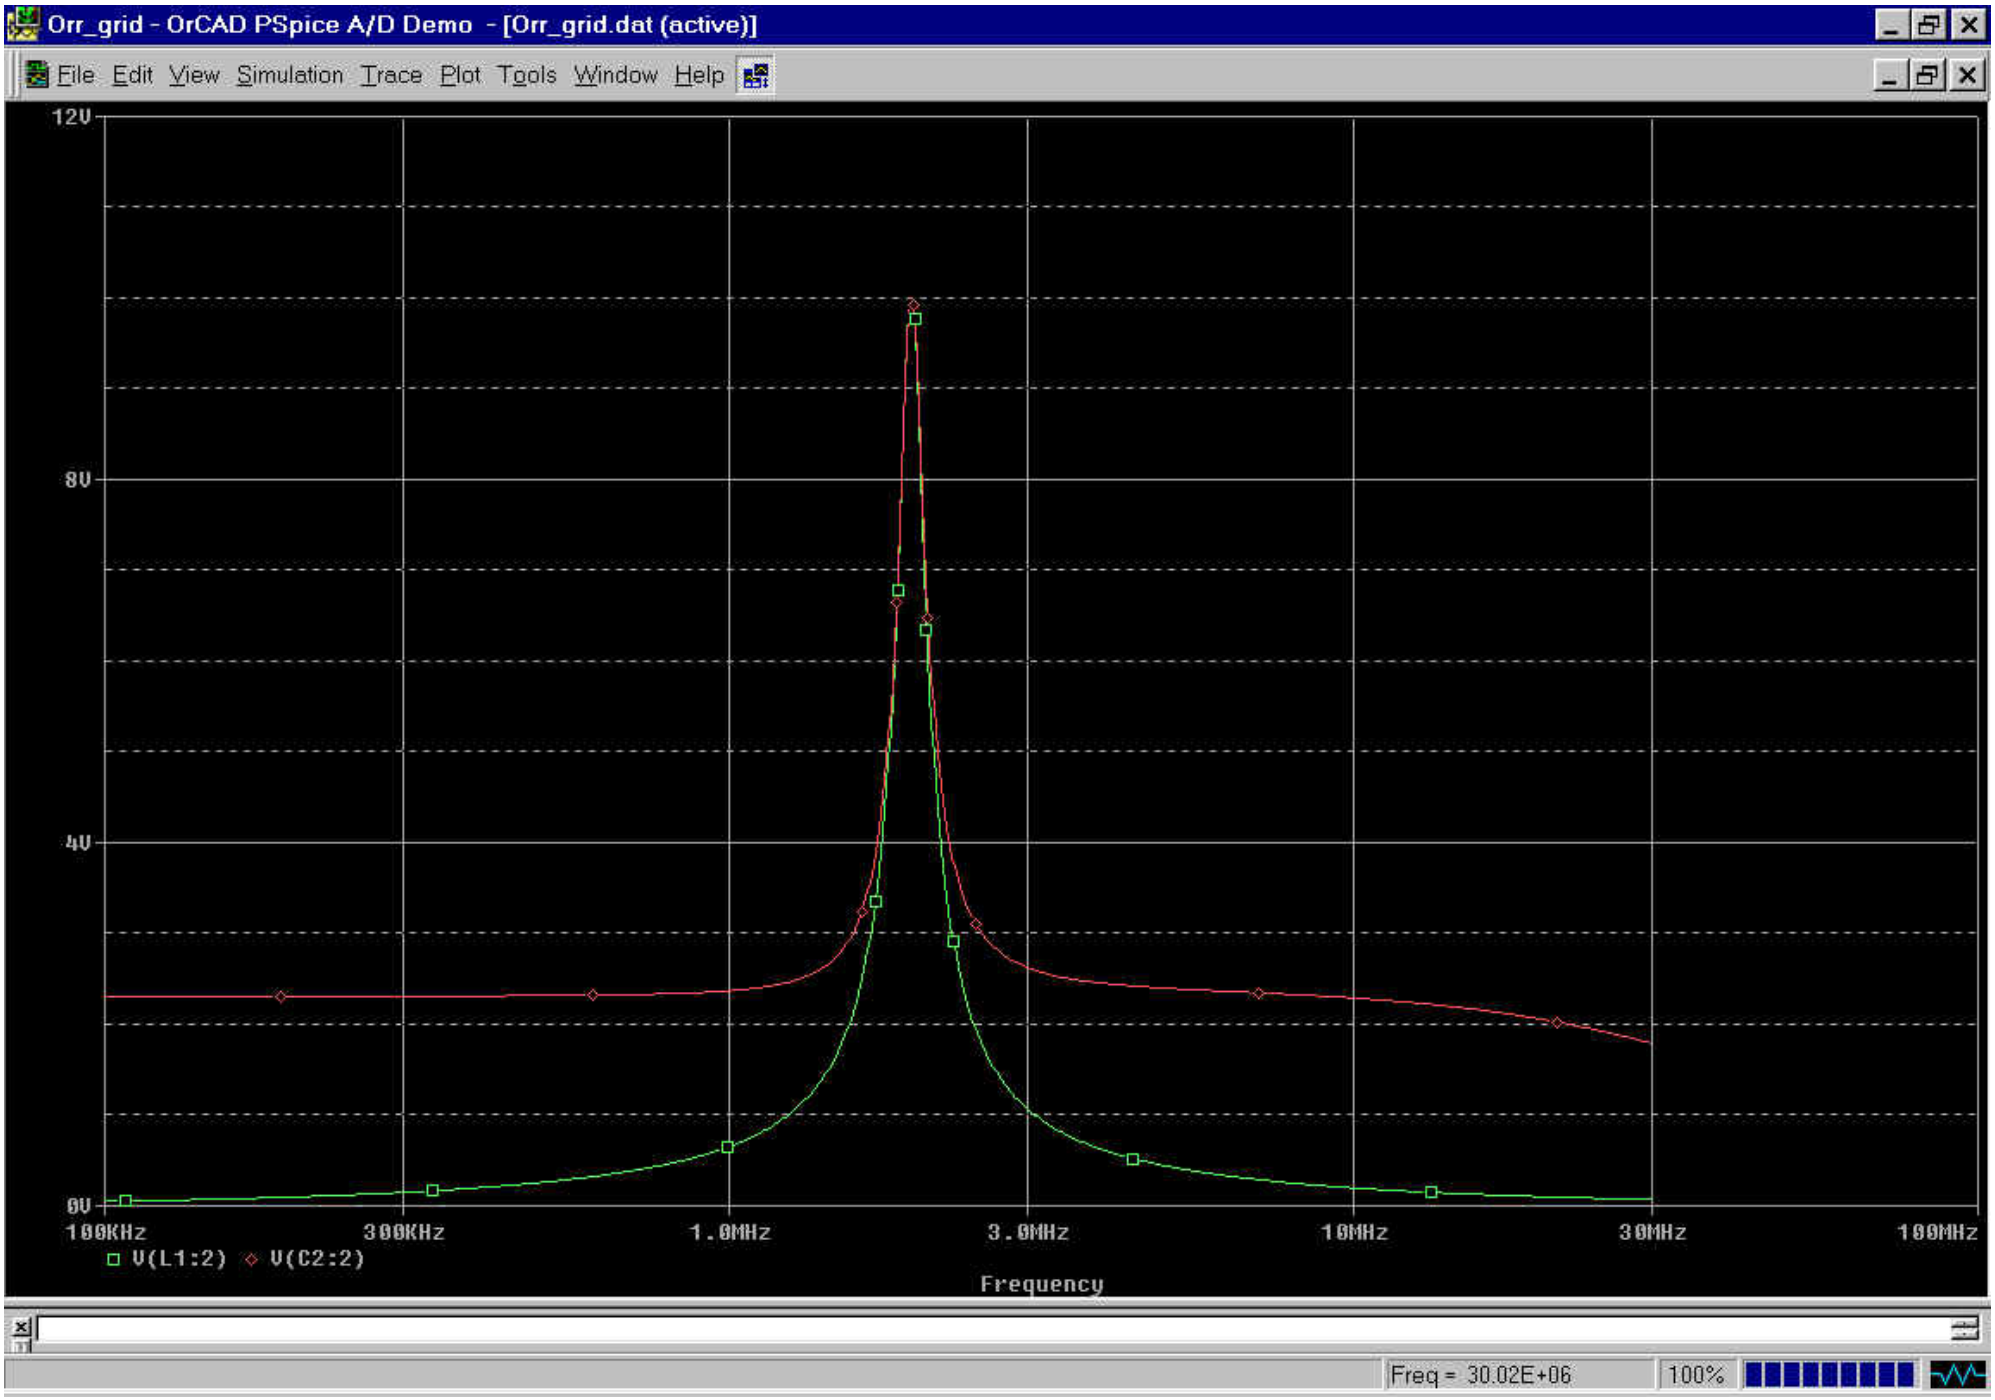
The grid connects at the junction of C1 and C2, while the cathode connects to the top of C2.

C2 is the internal stray GK capacitance of the tube

R1 is the time-varying grid impedance

R2 is added to allow us to see the input impedance change of the divider on a probe model.

Sweeping the system from 100KHz to 30MHz shows us the following:



What we see is a huge spike in grid-to-ground impedance at 2MHz, and very uneven response above that range. We did not even include the time-varying grid resistance and phase error,

since this would take up to much space on my web site.

By manipulating the value of L1 (the grid chokes) we can move the spike around, but we are ALWAYS left with some frequency where the grid isn't grounded! This is a serious violation of good engineering practices in a grounded-grid PA, and is actually at the root of stability problems in some PA's. Collins, for example, had a series of field modifications to the 30L1 grid system. The best idea would have been to abandon the bad idea that this system adds controlled negative feedback, and changed to a true grounded grid.

If they wanted negative feedback, the PROPER method would have been adding a resistor in series with the cathode by placing a series resistance immediately at the drive point to the cathode!

There are obviously major flaws with the super-cathode drive concept, when it uses a capacitor divider. Grid current causes grid-to-cathode impedance to constantly vary. When grid current is absent, the grid-to-cathode impedance is nearly an open circuit. Grid-to-cathode capacitance dominates the upper half of the divider, and everything appears to work as planned.

Unfortunately, a problem appears whenever the grid draws current. Even the tiniest amount of grid current causes grid-to-cathode impedance to decreases rapidly. With only a few dozen milliamperes of grid current, grid impedance drops to a few hundred ohms or less. As grid current is drawn, the decreasing grid impedance dominates the upper leg of the voltage division circuit!

There are also new potentially destabilizing resonances added in the grid path.

This system causes three major problems:

- Grid drive is effectively reduced as operating frequency becomes higher, just where we need the gain to flatten normal gain roll-off
- Feedback starts to show significant phase-lag with increased drive and reduced operating frequency
- Grid-to-chassis inductance at VHF and LF is increased, making the amplifier less stable

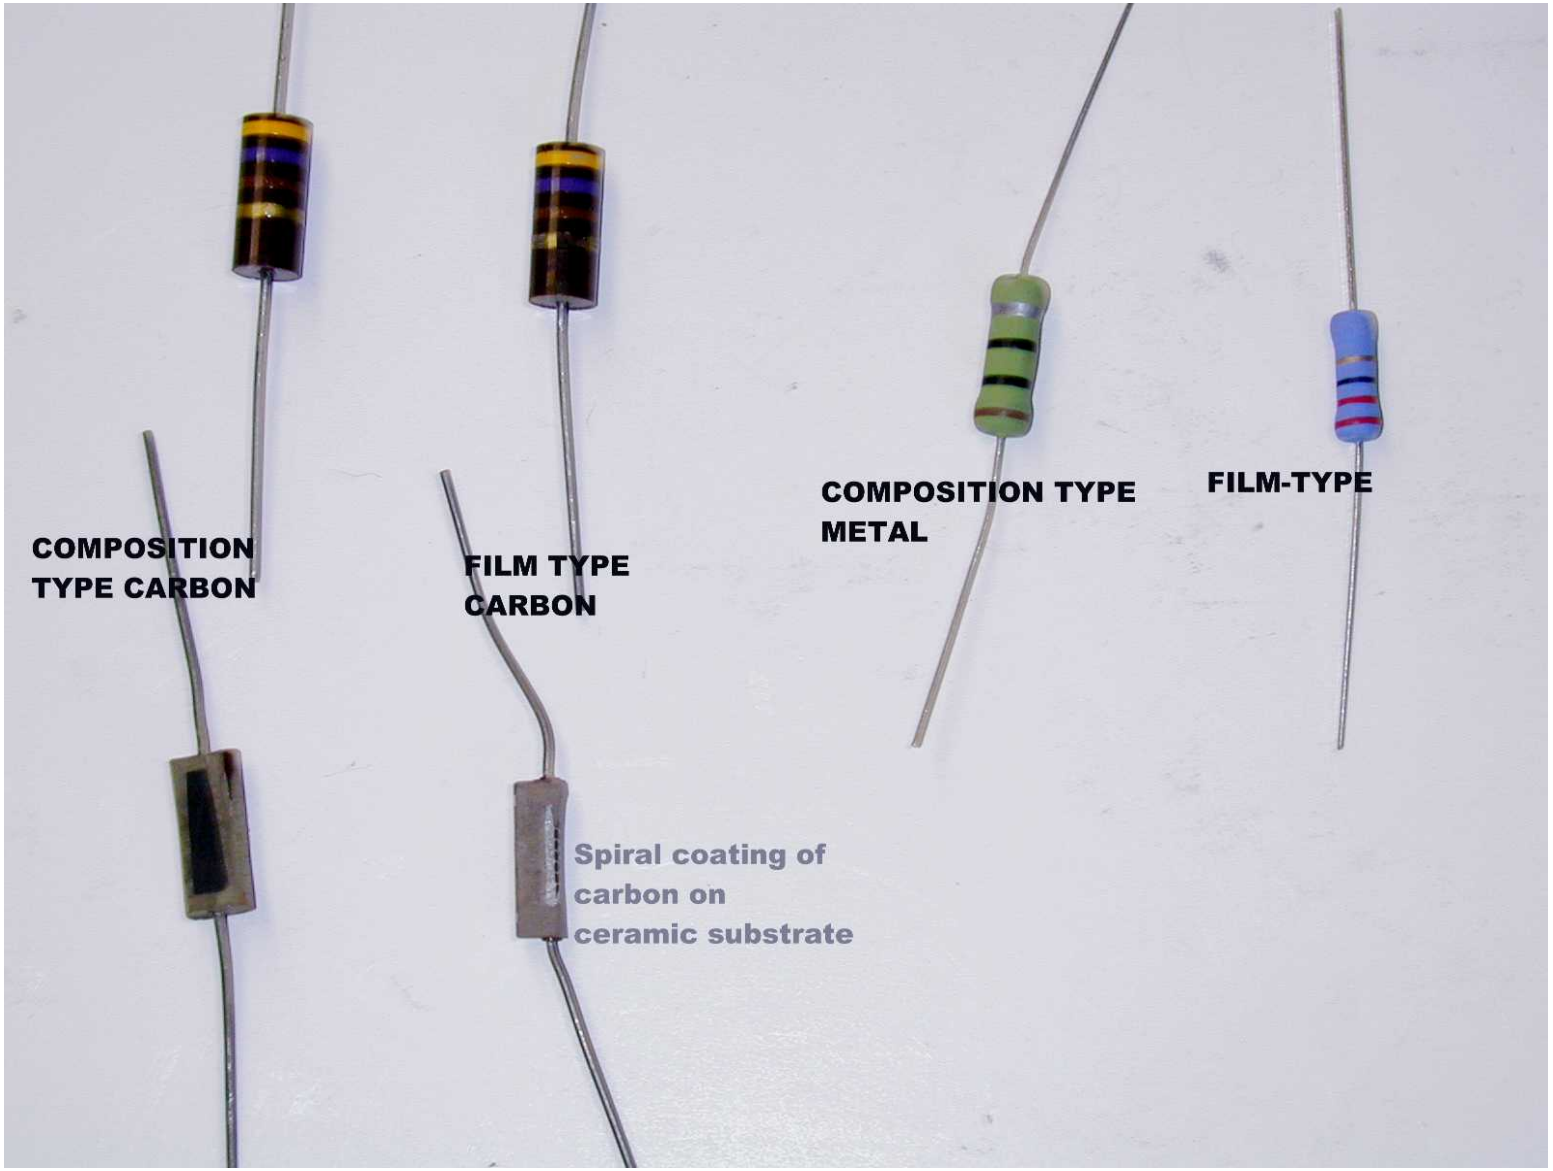
When I tested several amplifiers with and without this alleged "super-cathode" system, I found IMD performance decreased significantly under some operating conditions. Stability also significantly decreased.

Ground the grids either directly with short heavy leads or a low-inductance high-value capacitor with very ***short leads*** in any grounded-grid PA!

What Does the Parasitic Suppressor Do?

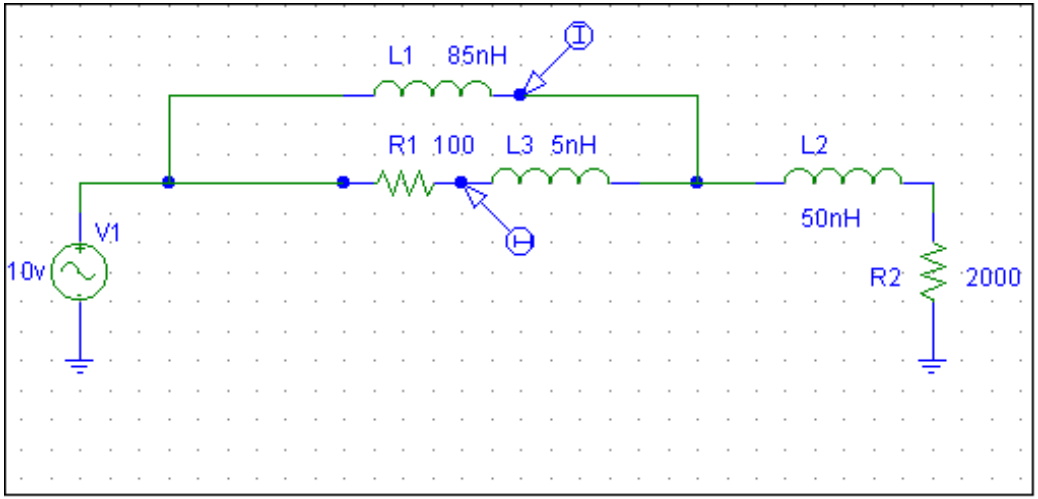
The parasitic suppressor normally has two components in parallel, a resistor and an inductor. At low frequencies, the path through the inductor dominates the system. At very high frequencies, the resistor dominates the system (assuming it is a low-inductance resistor).

One common problem is people assume brown carbon resistors are non-inductive. That isn't the case. For an example, look at the following resistors:

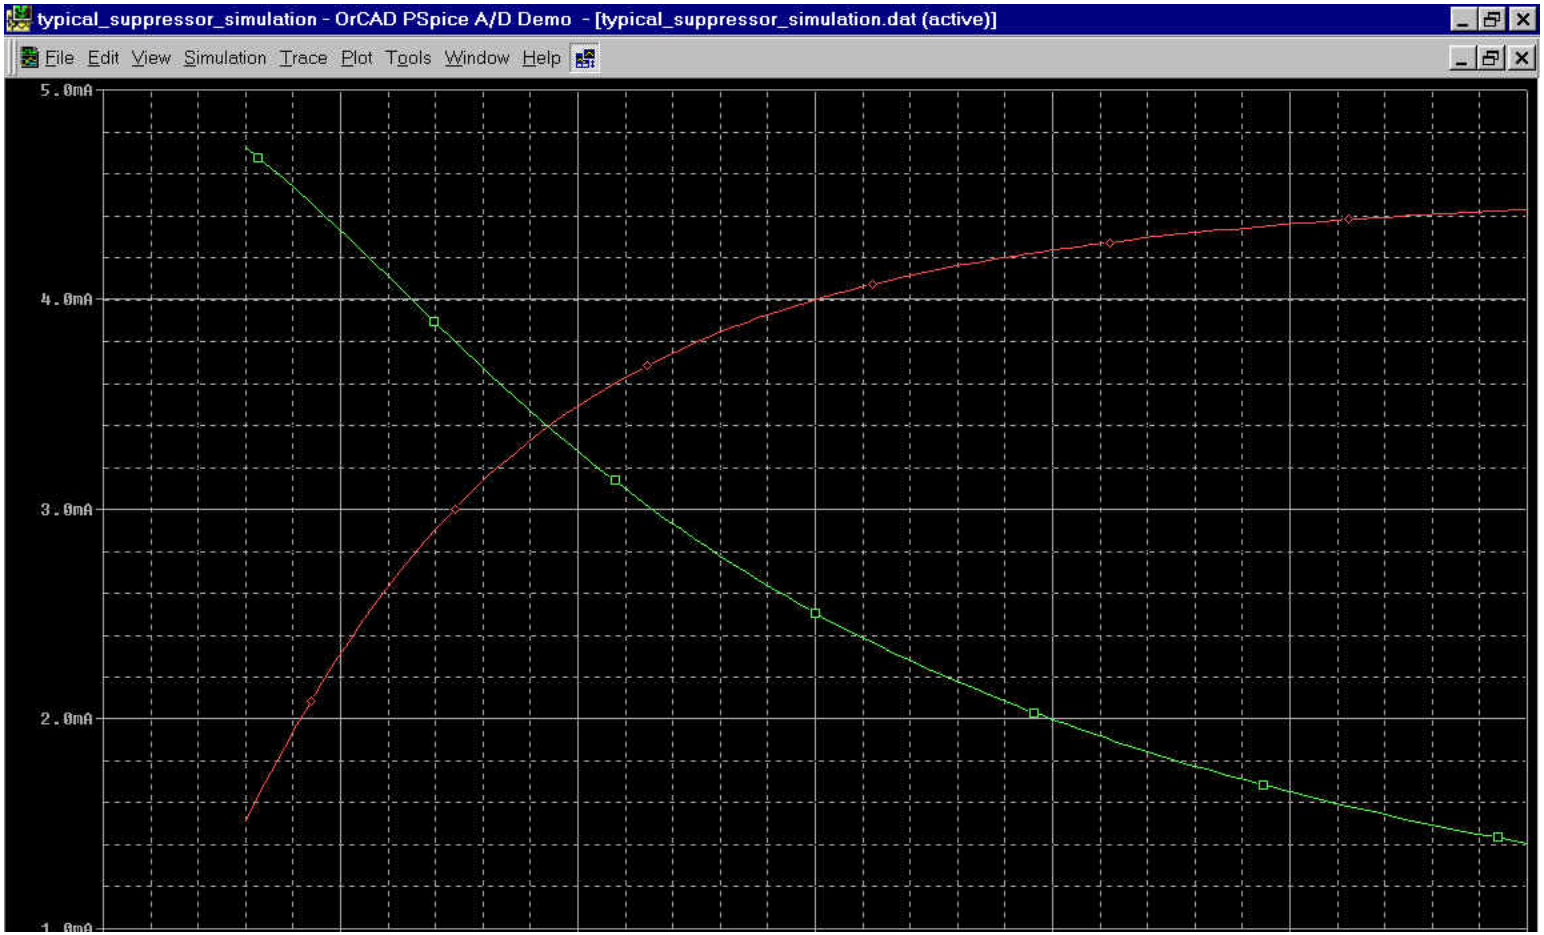


All of the spiral-conductor resistors above have significant inductance at VHF, and make very ineffective suppressors unless the reactance is cancelled. Only the true carbon composition resistors are useful in non-resonant standard suppressors.

This is a typical suppressor system, including inductance of the anode lead:



In this case V1 represents the tube. The following is a simulation of currents in the suppressor:



Starting at 30MHz, the ratio of current in the inductor to current in the resistor is:

Frequency	-I(L1)	-I(R1)
30MHz	0.0047	0.0015
60	0.0041	0.0026
90	0.0034	0.0034
120	0.0029	0.0037
160	0.0024	0.0041
190	0.0021	0.0042
220	0.0018	0.0043

This tells us something very important. The INDUCTOR dominates only at low frequencies. At 30MHz, current in the inductor is three times current in the resistor.

At 190MHz, in the range of the instability frequency of a 3-500Z, the resistor has twice the current as the inductor.

This tells us any changes in INDUCTOR design or inductor Q (such as use of nichrome wire) mainly lowers low frequency Q. It would have virtually no effect on very high frequency Q of the system.

- The dominant factor in controlling VHF Q is the resistor value, and any reactance in the resistor path
- The dominate factor in determining HF Q and performance is the inductor value, and any changes in inductor Q

This has been my point all along with the Measure's nichrome suppressor. Measures claims, incorrectly, his suppressors provide lower VHF Q while, in fact, they do exactly the opposite! A typical Measures hairpin suppressor actually produced significantly ***higher*** system Q in the anode of a 3-500Z (nearly twice the VHF Q), because the equivalent Rp of the suppressor in ***series*** with the anode lead was ***lower***!

The reasons HF PA's arc are explained at other pages of this site, and include incorrect relay sequencing, load faults, as well as improper tuning and exciter transients.

Reducing VHF Q

If we want a lower VHF Q, while maintaining high LF Q and efficiency, the system must shift current into the resistor faster as frequency increases. The suppressor must also have higher Rp, so it dominates the anode path inductance that is in series with the suppressor.

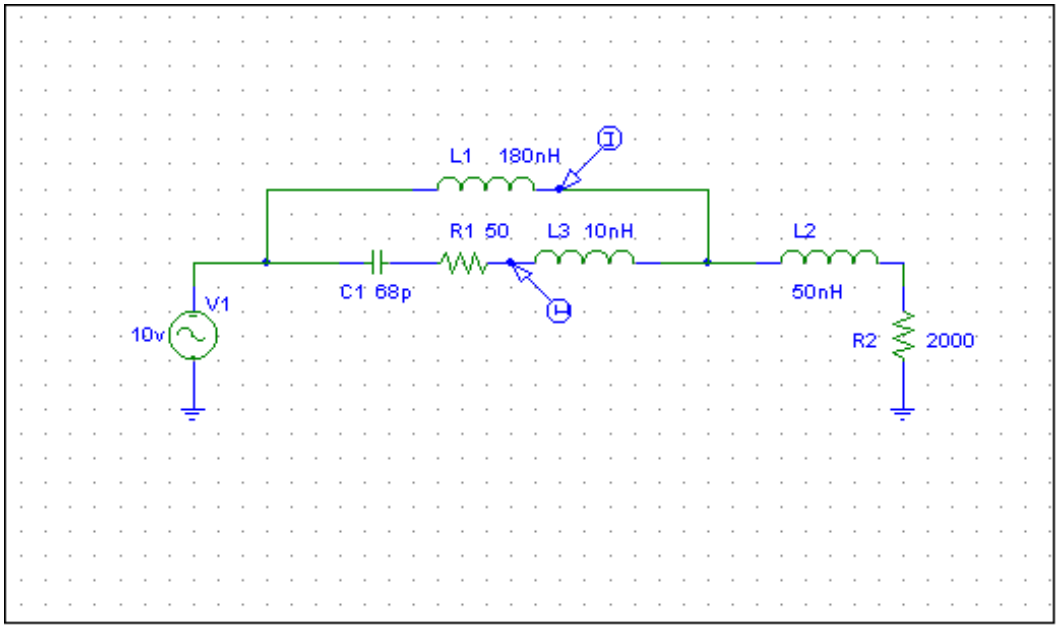
While Measures openly touts his "low-Rp suppressor", the fact is a low Rp suppressor results in higher anode system Q!

A Truly Improved Parasitic Suppressor

In order to reduce VHF Q, we must have a resistance dominate the anode system. This means, in a frequency sweep simulation, the ratio of currents in the resistance to

current in the inductance must be as high as possible. Let's call that slope ***the rate of transfer.***

The rate of transfer can be increased by adding a small value of capacitance in series with the resistor:



The old suppressor was:

Frequency	-I(L1)	-I(R1)	Ratio
30MHz	0.0047	0.0015	3
60	0.0041	0.0026	1.6
90	0.0034	0.0034	1
120	0.0029	0.0037	.78
160	0.0024	0.0041	.58
190	0.0021	0.0042	.5
220	0.0018	0.0043	.42

The new one:

Frequency	-I(L1)	-I(R1)	Ratio
30MHz	0.0069	0.0026	2.6
60	0.0050	0.0055	.9
90	0.0027	0.0052	.52
120	0.0019	0.0050	.38
160	0.0013	0.0048	.27
190	0.0011	0.0047	.23
220	0.0009	0.0047	.19

Graphically we see the currents are:

The green curve is current through the inductor, the red curve shows current through the resistor. Notice how flat current is in the resistor, and how sharp roll off of current in the inductor becomes.

This means we will have very low ***anode SYSTEM*** Q starting at a low VHF frequency of 50-60MHz, and continuing up to UHF. Dissipation in the resistor is still reasonable at HF, efficiency and tank Q at the operating frequency remain high, yet VHF suppression is greatly improved.

Selecting Component Values

Optimum resistor value can actually be determined by measurement, or determine empirically.

If the anode path is long and thin, the impedance will be high. A high anode path impedance (thin or long leads) requires higher values of resistance, because we want the resistor to dominate the anode system impedance. The best value for a resistor is generally one that is approximately equal to, or slightly higher than, the anode path reactance at the frequency of instability.

That impedance can be measured on an impedance test set, or other ways by creative engineers or technicians, but as a general rule long, thin anode leads like 811A's require 100-150 ohms of resistance while shorter thicker anode leads like those in 3-500Z tubes require 50-100 ohms of resistance. Stable tubes with external anodes often can just use anode lead resistance, using brass or other materials, to adequately dampen anode path reactance.

The inductance has to present a significantly higher reactance than the suppression resistor value at the frequency of instability. This causes the majority of current to flow through the resistance at the very high frequency, and not the inductor.

If you look at amplifier designs, you will find tubes like 811A's generally have higher value resistors and many turns of wire in the suppressor. Tubes like 3-500Z's have significantly fewer turns, especially when grid leads are kept very short and direct to the chassis, and lower value resistors.

The more unstable the amplifier tube, the larger the inductor and resistor must be.

One way to view this is to consider the frequency response of a Hi-fi amplifier. Larger values of plate load resistors in amplifier stages reduce higher-frequency gain. The same is true in HF PA's.

Lower frequencies of instability require larger inductors, so the RF path is shifted over to the resistor at a lower frequency.

Uses For Improved Suppressors

Series-resonant suppressors are used with slightly inductive resistor paths, and larger-than- normal shunt inductors. A small capacitor is placed in series with the inductive resistor path, and this capacitor series-tunes the resistor path. This results in a very rapid shift of current into the resistor as frequency is increased. This works well with amplifiers operating at 1/3 to 1/2 the instability frequency, minimizing resistor heat while providing perfect stability.

Typical applications are 3CX1200A7 and D7 tubes, 572B tubes, and 811A tubes.

Shunt suppressors with series-resonant tuning are also sometimes used, the normal application is very high power stages with substantial anode-to-tank currents. These suppressors consist of a series R/L/C system, where the C is normally just stray capacitance to the tube anode. Sometimes these suppressors take the form of a ferrite block placed between the anode and chassis. The inductance of the block series-tunes stray capacitance, and the losses act like a damping resistance in series with that path. I've stabilized 50-100kW VHF transmitter designs using shunt suppression.

Other Instability

Some PA systems are prone to oscillation at low frequencies. Yaesu and Dentron amplifiers using 572B's, and the Collins amplifier using 811A's are good examples of production amplifiers with stability problems.

These amplifiers tend to oscillate NEAR the operating frequency.

All of these amplifiers, except the Yaesu, use tubes with high anode-to-grid feed-through capacitance and no neutralization. Worse, the Collins floats the grids for RF, reducing the already poor isolation of anode-to-cathode feedback path in the 811A.

Yaesu uses one of the poorest engineered feedback systems of all, with a capacitor from the output of the pi section back to the cathode! Phase shift in that path would vary wildly with tank circuit tuning and load impedance on the PA, as would the amount of feedback!

The Yaesu amplifier is a particular problem with Chinese 572B tubes, because grid mu is lower. Negative grid bias has LESS of an effect on cathode current, so the Chinese (and Russian) tubes draw extra quiescent current when the antenna relay is open. This additional current allows the tube to amplify while the amp is in standby. Since the antenna and input source are removed in standby, and the improperly designed feedback path to the tank output remains in place, the PA oscillates near the operating frequency with no load! Voltage in the tank builds up to many thousands of volts, because no energy is extracted to a load. The fact the oscillation is at a low frequency allows the bandswitch to see the full voltage, and it fails.

Amplifiers can create extremely large voltages when RF is applied and a load is not present!

All of the amplifiers discussed above would be greatly improved by:

- Adding a proper bridge neutralization circuit like Heathkit, Ameritron, and Gonset used in 811 amplifiers.
- Grounding the grids either directly or through low reactance very-short-lead capacitors, directly between the socket's grid pin and chassis.
- Using the improved suppressor outlined above to de-Q the amp at lower VHF.

Conclusion

I hope this information is useful, and helps people understand what really goes on in a parasitic suppression system. As time permits, I add more articles about curing unique problems in amplifiers, and diagnosing amplifier failures. I hope these pages are a good start.

Sorted by IM3

[Home] [Up]

Sorted by Intermodulation. Best receiver first.

This is a measure of how badly a close-spaced signal will trash your receiving with spurious signals or splatter sounds, and you might blame it on the other guy thinking your receiver is just great. Remember that even in my very quiet rural location where I have to "beam" through the east coast to hear Europe, 80dB or so IM3 is probably more than enough. The reason my Drakes are so good is because they were built to duplex on the same band with my own transmitters running!! Unless you are in a situation like that, anything over 80dB is likely wasted.

Most transmitters are really the source of problems. The exceptions to transmitters being the primary source of problems occurs when:

1.) You use a noise blanker. Most noise blankers kill receiver IM and blocking performance.

2.) You don't have good narrow IF filters.

3.) You use too much gain in the receiver front end.

4.) You have a receiver with a design problem (less than 80-85dB close-spaced IM3 DR) .

Beyond the above, most transmitters are the real problem. Look at transmitter IM tests on SSB and read about keyclicks.

Poor Designs

Poor designs include:

1.) Many different Yaesu's without noise blanker mods. NO, changing the diodes doesn't do a thing! Been there, done that. The hissing noise comes from a FET following the narrow filters, the IM comes from the silly Yaesu noise-blanker design that hangs an FET right on a wide IF line with the potential for that FET to be at full gain even when the NB is OFF!!!

2.) DSP filter only radios. They aren't that good to date, and some of them are downright crummy.

If you have a DSP radio without a roofing filter that matches the mode, you probably have a ***poor*** receiver.

3.) Radios with spurious response problems. The JRC JST-245's I've tested and used all test good, but they have so many spurious synthesizer responses on 160 meters I'd never consider using one for serious weak signal work. I don't know how they are on other bands, but they sure stink on 160.

Here's how a few receivers stack up. Look at how much the FET in the Yaesu hurts the performance. Look at how poor a stock early R4C really is. Notice almost anything is good at 10kHz, even some very poor receivers.

	Model (in some cases serial included)	MDS	2kHz BDR	10kHz BDR	2kHz IMDR	10kHz IMDR
1	R4C heavy mod. Experimental. See note 5	-143	127	131	118	119
2	R4C 17816 med mod. See note 4	-140	96	115	92	103
3	TenTec Orion	-129	98	100	92	92
4	FT1000D/W8JI mods	-136	73	87	89	88
5	TS-870 Inrad 400Hz IF filter mod (AIP)	-139 (-125)	74 (82)	94 (98)	86 (81)	90 (91)
6	FT1000MK V W8JI mods	-131	80	89	85	90
7	IC-751A	-140	83.5	98	79	91
8	IC-7800	-127	80	98	78	88@5 kHz

9	FT1000MP 8N370165	-135	73.5	84	62* 75.5** note 1	70.5* 80** note 1
10	FT1000D	-134	68	85	72	81
11	R4C S/N 22291 stock	-139	80	116	68	86 note3
12	IC-756 PRO	-133	N/A	78	67	77
13	FT1000MK V stock	-131	74	86	60 note1A	77 note 1A
14	R4C S/N 17816 stock	-132	57	109	48	82 note2

Note 1: The FT1000MP has the same inherent problem as the FT1000 and FT1000D. **A noise-blanker amplifier FET is left on *even when the noise blanker is turned off with front panel NB and NB-W switches*.** This FET connects directly to the IF, and overloads when strong signals are present. Unlike the FT1000 and FT1000D, the front panel noise blanker level control affects the FT1000MP IMD performance. * is with the NB gain control fully advanced, ** is with the NB gain control fully off. ***In ALL cases the NB off-on switch is OFF!!***

Note 1A: Yaesu copied the same basic NB from the FT1000D, and so this radio also has a NB problem even when the NB is switched off. This test was with NB gain menu set for minimum gain. The radio is worse when NB gain is increased in the NB gain menu.

Note 2: This is a MOSFET 2nd mixer R4C, aligned and in good shape but with no changes. This receiver is almost useless for weak signal CW work of any kind because of poor IM performance and filter blow-by.

Note 3: This is a tube 2nd mixer R4C, aligned and in good shape but with no changes. This receiver is almost useless for contesting or crowded bands because of poor IM performance and bad filter blow-by.

Note 4: This is the same receiver in note 2, but with the following changes:

1. Increased screen voltage on RF amplifier to 130 volts.
2. 6J6 first mixer with oscillator injection increased to 5 volts.
3. Diode double-balanced 2nd mixer with +10dBm injection.
4. 10dB of gain removed from first mixer and first IF and redistributed behind the narrow filter.
5. Sherwood Engineering 600Hz roofing filter.
6. New AGC system. After narrow filter only, no AGC on front end.

Note 5: Gutted and rebuilt with solid-state double balanced high-level mixers. No vacuum tubes in signal path. Sherwood 600Hz roofing filter. Experimental receiver for full-duplex operation on 160 meters. This receiver allows me to hear weak DX while I am transmitting, as long as they are a few kHz off frequency.

Detuning Towers

[Home] [Up]

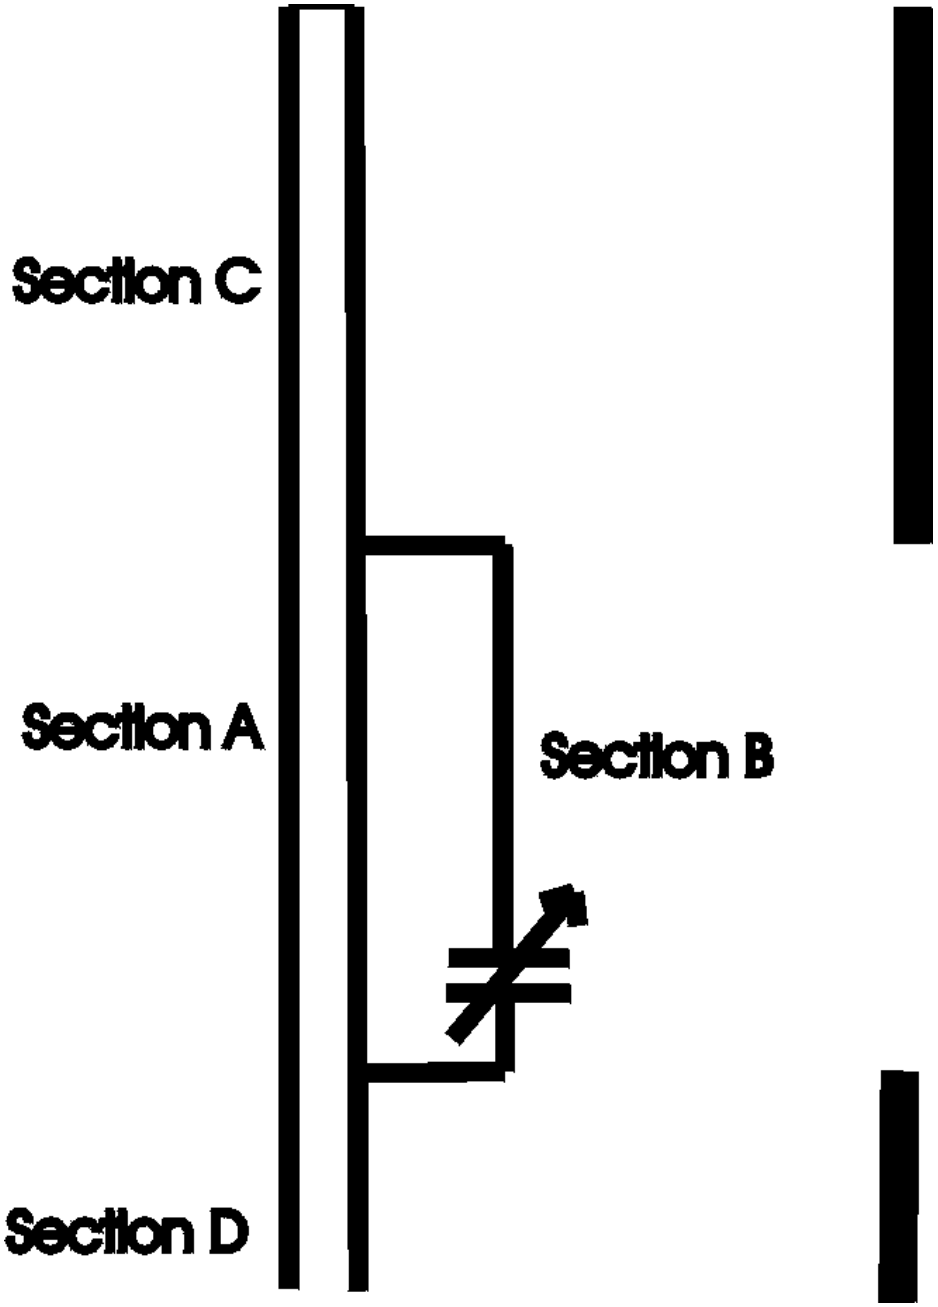
Detuning Towers

The goal of detuning is not to avoid resonance, but rather to minimize re-radiation and/or current in the interfering structure.

When large enough, structures can re-radiate and cause severe pattern distortion even when they are NOT resonant. Consider, for example, how effective a large non-resonant screen or solid disk is at reflecting signals even when it is nowhere near resonance.

We can minimize re-radiation by making an area or areas of the structure "electrically vanish". We often call this "de-tuning", even though it is more correctly electrical trapping or sectionalizing of a structure.

Most structures or towers, when detuned, have a section adjusted to represent a ***parallel tuned*** circuit.



Section A and B carry out-of-phase currents. Picture the current flowing upwards in A. It must then flow downwards in B. Since it is a closed loop, these out-of-phase currents are equal and flow in ***opposite directions*** at resonance. The result is radiation from sections A and B cancel each other. When section A and B are exactly resonant, sections D and C are isolated by a high impedance. The high impedance is caused by or related to the high current though the capacitor and the inductance of section A. When current is maximum, voltage drop is maximum.

This results in the electrical structure on the right, with section A and B removed!!

In effect, we have created a trap much like the trap in a dipole. As in the trap dipole, current is maximum in the trap at the trap's resonant frequency.

NOTE: ***The condition of proper tuning occurs with MAXIMUM current in section B, NOT minimum current!! To electrically sectionalize the tower and isolate C and D (and minimize radiation from A) section B must be tuned for MAXIMUM current!***

As either section C or D approach resonance by themselves, the tuning condition will change. This would occur when D is grounded and near 1/4wl or an odd multiple of 1/4wl long, or when C (with whatever is mounted on it) is self-resonant with section A removed!!

Under this condition, you would either need to sectionalize and detune C or D with additional detuning, or move the location of sections A and B to a new point that (when isolated) prevents resonance in C and/or D.

A few general rules apply. Pay attention to these guidelines to insure best results:

- Never parallel-tune a large area. Certainly not an area over 3/16th wavelength long
- The detuning "loop" must have a good solid connection to the structure being detuned. Don't connect the detuning wire out to a separate object or earth stake
- We want to adjust for MAXIMUM current in section B, the exception being when that would cause resonance in C or D
- We can not have any electrically large structures or wires hanging from the tower in the area being detuned.
- Ideally any cables passing the detuning area should be grounded to the tower at the top and bottom of the detuning area, or pass through that area in the center of the tower or mast. At the very least, cable shields should be bonded to the tower at the top and bottom of the cable run and unshielded cables placed inside the tower.
- Tuning is fairly narrow. ~5% total BW is about all that can be expected in most cases, but this varies greatly with the system including distances to the other affected antennas and the amount of pattern distortion tolerated

Note: I added the section about cables on Feb 17,2003. I'm surprised cables are often not grounded at the top and bottom of tall towers, and that unshielded control cables are not passed through the inside of towers. Cables should always be treated that way for lightning protection if for no other reason!

Capacitor Size

The amount of capacitance and the voltage rating of the capacitor is not easy to predict. The size depends on unwanted power levels that excite the detuned structure, the electrical characteristics of the detuned structure, and the Q of the detuning section. Capacitance values will be fairly high with short sections on lower bands like 160, almost certainly in the range of a few thousand pF for ~20 foot long sections. The exact value would depend heavily on dimensions of the A to B loop.

Voltages across the capacitor are generally not high, although they can be at times. The "loop Q" of A and B affects voltage, as does the amount of excitation and load presented by the impedances of C and D.

MFJ sells a clamp-on calibrated current meter that will not perturb the system. It is a cheap version of a current meter I designed. This is a calibrated meter with internal amplifier that measures current from a few mA to 3 amperes, not the uncalibrated RF-sniffer commonly sold. Some RF-sniffers, including those by MFJ, actually change the impedance and resonant frequency of the system because the pick-up transformers are not properly designed and terminated current transformers. Avoid loop-stick type current meters, since they measure ANY external field and can provide misleading results. Use a current meter that is directly inserted in line B, or clamps around line B with the closed core of a terminated current transformer. Use a meter that does NOT perturb the system when removed!

Lacking a current meter, it is possible to tune this system with a grid dip meter, by forming a small one or two turn coupling loop. As an alternative, the loop can can be broken at any point near the capacitor and a MFJ-259 or similar antenna analyzer connected in series. Proper adjustment is at the point were minimum impedance occurs. If that impedance is not low, you probably are not effectively detuning the structure.

Multiple Stacked Antennas or Tall Structures

When multiple stacked antennas are used, especially on a fairly tall tower, it may be necessary to sectionalize multiple points. Individual sections between antennas can be resonant, or appear electrically long.

If the tower or structure or any part of the structure or tower becomes resonant when section A is tuned to present a high impedance, then we need to move section A or tune it to some condition other than maximum current (resonance). Adjustments under this condition can only be made two ways:

- A sampling loop can be mounted on the structure 1/10th wl or more above or below section B and adjusted for minimum terminal voltage
- Field strength of the pattern can be plotted, and the structure tuned for minimum pattern distortion
- Never detune an area that contains large yagis or other electrically large objects, like long conductive guy lines, dipoles, or cables leaving the tower

Omega and Gama Matching

[Home] [Up]

Omega's and Gamma's

Impedance Limits

The best matching system for feeding a grounded Marconi element, unless we are very lucky or very careful in planning the installation, is a simple gamma capacitor and shunt feed conductor with the tap point adjusted to find 50 ohms resistive.

While losses are ***not*** significantly increased when using an Omega match with reasonably sized components, matching range is not significantly extended either! At best, the Omega match saves us a few trips up and down the tower while searching for the precise shorting strap position between the gamma wire or cage and the tower. If we are already at the top of a tower with the gamma tap point, and if at that point we find resistance (after reactance is cancelled by adjustment of the gamma) is too high, an Omega will not help. The Omega can only match loads ***LESS*** than 50 ohms resistive by stepping the resistance up! It can NOT step or transform antenna feed resistance downwards when using capacitors, and neither the Omega or Gamma can match capacitive antenna loads.

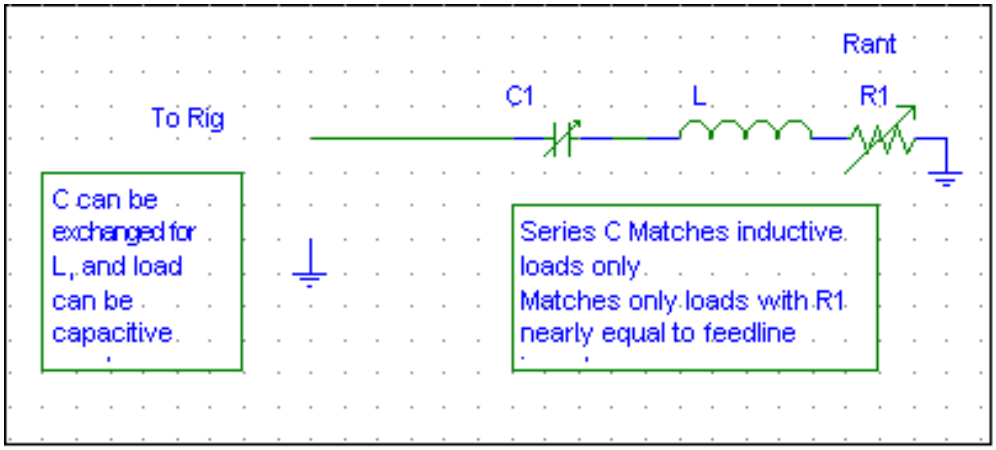
By adding an inductor, we can greatly extend the matching range. The extra time, expense, and complexity of adding a high-Q inductor would not offset the slight reduction in effort to simply find the correct shorting point for gamma and omega capacitor systems.

Gamma Match

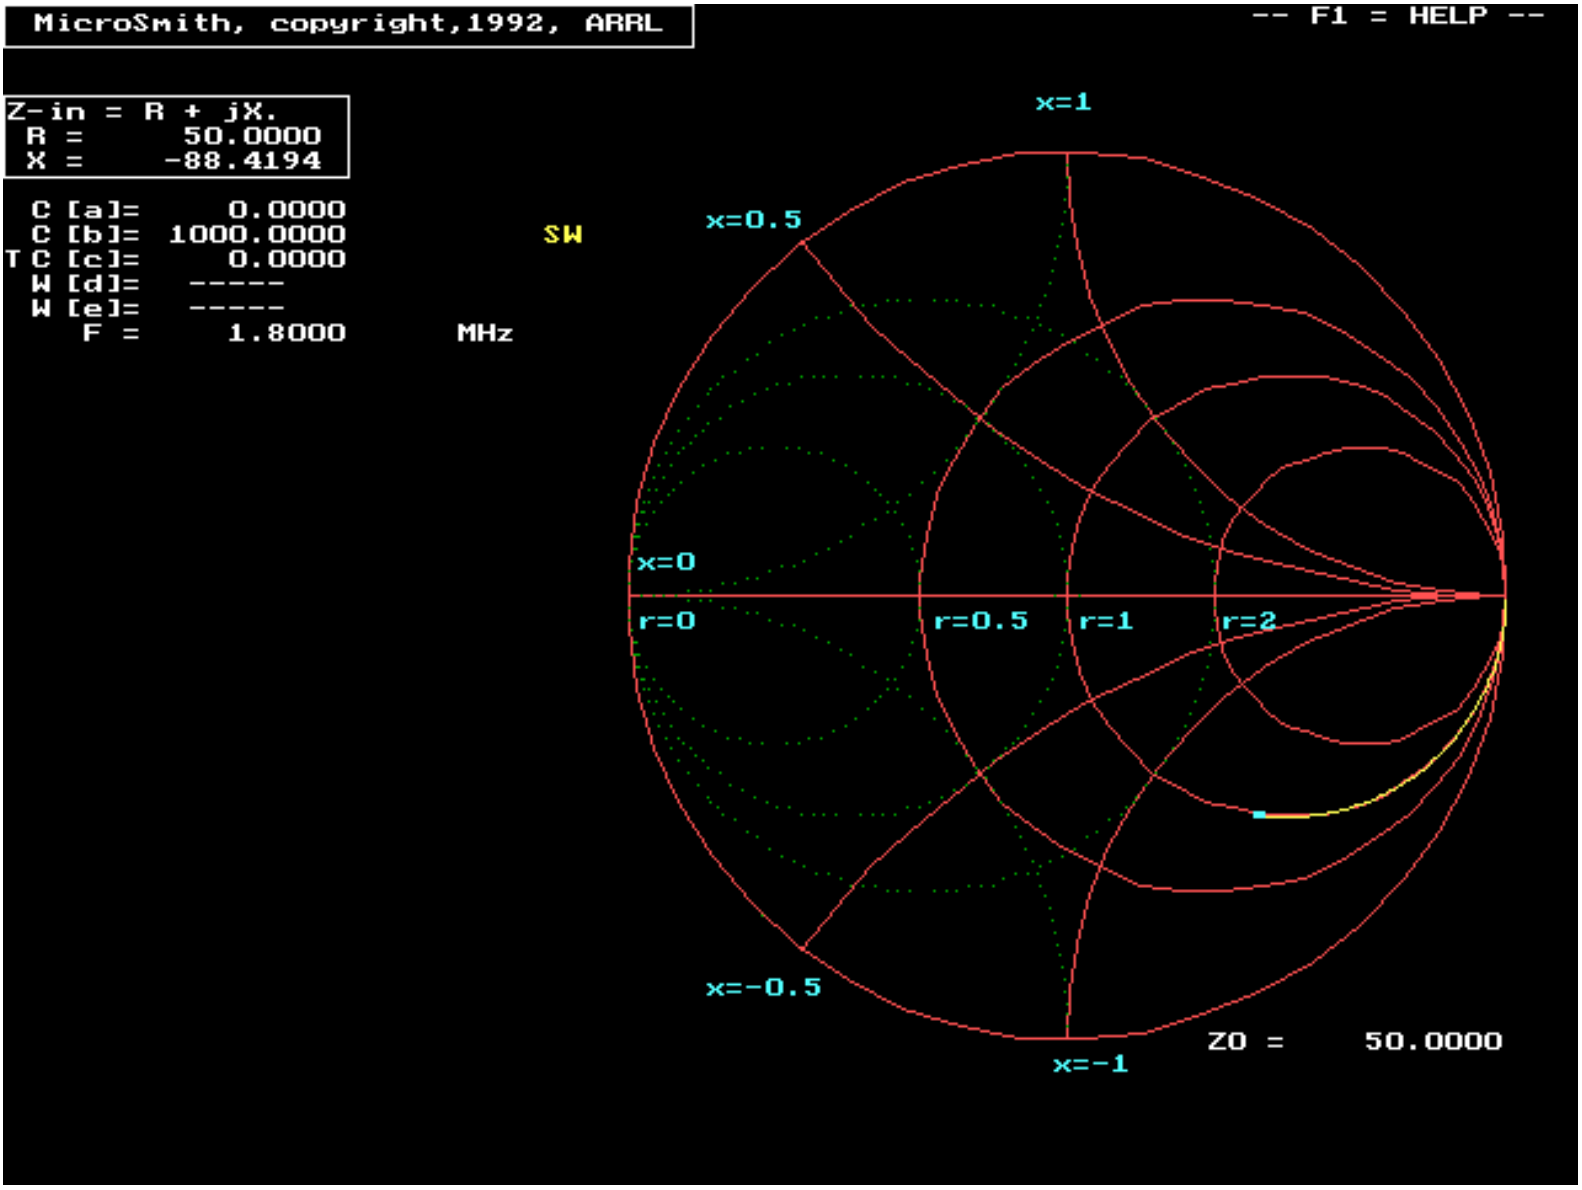
The gamma match capacitor can only cancel reactance, it can not modify the "real part" (resistance) presented to the feedline. It is the most simple form of matching, and has the lowest operating Q and loss of any system (when it is useable). Adjustment of resistance (real part) requires adjusting the diameter, spacing, or length of the gamma section.

The voltage rating of the capacitor is simple to find. It is Y*I*X where Y is the safety factor and adjustment for peak voltage (RMS*1.414), I is the RMS current from the feedline, and X is the reactance (in ohms) of the capacitor. Y is normally a factor of four to allow for peak conversion, SWR, component flaws, and transients.

The current rating is simply the RMS current plus a safety factor. Component physical size as well as Q control the current rating. See component ratings.



Looking at a Smith Chart, we see a single line (yellow) following a portion of the resistance circle with a resistance value of 1 (1 is normalized to 50 ohms). The gamma match can not deviate from that resistance circle, and so the resistance must be adjusted or transformed by other means. We normally adjust the gamma system's tap point by using a movable shorting strap to change R. Just moving a short is enough, it is not necessary to remove the extra "unused" portion above or beyond the shorting strap.



Let's consider a 1500-watt transmitter and 50-ohm transmission line, with a 1:1 VSWR. The matched line current is found using $I := \sqrt{\frac{P}{R}}$. The result is 5.5a RMS current.

With 1500 watts and 50 ohms we have 5.5 amperes RMS. Assuming the match requires 300pF at 1.8MHz we have: $Xc := \frac{1000000}{2 \cdot \pi \cdot F \cdot C}$ $Xc = 294.731$

4*295* 5.5 = 6490 volts. It's easy to see why arcing is a problem when capacitance is low! Very few air variables would take such a high voltage, and insulators (especially when exposed to moisture) also become a problem. This is typical of a shunt-fed element when the matching section is a thin long wire.

We can decrease reactance by increasing the effective diameter of gamma conductors, and this will increase required capacitance value. One way to decrease reactance is to use a cage of wires spaced as far apart as possible. ***Halving the reactance (doubling the capacitance value) will cut peak voltage in half, with no other changes. This has the effect of quadrupling the power rating when using the same breakdown voltage ratings in components!***

A thicker gamma conductor also lowers operating (loaded) Q. This is a series-resonant system, operating Q is set by the amount of reactance in series with the load resistance (50 ohms). Reducing operating Q has the effect of increasing bandwidth while simultaneously reducing loss and increasing power rating.

Note that bandwidth increased while efficiency increased. This happens in many cases. Popular folklore tells us narrow antennas are efficient, but that is true only in a few specific cases. In most cases, bandwidth by itself tells us nothing about system efficiency!

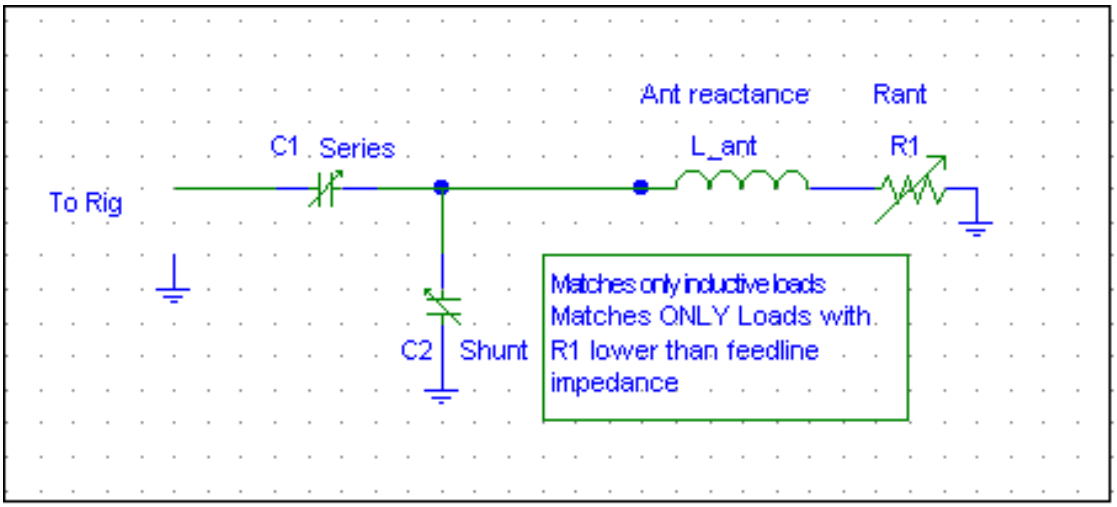
One example of a conundrum with gamma capacitors is found in yagi antennas. If we increase capacitor dielectric thickness by decreasing inner rod size, the voltage across the capacitor can actually increase at a faster rate than insulation thickness increases! The same is true if we increase gamma capacitor length in an effort to restore capacitance after increasing outer conductor diameter. The effect thicker insulation and higher voltage rating, if done incorrectly, can be to make little change or perhaps even ***decrease*** gamma capacitor power rating!! Always use a large diameter gamma rod, and increase the dielectric thickness ONLY by increasing the outer rod to accommodate dielectric thickness changes. At the same time, the inner rod should be increased to avoid any requirement of making the gamma capacitor longer. Avoid sharp points or edges on the rods, just as you would avoid sharp points in any HV system....especially inside the "capacitor".

The above example of decreased power rating is especially important to Amateurs using coaxial cables as capacitors. Voltage is NOT constant along the length of a long coaxial capacitor. Maximum voltage in the component is always ***HIGHER*** than the actual voltage across the terminals of the "capacitor", and it is higher than the voltage calculated by the current through the capacitor! Coaxial capacitors or linear stubs used as reactive elements always have significantly lower operating Q, higher power loss, and operate under more electrical stress than a well-designed lumped component. Stubs and linear loading does have the advantage of spreading heat out. You won't notice the heat as much, even though there is a lot more heat energy! Just don't let the smaller temperature rise fool you into thinking the system has less power loss.

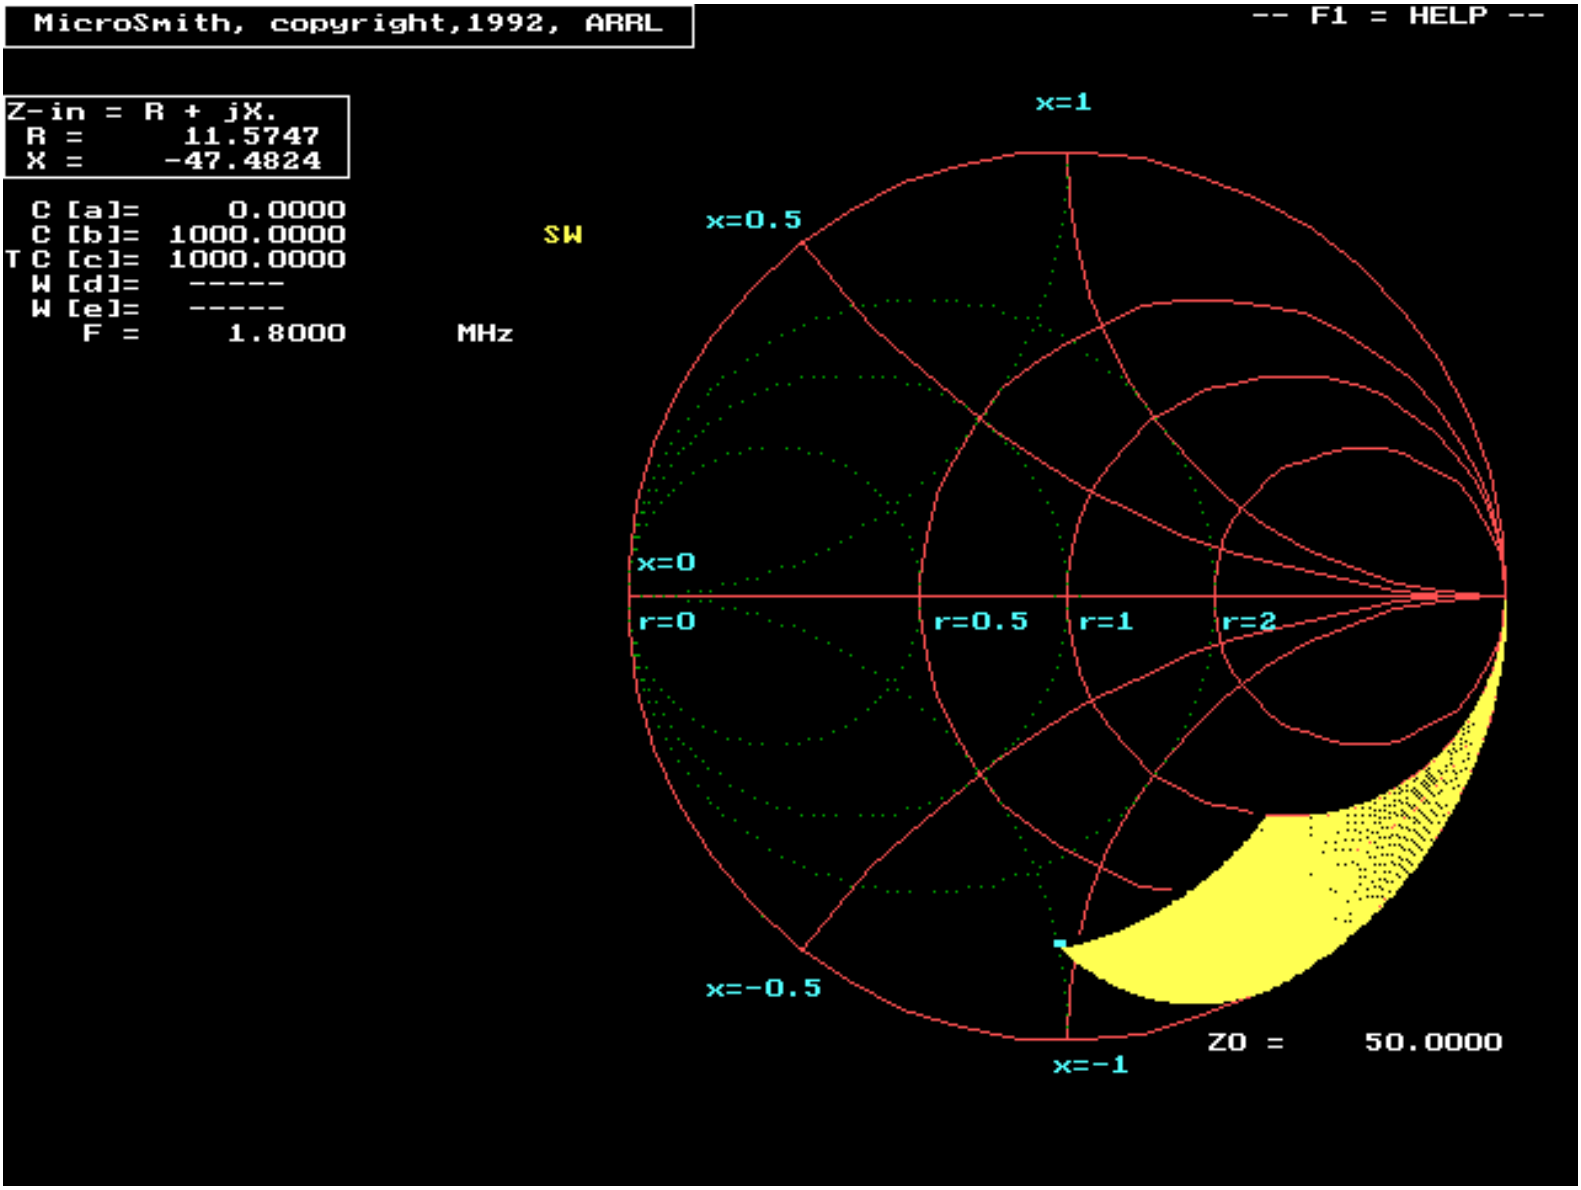
Omega Match

The Omega Match is really just a form of the simple L-network.

Traditional Cs/Cp Omega Match



In this system, C2 parallels the shunt terminal and primarily sets the resistance transformation C1 is in series with the feedline, and primarily cancels reactance. If we look at this network on a Smith Chart, we see the resistance range is somewhat expanded over a conventional Gamma Match.



We also can see it is not the panacea often claimed. Look at the "r" circles on the above chart. "r=1" is normalized to 50 ohms. With that in mind "r=2" is 100 ohms, while "r=0.5" becomes 25 ohms. The Omega's resistive matching range, using 1000pF vacuum capacitors, would only from 50 ohms ***downwards***. Voltage ratings are still a problem when the system requires capacitor C1 to have a small capacitance value (high reactance), and now we have two capacitors that have to handle essentially the same high voltages when C1's operating capacitance value is small!

This arrangement once again requires antenna shunt wire impedance to be ***lower than feedline impedance***. The network, since it only uses capacitors, ***must be used with inductive loads*** or the feedline terminal will be reactive.

One useful application of this circuit is in matching very short non-resonant vertical element, sometimes called a "Hairpin Monopole". Well-designed capacitors, such as vacuum capacitors, have such high Q they are essentially lossless. With vacuum capacitors and very good connections, losses in the matching system are very low even with very high currents. We shouldn't be misled into thinking we have a "free-lunch" magical short antenna! We "pay for our meal" in greatly increased conductor losses in the antenna conductor. The conductors not only carry common-mode radiation currents, they also must carry significant circulating currents involved with the feed-system. These high currents causes distributed conductor losses to be much higher than conventional

loading systems using a reasonable-Q lumped inductor. Bandwidth and radiation resistance for a given element size is often significantly less than conventional series-feed when using a hairpin monopole with Omega loading and matching, although the system has the advantage of being easily tuned to new frequencies. The Omega/hairpin vertical also allows the feedpoint resistance to be adjusted to nearly any value we might require.

C1 is primarily for power factor (reactance) canceling. It is rated exactly as in the gamma, voltage and current being determined by the required amount of operating reactance and the line current.

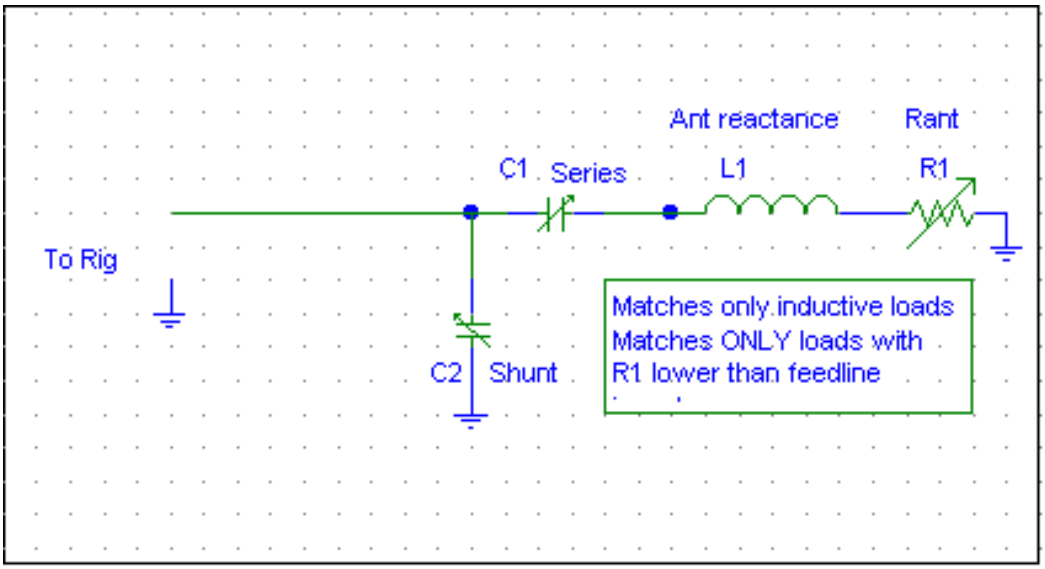
C2 primarily sets resistance transformation. The component's electrical requirements are found only by knowing the load impedance and the reactive voltage and current in that branch of the system. It handles a portion of the input current, as well as a portion of the shunt current, so the current in C2 is always higher than the current from the source flowing through C1. The required voltage rating of C2 is also always higher than C1.

Assuming we have 10-1000pF variables, the normal matching range covers inductive reactance ranging from 80 to 4000 ohms with a resistance between 1 and 50 ohms. Lower reactances are only able to be tuned when the resistance is near 50 ohms. As you can see, resistive matching range is wide but limited to values below 50 ohms.

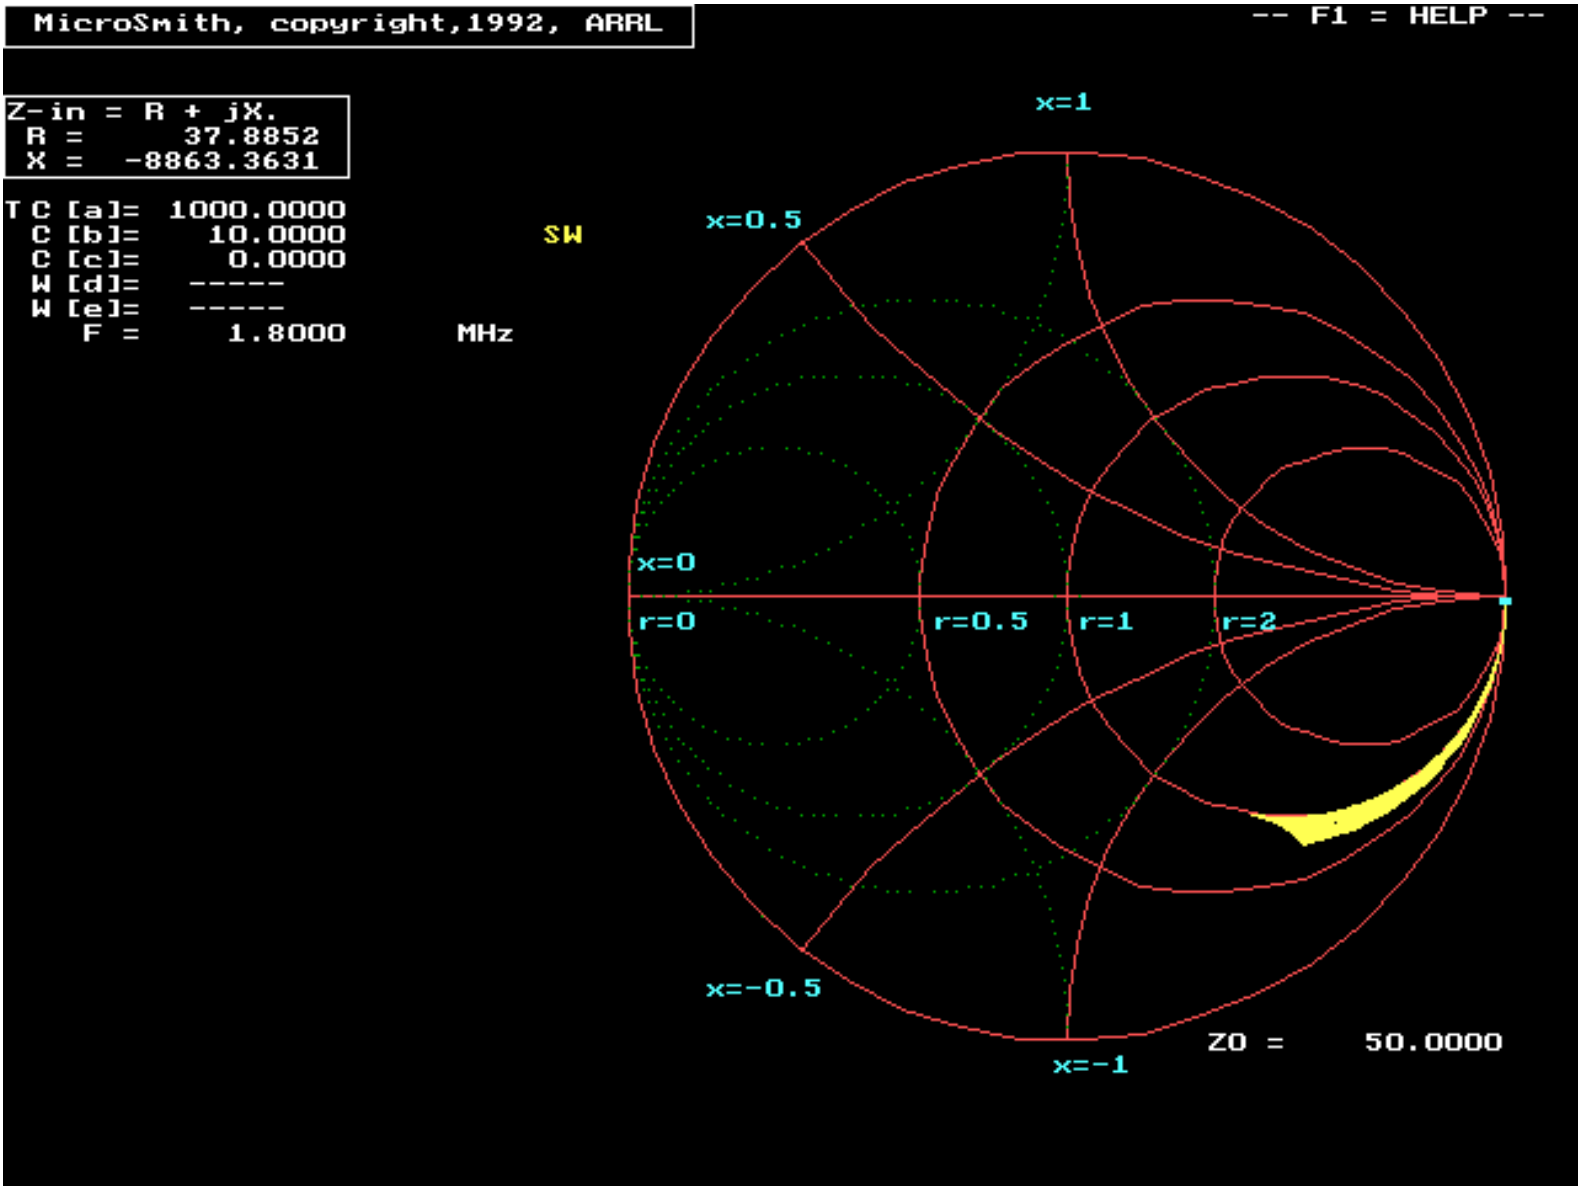
Cp/Cs Omega Match

The parallel-C input, series-C output is also a form of the L-network. The output, once again, must be the lower impedance while the feedline must have the higher impedance. Once again, this system only matches inductive loads.

It is not a very useful circuit, except in specific applications. The only advantage of this arrangement is C2 operates at significantly less voltage. The voltage across C2 is always no greater than the transmission line voltage, larger receiving-type air variables will operate at 1500-watt and higher power levels. Because C2 is under significantly less electrical stress, It is the better choice if you are very close to having a match and only need adjust resistance upwards slightly for perfect match.



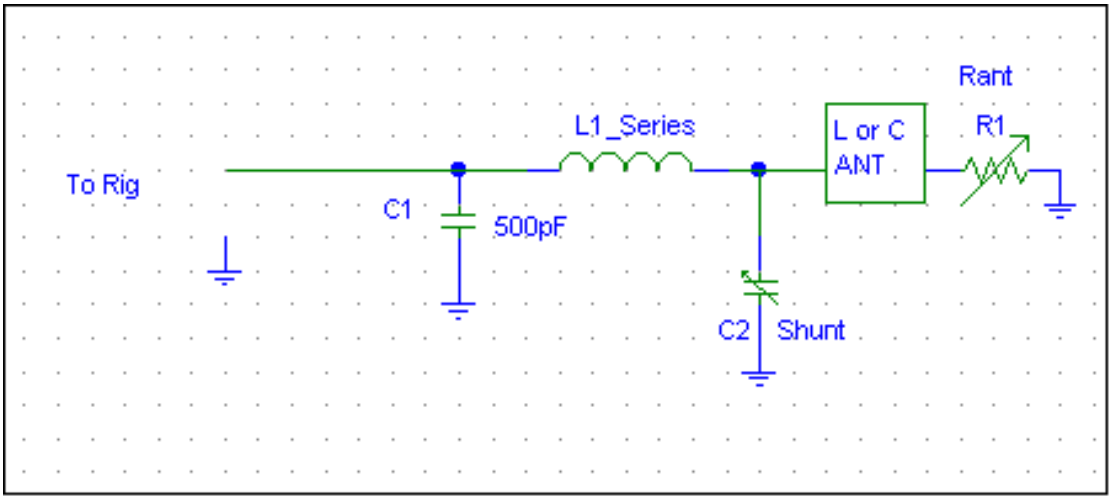
C1 primarily sets reactance, while C2 primarily sets resistance.



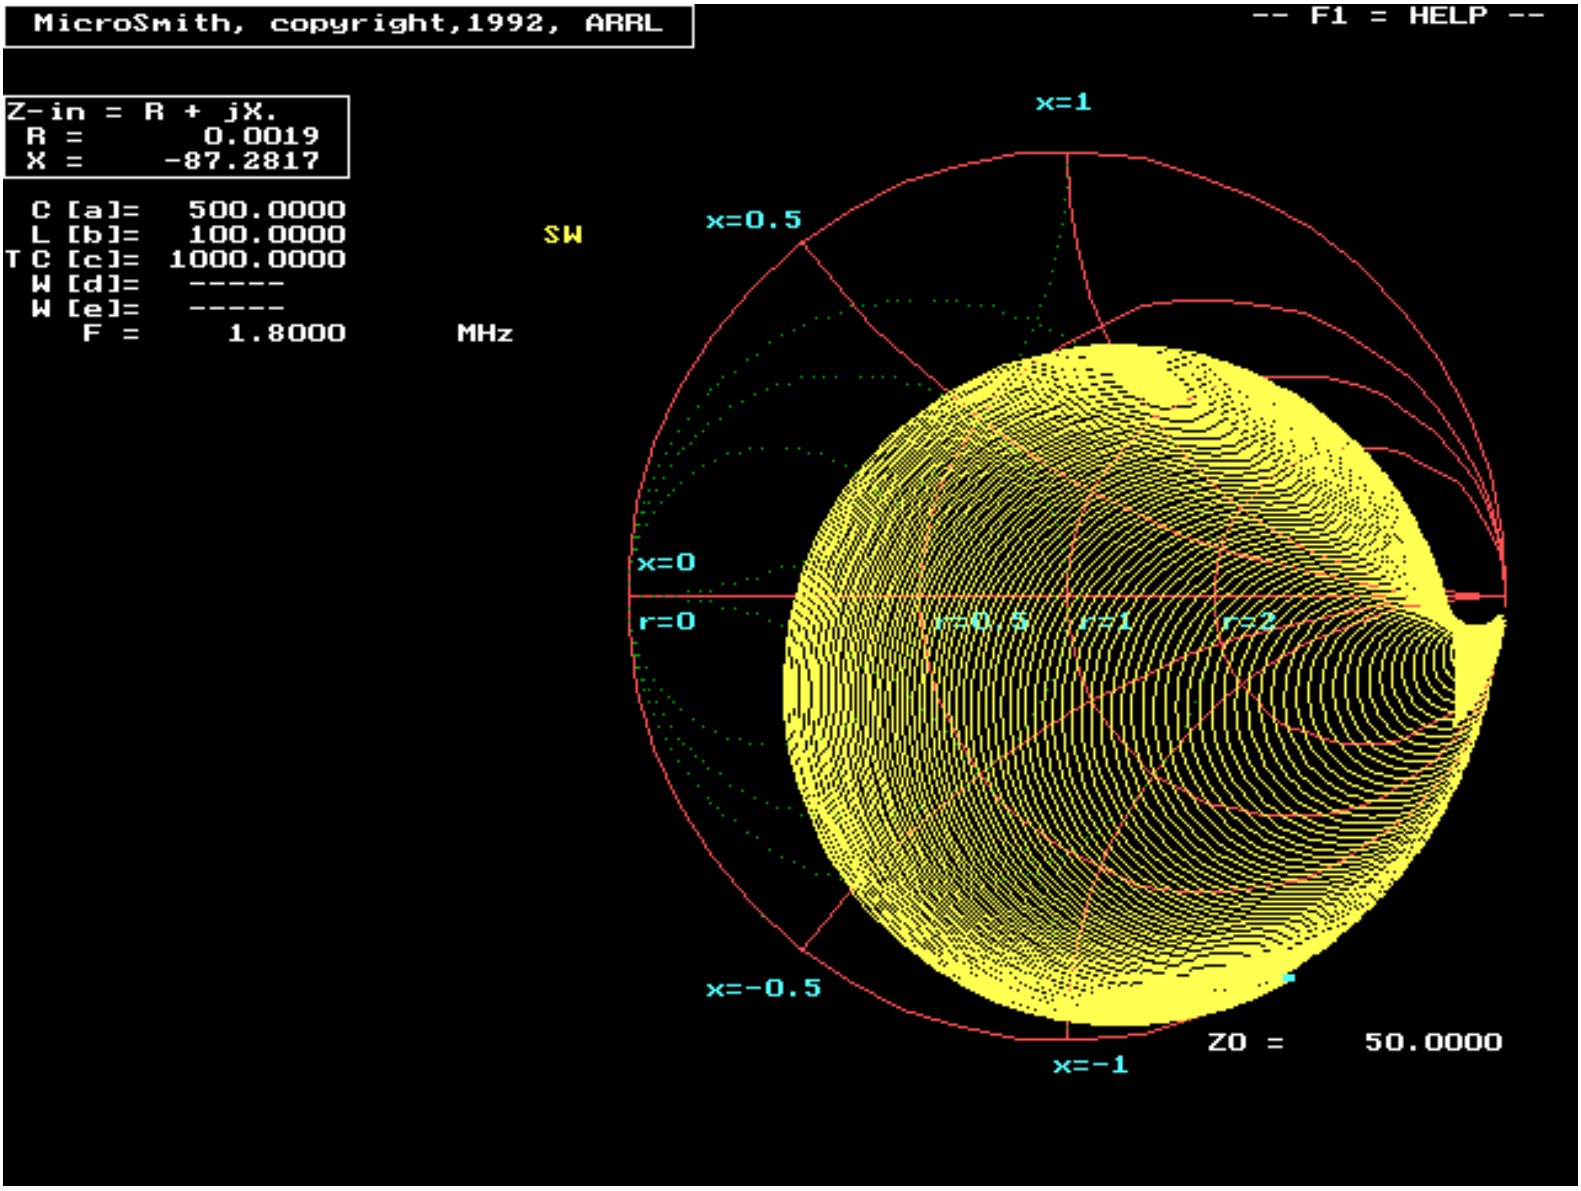
Assuming we have 10-1000pF variables, the normal matching range is reactances up 8000 ohms inductive and resistances between 38 and 50 ohms. As you can see, resistive matching range is very limited. C2 would need to be a very large capacitor (very low reactance) to have a wider resistance range.

Pi Matching

In cases where we can not find a 50-ohm tap point, we can add an inductor. In this case C1 can be a fixed or variable capacitor capable of handling modest voltage and current, such as a snubber-mica or receiving-type air variable.



L1 has to be fairly large to match high resistance and reactance ratios, at least 100uH on 160 meters for the extremes shown in the Smith Chart below. Assuming a 10-1000pF capacitor for C2, a 500pF capacitor for C1, and a 100uH adjustable inductor for L1 we would have the following matching range:



Matching range is greatly extended, and even covers capacitive loads.

Power Ratings

Heating is a long term problem that accumulates with time. Failure occurs when the heat causes a component to physically change from excessive heat. Heating is related to power dissipated by a simple formula $P := I^2 \cdot R$ The resistance is normally determined by knowing the component's Q (not the operating Q) and the current through the component.

The series resistance that dissipates energy as heat is found by dividing reactance by component Q. With 88 ohms and a Q of 5000 (typical of a good large air capacitor) Equivalent Series Resistance is 88/5000 or .0176 ohms. Heat is given by .0176 squared times 3.11 amperes. Heat is .0176*3.11*3.11 or .170 watts, not bad for an air variable capacitor. (Multi-layer chip capacitors can have Q's in the tens or hundreds of thousands, as can vacuum capacitors. Simple ceramic disc and small mica capacitors generally have Q's in the upper hundreds to many thousands.)

Current through C2 is found by dividing 274 volts by R-ant. If R-ant were 15 ohms the current would be 274/15 or 18.27 amperes. Voltage would be C2's reactance of 88 ohms times 18.26 amperes times the safety and peak factor of 4. Peak voltage would be 6500 volts for an 88-ohm reactance capacitor. This is a good example of why "T" antenna tuners arc with low load impedances while working fine at higher impedances, and handle more power when tuned to use maximum possible capacitance.

Arcing is an instantaneous voltage problem. In general a solid dielectric (insulation) punches through and fails almost instantly. Voltage rating is reduced with every arc, even brief unnoticeable arcs. As a general rule solid dielectrics suffer non-recoverable damage from any arc, even a very brief arc (such as a momentary low-current static discharge.

If the dielectric is a vacuum, liquid, or gas, and if the component's conductors or dielectric do not physically distort or change from heating, the insulation can "heal" and full performance is often restored. With an air capacitor, ionized air must circulate out of the capacitor.

If an arc causes a physical change, such as a hole, carbon path, sharpened or raised edge, breakdown voltage is almost always permanently reduced. One exception would be when an arc removes debris or sharp points, such as melting copper whiskers in a vacuum capacitor (copper can actually grow tiny whiskers in a high vacuum). Sharp points, even microscopic sharp points, greatly reduce breakdown voltage. If a sharp point is reduced and rounded by an arc, voltage breakdown will increase. If we actually melt the plate, voltage rating is reduced. Surfaces must be micro-polished, we cannot sand a capacitor plate to restore full breakdown levels if a capacitor is arc-damaged (variable capacitor plates are commonly polished by tumbling them in a very soft abrasive like walnut shells).

Capacitors in parallel with a known resistance. RMS sinewave voltage across the component is given by $E := \sqrt{P \cdot R}$ where P= maximum possible level of PEP applied. R=resistance the capacitor parallels.

Capacitors arc and fail from instantaneous voltage peaks, not from average or RMS voltage. We multiply the

RMS voltage across C1 times 1.414 and add an important safety factor. Multiplying RMS voltage by four normally works for outdoor mounted air-capacitors, as long as they are kept debris and moisture free.

A 50-ohm feedline with 1500 watts of absolute peak power (1500 watts CW or FM carrier or 1500 watts PEP SSB or AM) applied results in 274 volts RMS times 4 or about 1.1kV. Use a 1.1kV or higher voltage variable. This would be about .030" air gap in a typical construction air capacitor with normal manufacturing irregularities (generally very safe to assume .01" spacing for every 300 volts). With 50-ohm matched lines and a 1500-watt PEP (or CW carrier) transmitter, smaller transmitting or larger receiving air variables will work.

Heating

Current through resistance causes heating. The resulting heat over some period of time can cause physical changes that physically alter the component. In the short term, this can change the electrical parameters such as capacitance or voltage breakdown.

To find electrical energy converted to heat, we have to know the equivalent dissipative parallel resistance and voltage across the component or the equivalent series resistance (ESR) and current through the component. I generally work with current and ESR.

The current is a function of reactance and voltage across the capacitor, just like current through a resistance is found from voltage across the value of resistance. Assuming we have 1500 watts and 50 ohms resistive load directly across the capacitor, we have 274 RMS volts across the reactance of C1. This voltage, over the reactance in ohms, gives us the RMS (heating) current flowing through the capacitor.

Use the formula I = E/X. With a 1000pF capacitor (88 ohms on 160m) we have 274/88 or about 3.11 amperes.

Note: This is not exact because capacitors have complex series-impedances, but it is close enough for our questions as long as we have reasonably good capacitors. One common exception where this simplification will not work is with long coaxial stubs. Long coaxial stubs have a considerable amount of distributed series inductance. This causes a voltage increase as we move away from the feedpoint in an open stub, or a current increase as we move out on a shorted stub. This increase in voltage or current increases loss, decreases bandwidth, and increases effective loss resistance. Not only that, a stub (or linear loading) has higher distributed resistance because it has long conductors, rather than thick compact conductor area like a conventional component.

Loss and Component Failure

We often gauge system "loss" by the temperature of the component. We often assume a "cool" feeling component has low loss and a hot feeling component has very high loss. Using "touch or feel" temperature without considering size and ability to transfer heat is a good way to estimate component life, but it is not a good way to estimate system efficiency or component losses. Unless we carefully consider the complex issue of physical size and ability to transfer or dissipate heat to surrounding objects or air, we will have no idea how much power is actually lost in the component. Small components not only get hotter, they get hotter much faster than large components!

A physically long coaxial capacitor has a large surface area to dissipate heat. Even a very lossy coaxial capacitor

will have significantly less temperature rise than a small very low loss compact disk capacitor, because the capacitor concentrates all the heat into one very tiny area. We might form the impression we have an inefficient system because the small capacitor drifts in capacitance value or fails from heat, yet it is usually the cool-running stub that has much higher power loss!

This doesn't mean we shouldn't use a coaxial stub as a reactance if they are reliable, but it does mean we have to be careful assuming it is the best solution for loss.

Bandwidth

Bandwidth tells us nothing about efficiency, unless we understand the entire system in detail.

In general the largest bandwidth occurs with the fewest reactive components. Any unnecessary reactance will increase system operating Q. One exception is when multiple networks with low loaded (operating) Q are used to obtain a large phase shift, rather than a few components that would require high operating (loaded) Q.

Stubs act like a combination of many small series-inductances with multiple shunt-capacitors. Coaxial capacitors not only generally have more loss than reasonably-constructed lumped capacitors, they also have less bandwidth. A stub's reactance changes faster with frequency than reactance in a compact lumped component, because it contains "unnecessary" distributed reactances. The stub also has higher internal voltages and currents, because of the distributed reactances. A coaxial stub may be cheap and "feel cold" in operation, but we shouldn't delude ourselves into thinking it is less lossy than a small capacitor. Remember it isn't only power dissipated that determines temperature rise, we must consider the total area heat is distributed over. 1 watt of heat feels very hot in a component the size of a pencil eraser, while 100 watts of heat could be undetectable by touch in a long thick piece of coaxial cable!

Transmitting

[Home] [Up] [TX_four_square]

160 Meter Transmitting Antennas at W8JI

200-Foot 12-inch face Tower

160-meter vertically polarized transmitting antennas center around this 200-foot tower.

When I moved here in December 1998, this tower was hastily erected as a quick way to get on the air. A single 0.5" diameter 50-ohm feedline and 8-pair control line run to the tower. A large outdoor storage box at tower base holds 160-meter phasing and matching systems.

OMNI Pattern

This 200-foot tower is the main omni-directional antenna. It is series-fed against a ground system of about one-hundred 200-ft radials. The radials are shallow buried 16-gauge bare solid copper wire known as "buss wire". A small low-pass L-network using a vacuum capacitor and variable inductor matches the tower. A 50-foot transmission line coiled around an insulated form between the L-network and RCS-8V antenna relay detunes this tower when the four-square is used. The four-square is detuned when the omni-tower is used.

318-foot 18-inch face Tower

High and Low Dipoles are supported by this 318-foot tower.

Most of my dipoles are supported by this "dipole support tower". This tower is 318-foot tall and sits on a base insulator.

This tower started as an elevated radial test tower and grew from there. Because of the early elevated radial experiments, the 318-foot tower has the remains of 60 1/4-wl buried radials below it.

At the top: Our two-meter repeater antenna

Three nylon U-V resistant 7/16-inch ropes over pulleys for pulling up antennas.

Guy lines are EHS steel, with sectionalizing insulators. There are three anchor distances. Look at guyline slope.

At the 170-foot level, two more ropes over pulleys. Just below that, the middle marker lights.

Want to climb up?

View from 318-foot tower

We are only at around 250 feet here, and looking towards the east. The far right horizon has a water vapor cloud from a power plant near Juliette, Georgia about 15 miles away. Nearby is the Whistle Stop Cafe, from the movie Fried Green Tomatoes.

Ground height is about 800 feet above sea level, but the important thing for VHF and UHF is the ground slowly rolls away in three directions. The effective height above average terrain for your view for the next 20 miles is around 300-feet, even though you are only 250ft above ground.

The rope in this picture comes from the end of one of my 318-ft high apex Inverted Vee Dipoles for 160 meters, and goes out over those tiny 80 to 100-foot tall trees about 700 feet away.

My 28 Beverages and 12 vertical receiving antennas are out in the pastures, spread over a 1500 by 3000-foot area. They are controlled by BCD data over underground control cables. Eight coaxial trunk lines feed the receiving antennas by running to switching hubs, where smaller antenna feedlines leave.

For stereo recordings of 160-meter signals, click here.

Higher Bands

I'm embarrassed. Most of my work is on 160 meters, so I neglect the other bands. I'll work on 80-10 meters someday soon, I hope! At the moment, I only have a single rotating 160-foot tower that supports Yagis for 40 meters up through 6 meters. The hardware comes from K0XG, and has been trouble-free. It has sixty 140- foot long buried radials for lightning protection and to help with low NVIR antennas like dipoles. There are more antennas and feedlines on that tower now.

TX_four_square

[Home] [Up]

Four-Square

The 200-ft tower has five catenary lines, each about 500 feet long. Four of these lines, running NE, SE, SW, and NW support four 1/4-wavelength wire verticals used in a 160-meter four-square antenna.

Each four-square element is made from a "bow-tie" of #16 wire, which fans out 12 feet at the top. The elements are fed with 50-ohm RG-8 type coaxial cable. Each element has about fifty 1/4-wavelength radials. These radials are bonded to the large radial system of the 200-foot tower at points where more than two wires cross. This makes the entire grounding system for the 200-foot and four-square elements more similar to a large screen rather than just than individual radials.

Four-Square Design

One item overlooked throughout the history of the four-square is the effective element spacing. Effective element spacing is not the same as the distance along each side of the square. The effective spacing is less than that distance, because the array fires from corner to corner. The effective array length is 1.414 times the spacing along each side, not twice that length. With 90 degree per side array size, we really only have a 127 degree long end-fire array when firing across diagonal corners. The correct phasing for an optimum null at zero degrees elevation directly in line with the array is not 90 and 180 degrees, but is actually around 117 and 234 degrees! With the traditional 90 and 180 degree phasing, the array should be stretched to a corner-to-corner distance of 180 degrees, making each side 127 degrees long. Unfortunately feedlines of 1/4-wl electrical length won't reach that distance with velocity factor and connection lengths involved, so the obvious choice is to use greater than 90-degree phase shift. As an additional benefit, the directivity and gain are higher with closer spacing and larger phase shift. Performance is better for both receiving and transmitting.

The phase and spacing used are obviously not optimum, and the popular coupling units almost certainly do not do what we expect. They sacrifice gain because any four-square 1/4 wl on a side really does not "want" 90- and 180-degree phase shift, and they really are not designed for the real impedance presented by the feedlines from the elements. Why do we use such a design? Probably because it was originally used, and no one ever looked at the array in any detail. It was easy to copy the original concepts, and no one thought to check and see if the phasing systems were optimized.

Array Transmission Lines

(the following assumes lines have negligible loss)

I use 1/4-wavelength 50-ohm lines feeding each four-square element. 1/4-wavelength lines have a unique property. When ***odd-quarter-wave*** lines are sourced from ***equal voltages***, the load ends of the line ***will source equal currents into any load impedance.***

There is a second important often overlooked property. When a line is misterminated and has standing waves, total phase shift along the line does not equal the electrical length of the line. An exception occurs when the line is any multiple of 90-degrees.

Just as impedances invert every 1/4 wl, the fixed source voltage at one end becomes a fixed source current at the other end. Not only that, phase shift is constant even though the lines are terminated by different load impedances. Many arrays use this concept to advantage, and a current sourced 1/2 wl line would work just as well as the 1/4 wl lines if we fed the line with equal currents instead of equal voltages. (As a matter of fact that concept is behind a two-band transmitting array I designed.)

Current Distribution

A two-element directional system requires *equal current* at the current maximum of each directional element for maximum F/B ratio and gain. A three-element array would require a binomial 1:2:1 ratio for best pattern. The center element, in effect, has to supply a field for each of the two outer elements to work against, it is doing double duty. The four-square is a novel approach to a three-element array, the center two elements are fed in phase, and act as one common element. If all four elements have equal current, total center element current is twice the current in each end. The 1:2:1 current distribution is satisfied.

With elements series-fed at the point of current maximums, each element requires equal current at the feedpoint. (If the elements were voltage-fed at the voltage maximum, they would require equal voltages at the feedpoint to have equal currents in the elements!) This makes transmission-line type phasing systems easy to design. We simply design the system so each phasing-line has unity standing wave ratio, and tie the elements directly to the phasing lines. Because voltages are equal everywhere in the phasing system, element currents are equal at the end of each 1/4-wavelength feedline.

Phasing Systems

My design operates the phasing line without standing waves. Since the phasing line is not a multiple of 1/4-wl, if the delay line were misterminated phase shift would not equal the line electrical length.

Voltage at each end of the delay line would also be different. Since the line is matched, phase shift will be equal to the electrical length of the line and voltages will be equal at each end of the delay line.

There really isn't any need for "dump" resistances or hybrids in any phasing system. If you look at the systems, the dump resistances really don't guarantee performance. A four-square system never requires controlled "power splitting". As a matter of fact, equal power in each element would guarantee poor F/B ratio and gain.

Keep in mind that each element, other than the two in parallel, has a different feed impedance. With different load impedance at each element current can't be equal in each feedline element group if power is divided evenly. The four-square system, at least one with 1/4 wl feedlines, actually requires equal voltages. Equal power insures a poor pattern, while equal current at the element (or equal voltage at the start of the 1/4 wl feedlines) guarantees optimum patterns. Most four-squares work as well as they do only because the array is somewhat forgiving. They are a good example of reasonable performance through oversight, rather than careful planning.

I solved these problems in my system by placing the phasing common-point in the direction of maximum radiation and using crossfire phasing. This is very similar to the feed-system of a log periodic, except I optimized phase shift and current distribution.

A crossfire delay line system feeds the center two elements in my array. This is similar to the scheme I use in my phased receiving antennas. Each center element has around 25 ohms of operating impedance, and that produces 100 ohms at the end of the 1/4-wavelength 50-ohm feedline that goes to each element. The center two elements, when paralleled, have a combined impedance of 50 ohms.

The delay line from the common point to the center two element junction is 60-degrees of RG-8 coax. The 180-degree "flip" comes by using a choke balun. This is similar to the technique I use in receiving antennas. The primary difference is in core size and materials, my high-power inverting transformer uses eight 2-inch diameter 65-material cores and Teflon insulated coaxial cable. This choke allows the shield and center to be transposed at one end of that delay line. Loss is low in the delay system, because it is a matched 50-ohm line. It is also only 60-degrees long and only handles only about 2/3 of total system power (almost 1/3 of the system power is applied directly to the front element).

The rear element offers a slight problem, because that element has a very low impedance. It almost has enough current, through mutual coupling alone, to be fully functional. As a consequence, it requires very little common point power. With a 1/4-wavelength feedline and parallel reactance canceling, the rear element presents several hundred ohms of resistance to the phasing network. My solution for feeding the rear element was to build an artificial transmission line using lumped components. For the rear delay line, I used multiple L/C sections to simulate a transmission line

with a characteristic impedance matching the rear element. This has three advantages:

1.) Q is low, making phase-shift much less frequency critical.

2.) Voltage is equal at each end of the artificial transmission line, allowing the delay line to all parallel each other at the conmmon point.

3.) I can easily "tweak" delay line characteristics with a few adjustments and optimize the array null.

In effect, I created a high-impedance transmission line from individual L/C components, and only needed to use 120 degrees of lag (the 240 degree lead I needed is electrically the same as a 120 degree lag) in the network. This is all very similar to the system in my small receiving four-square. Because current is low, components can be modest sized. The end result is more bandwidth, more stability, and less loss than a simple one-stage network.

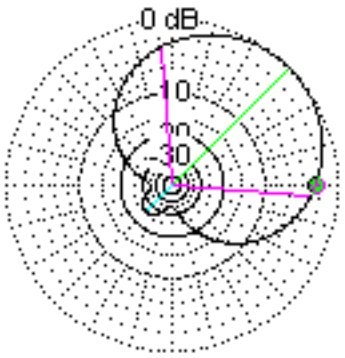
The Results

While this may sound like a complex system, it is very simple in practice. This array has exceptional bandwidth, exhibiting useful F/B ratio and gain over the entire 160-meter band. This also means a similar array for 80-meters would cover almost all of 80 and 75 meters. Additionally, this array has very low loss regardless of operating frequency. It does not divert power into a dump resistance.

My phasing design produces higher gain than conventional 90/180 degree phased four-squares through a tighter pattern and less loss.

Becuase the pattern is "tight", I added a simple system that provides a wide East, South, West, or North pattern. That pattern nearly equals the gain from a traditional four-square, and provides equal or better gain than traditional four-squares in all directions over a wider frequency range.

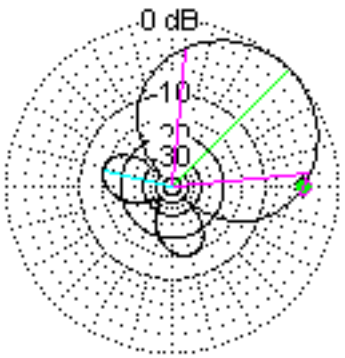
Here is the pattern of a traditional four-square at 15 degrees elevation, assuming perfect distribution and phase:



Azimuth Plot		Cursor Az	0.0 deg.
Elevation Angle	15.0 deg.	Gain	5.52 dBi
Outer Ring	8.0dBi		-2.48 dBmax
Slice Max Gain	8.0 dBi @ Az Angle = 45.0 deg.		
Front/Back	25.61		
Beamwidth	98.4 deg.; -3dB @ 355.8, 94.2 deg.		
Sidelobe Gain	-17.61 dBi @ Az Angle = 225.0 deg.		
Front/Sidelobe	25.61 dB		

Note the gain is 8dBi, and the 90-degree azimuth gain is -2.5dB maximum or a net gain of 5.5dBi in the "between" directions

Here is the pattern of the same array with 120/240 degree phasing:



Azimuth Plot		Cursor Az	0.0 deg.
Elevation Angle	15.0 deg.	Gain	5.13 dBi
Outer Ring	9.14dBi		-4.01 dBmax
Slice Max Gain	9.14 dBi @ Az Angle = 45.0 deg.		
Front/Back	37.28		
Beamwidth	78.8 deg.; -3dB @ 5.6, 84.4 deg.		
Sidelobe Gain	-5.48 dBi @ Az Angle = 166.0 deg.		
Front/Sidelobe	14.62 dB		

The gain is 9.14dBi, and the cursor azimuth gain is -4 dB maximum for an "in between" gain of

5.13dB. You only give up .4dB FS at the worse point for a net gain of 1.14dB in primary directions.

Gain increase through the phasing change is just over 1 dB through pattern changes, and is more than that through decreased loss (the model neglect phasing system and feed system losses. F/B ratio change is quite noticeable, as is the ability of the antenna to receive.

My actual working array is even more flexible, allowing the choice of eight directions plus omni.

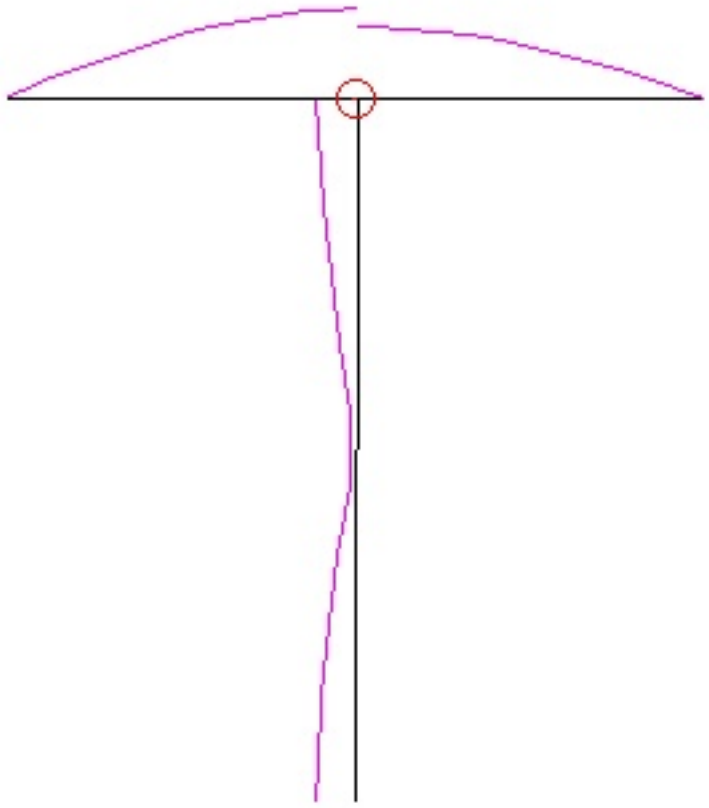
In concert with a large ground system (the array sits in an area that has ground systems extending for at least a wavelength in all directions) and reduced loss in the phasing system, overall performance has been enough to offset salt-water path and distance advantages of northeast stations using smaller systems. Better F/B while achieving higher gain and more bandwidth is a definite advantage, although any one of the three might have caused me to use this system (besides the satisfaction of making something work as well as possible).

Baluns on Log Periodic Antennas

[Home] [Up]

Some antenna manufacturers place baluns at the incorrect location in LPDA arrays. If we consider what the balun does we can see how the mistake occurs.

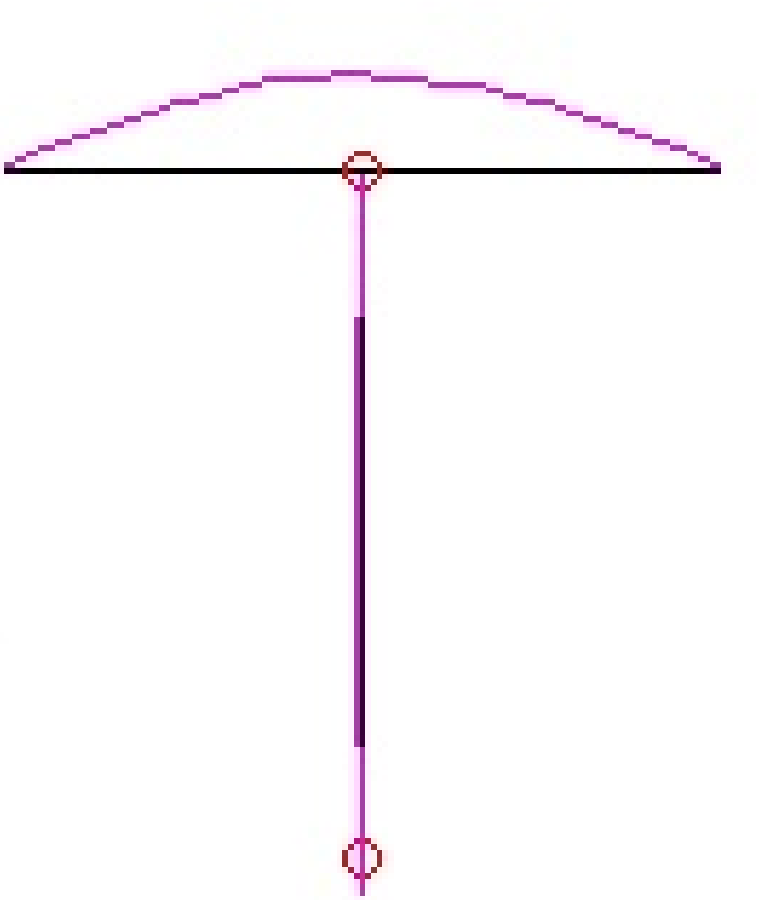
In the case of antennas, a balun isolates the shield of the cable from excitation by voltage differences between the feedline's termination and ground. In one case the termination might be a balanced dipole, with each terminal connection terminal having voltage to "earth". If the dipole is balanced and has 100 volts across the feed terminals, the feedpoint would have about 50 volts to an imaginary ground at the antenna.



The above current is for a 1/2 wave dipole 1/2 wl above ground, with coaxial feed. You can see the

feedline shield has significant current. In this case about 40% of the antenna's maximum current!

We can simulate a choke balun by adding a current source in series s with the shield, and setting current for zero amperes. The voltage across that current source will indicate the common mode voltage exciting the feedline.



Adding a perfect choke balun, current on the feedline shield goes to zero and the voltage across the choke balun is now found from the source menu:

Source 1 Voltage = 61.02 V. at -0.01 deg.
Current = 1 A. at 0.0 deg.
Impedance = 61.02 - J 0.009274 ohms
Power = 61.02 watts

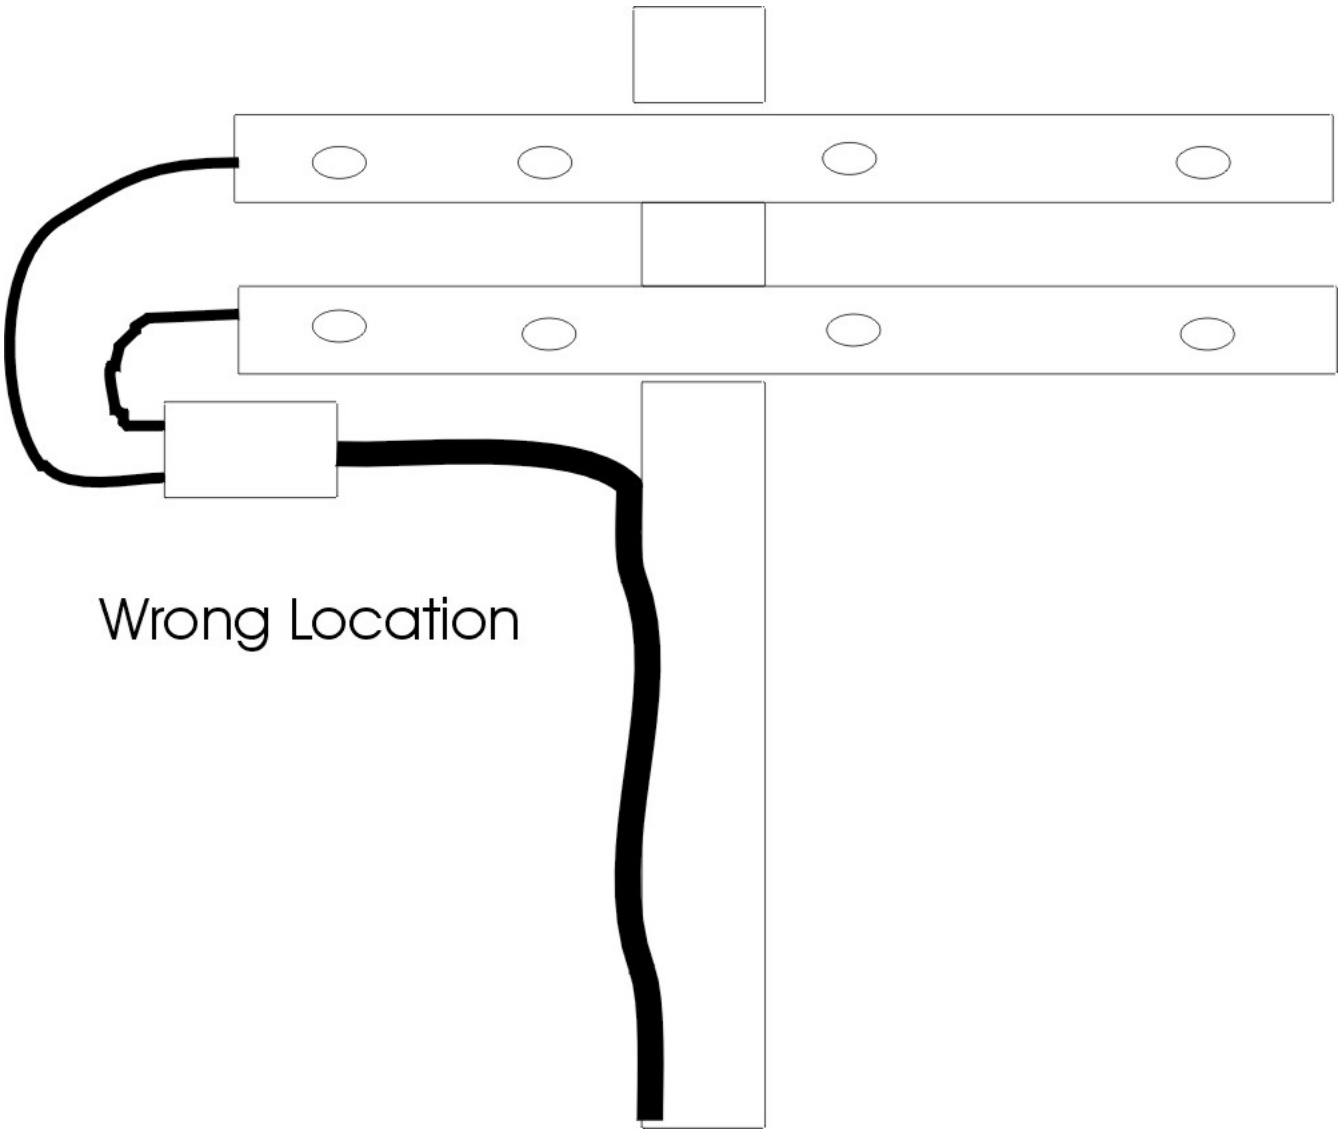
SWR (50 ohm system) = 1.220 (450 ohm system) = 7.375

Source 2 Voltage = 37.42 V. at 173.27 deg.
Current = 0 A. at 0.0 deg.
Impedance is infinite
Power = 0 watts
SWR (50 ohm system) > 100 (450 ohm system) > 100

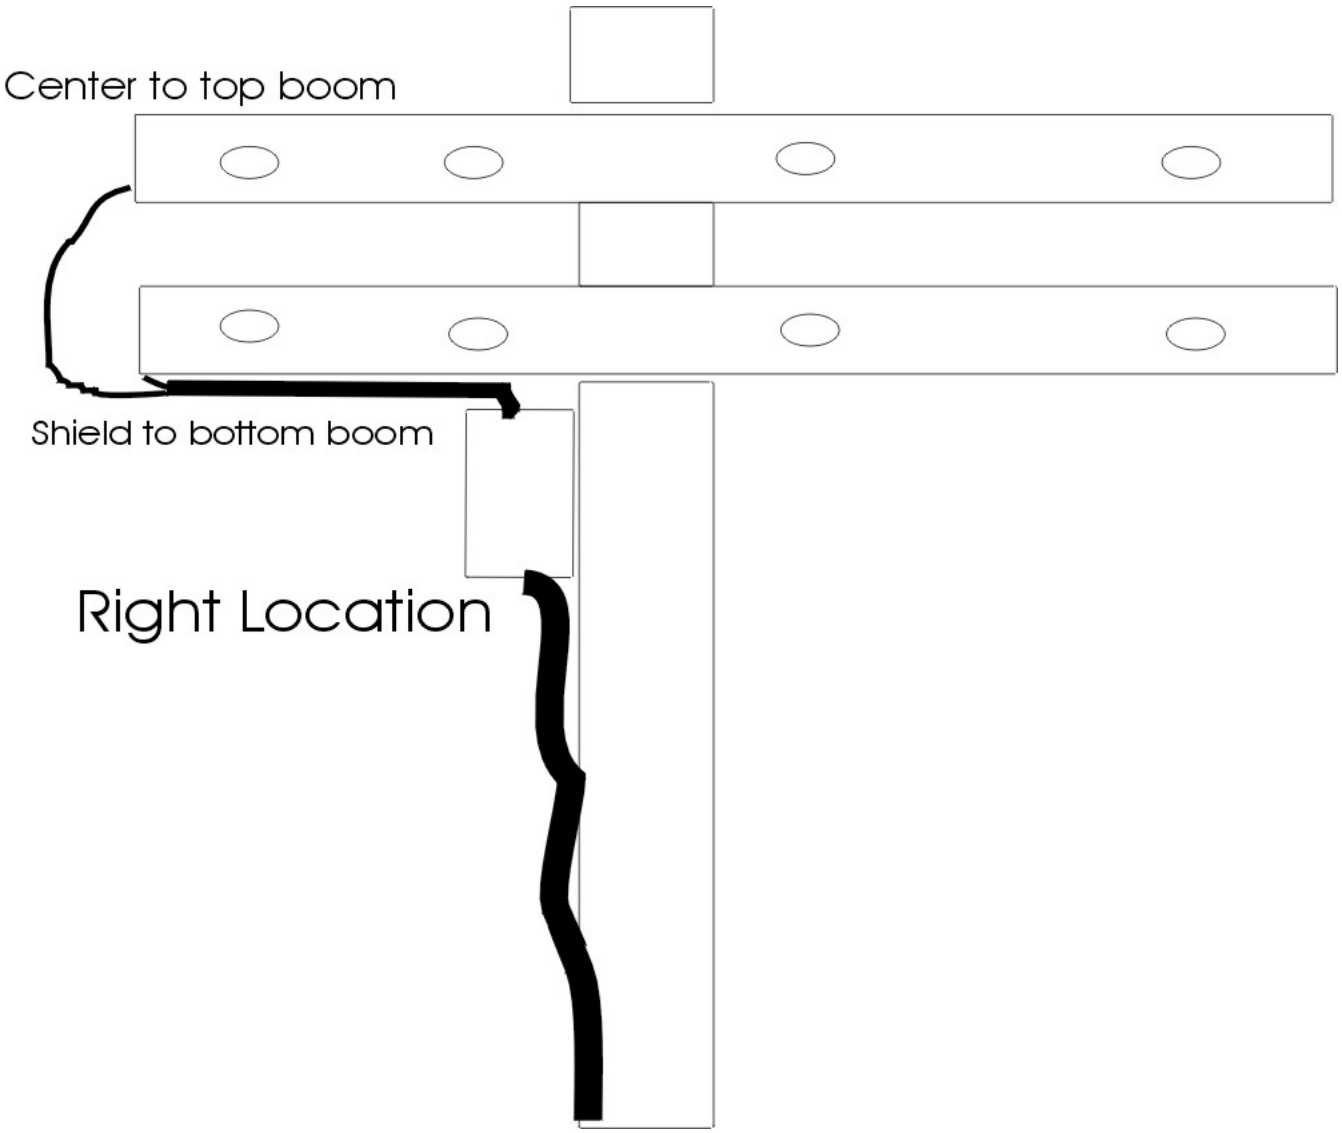
Source 1 is the actual terminal excitation of the dipole, while source 2 is the source that cancels common-mode feedline current. We can see the voltage across the perfect balun is indicated by source 2 as 37 volts, slightly more than 1/2 the feedpoint differential voltage. (We could also use a very high impedance load here, and do the same thing.)

What's Wrong with the LPDA Feed?

Some antenna manufacturers have you tape or otherwise attach the coaxial feedline along the length of a boom that is electrically hot, the boom feeding half the elements!! The very fact the boom feeds elements of the antenna requires the boom to have significant VOLTAGE along its length. Any cable parallel to the boom is excited by boom currents and voltages. Cables routed against the hot boom will have whatever the voltage is between the boom and the tower trying to excite current in the feedline shield.



If the log has a 1:1 balun at the feedpoint, you can simply tape the coax to the boom that the shield connects to without any balun at the log feedpoint. The best thing to do is to ground the coax shield to the hot boom at the exit point where the coax leaves the boom, and install a balun at that point! You can do this by installing a barrel feedthrough connector at the exit point and clamping the connector to the boom, then waterproofing the assembly. The balun goes between that connector and the feedline exiting the antenna boom and going to the station.



If the beam has an impedance matching balun at the feedpoint, or if you simply want to leave the balun at the feedpoint, you can leave the balun at the feedpoint. The feedline has to be suspended a few feet below the hot booms.

Snap on core material data

[Home] [Up]

Can anyone help me identify this core?

It is just over 1" long and about 1/2 inch diameter and snaps easily over RG58 or RG59 cables.

Please reply to W8JI at contesting dot com thanks!

Short dipoles and problems

[Home] [Up]

Recently I've been fielding problems from people using what has come to be called a "Cebik dipole". I also see people recommending this antenna to people with limited space for antennas. The problems I hear about generally center around tuner damage or failure of a tuner to match the antenna. An analysis of various installations has shown that the Cebik dipole is too short to be an effective antenna on the lowest band without some form of low-loss reactance compensation in, at, or near the antenna.

While pattern looks excellent on higher bands, lowest band performance of a short dipole (in this case 88 feet long on 80 meters or 44 feet long on 40) certainly leaves a great deal to be desired when feedline and tuner losses are included. It isn't the efficiency of the antenna that is in question, it is feedline efficiency and high voltages in the matching system that become problems.

The text below actually applies to any short dipole. If you don't like the dB or so loss of a G5RV system (including tuner and feedline losses), you ***really*** won't like an antenna shorter than a G5RV.

Loss in a Short Dipole

Power loss in short dipoles primarily comes from compensating reactances and matching to 50 ohms. This is because VAR (volt-amperes reactive) power is very high.

In a system with reactance, current and voltage are not in phase or in step. Because maximum current does not occur at the same time as maximum voltage, the simple product of current times voltage (I*E=P) can be much higher than the actual useful power. The higher reactive current causes increased current squared times resistance (I^2*R=P) heating and loss. The higher reactive voltage, in a similar fashion, causes increased dielectric losses.

In the worse case power loss caused by increased voltage and current in reactive systems can actually cause component failure.

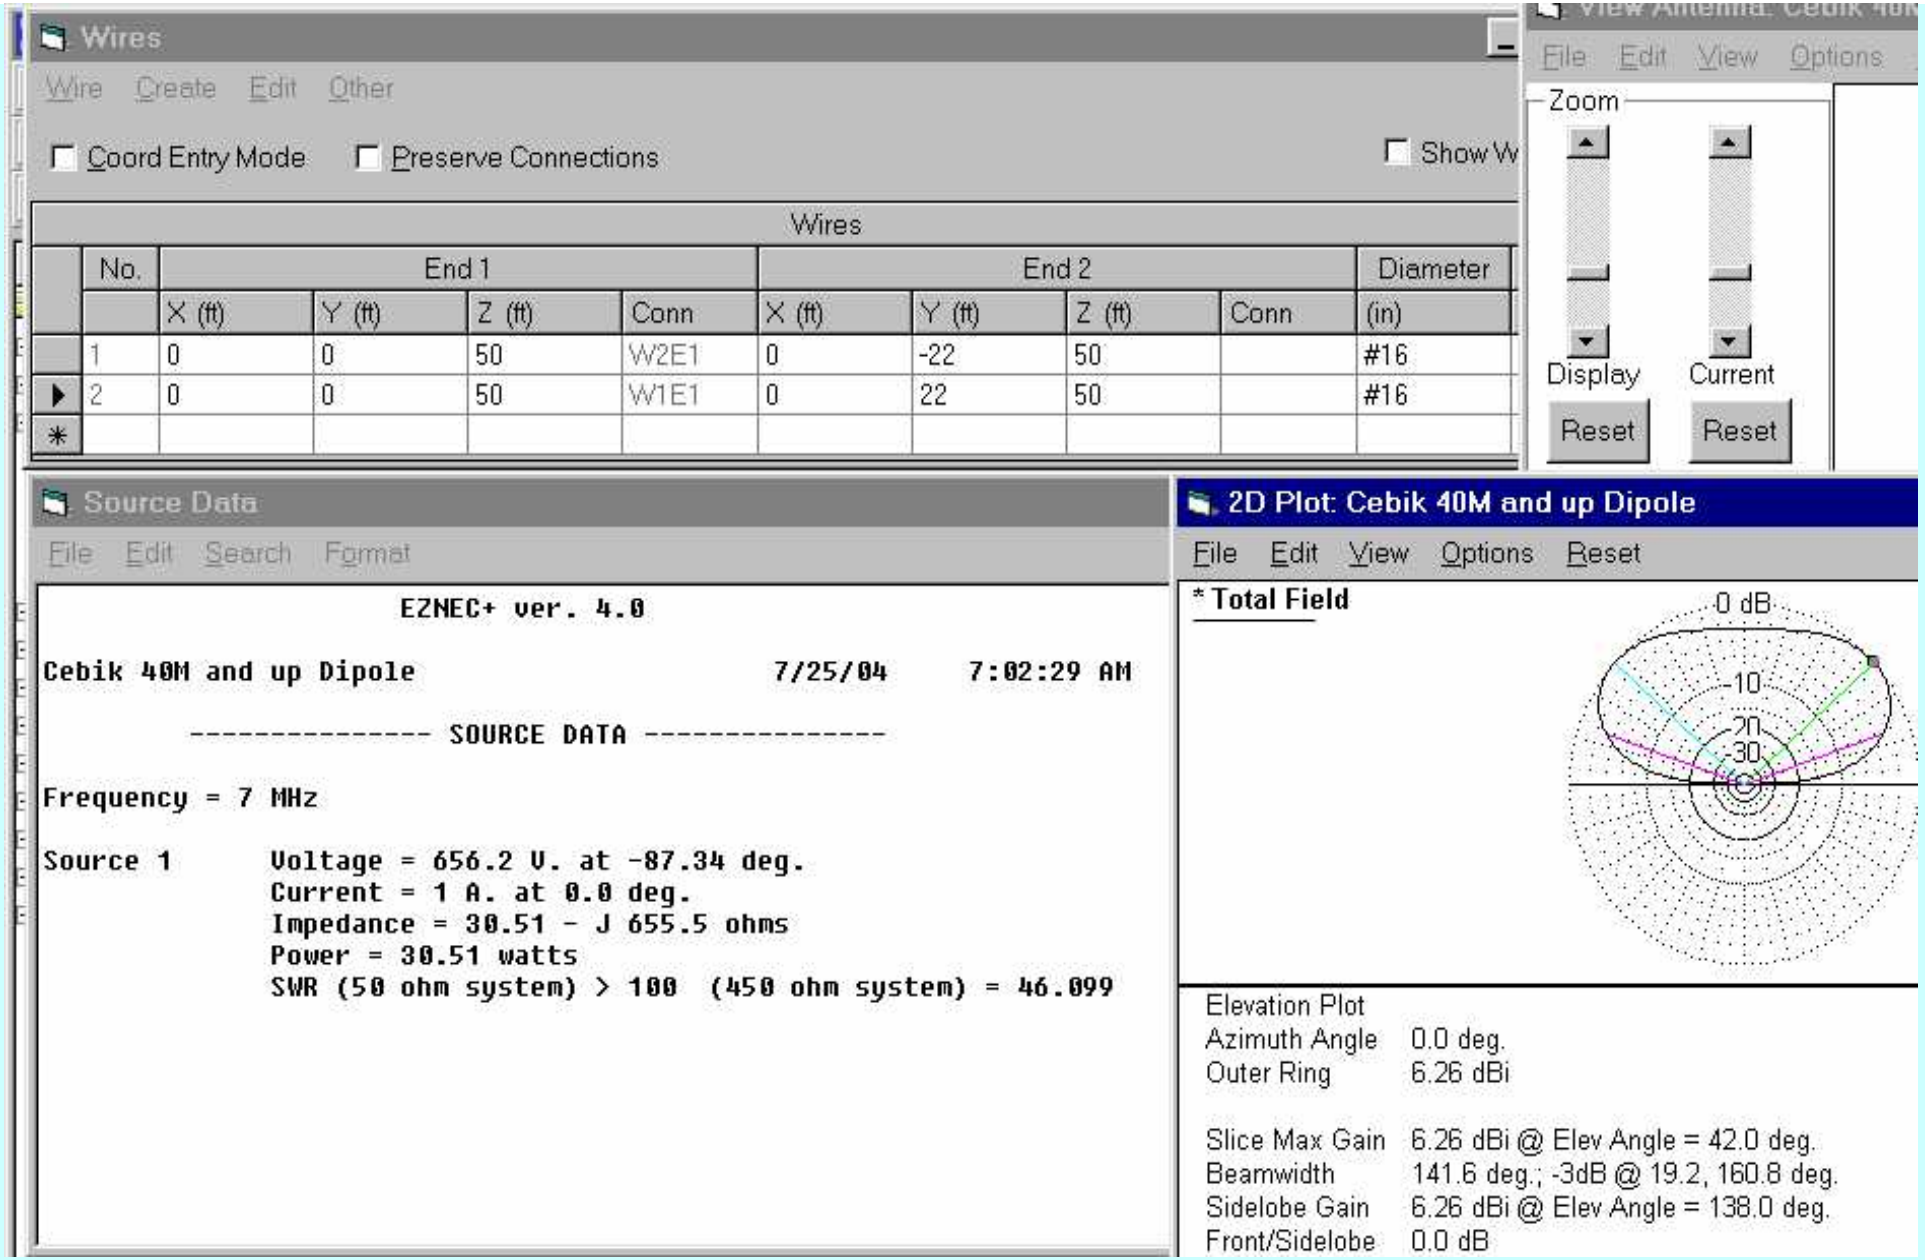
Short dipoles and verticals will almost always model with very good efficiency, because a model is a perfect lossless system if we do not include feedline losses and matching losses.

Let's look at an example by looking at the suggestion of shorting a dipole to approximately .33 wavelengths.

Dipole Impedance

Eznec shows a 44-foot dipole to have an input impedance of

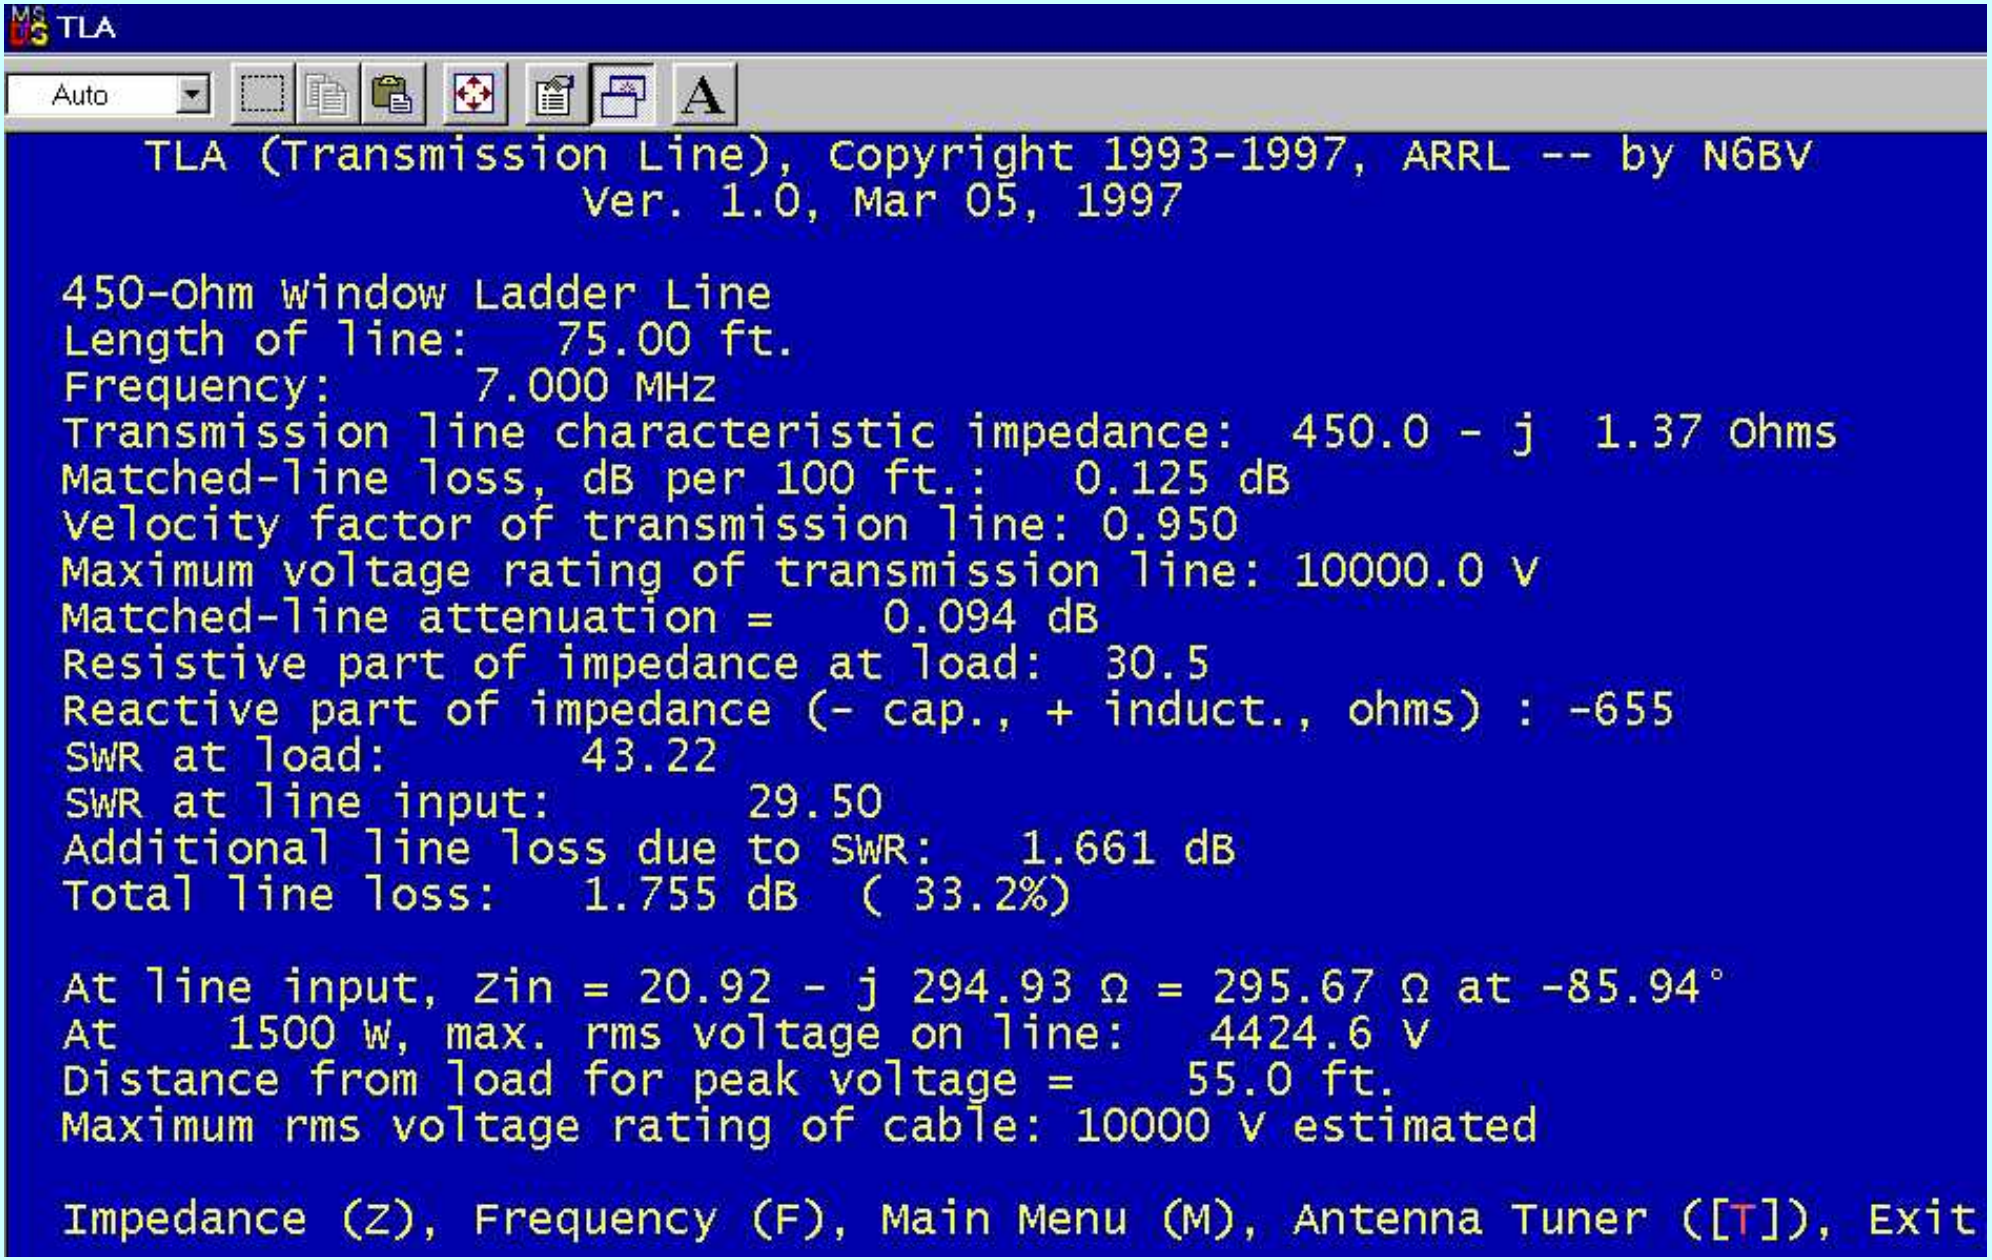
The model is shown here:



From this we see the impedance is 30 ohms resistive, not too bad. The problem is the reactance of -j655. This results in an SWR of over 47:1 on a typical "window ladder line", or 46:1 on a real open wire 450 ohm line.

I've verified the results of TLA (supplied with ARRL Antenna Handbooks) for dry new transmission lines, and it's pretty close. Unfortunately 450 ohm window line is a little worse than TLA predicts, and the impedance is generally lower. But we can consider TLA to be close.

Using TLA we find the following feedline losses for a 75 foot long feedline:



Note the following from the above:

- Line loss is now just under 2dB for a perfectly dry new feedline (it's actually just over 2dB if you use real losses, rather than TLA). This does not include tuner losses or less than perfect installation.

- The maximum RMS voltage on the transmission line is a staggering 4424 volts with 1500 watts. This is over 6250 volts peak voltage. (Even with 100 watts peak voltage would be 1600 volts!)
- Line input impedance is 21 -j295, this is what the tuner must match.

Suppose we add a typical "3KW" tuner to this system. Typical tuners have the following component values and Q's:

- Capacitors: 4.5kV, 250 pF, Q=5000 at mid-setting
- Inductors: maximum inductance 38uH with Q=200

We will assume a perfect balun without any loss. (It makes very little difference by the way if the balun is on the tuner input. Don't think moving a current or choke balun to the input of a tuner is a solution. The balun is under the same common mode stresses.)

With 250pF maximum capacitance, matching the odd impedance of this short dipole requires a tuner with the above component limitations to operate with a Q of 30.4. The resulting loss is 233.6 watts, and maximum voltage across a capacitor is 4250 volts! You are almost at the voltage rating of 4.5kV, so any small imperfections will cause a capacitor to arc. The inductor in the tuner would also dissipate 192 watts, which would damage most inductors unless duty-cycle was very low.

Some tuners (like MFJ Tuners) would be worse than the above values, Dentron tuners would be close to the above values, and many tuners would not even be able to match the load impedances. Automatic tuners and pi-network tuners would have a difficult time matching an impedance like this.

Conclusion

The lower limit in size of a multiband dipole, before feed system and matching losses move to the edge of severe problems, is about 200 feet on 160 meters, 100 feet on 80 meters, 50 feet on 40 meters, and so on.

A good rule of thumb is to multiply the band in meters by 1.25. The result is the minimum dipole length you can use without using a good matching system in, at, or near the antenna!

The G5RV length of feedline and antenna is the lower limit in size. A normal G5RV system, including tuner, typically has about 1dB of loss on 80 meters and less than 2dB ***system*** loss (*including loss from coax and matching*) on 80,40, and 20 meters. People seem to hate G5RV's, yet they now seem to be willing to further shorten the G5RV and recommend others do the same!

As an antenna is shortened from that length, losses in the feed system (even what Hams consider a good one) climb rapidly. 88 feet is just too short for an 80 meters antenna, because as you see above it is at the limit of what most tuners will match. It also places most tuners at their power limit at a few hundred watts of applied power.

The optimum length for a multiband dipole is near 1/2 wl on the LOWEST band, and the optimum open-wire feedline length is any odd multiple of 1/8th wavelength on the lowest band. This means an optimum 80-meter dipole would be about 125ft long, and the feedline would be 25-30ft, 75-90ft, or 125-150ft long. The longer the feeder, the more likely you are to having to trim it for optimum tuner performance.

Most tuners like to see impedances HIGHER than 50 ohms, and inductive loads at low impedances. Pi's and L's are NOT a solution to matching problems. They actually are significantly more restricted in matching range than a conventional T using the same general style and quality components!

Feedline voltage is also a good way to estimate wet-weather performance of "window" ladder line. If voltages are more than 1000 volts RMS at 100 watts, operation in wet weather will certainly cause tuning or loss problems. Use TLA and other tools as a way to plan antennas. Remember, there are more important things than pattern! A good pattern is useless if you cannot feed power to the antenna,

End-fed vertical j-pole and horizontal zepp

[Home] [Up]

Related Pages:

Verticals and baluns

The rule:

There is a rule that applies to end-fed antennas that cannot be broken. The rule is:

Current flowing into the antenna must be equaled by current flowing into a ground or counterpoise.

This means if you have any type of end-fed antenna without a radial or counterpoise system, the outside of the coax shield must carry an equal amount of current to that flowing into the antenna! This is true no matter how many series traps or choking devices you add at the feedpoint.

End-fed Myths

There are many incorrect ideas and claims surrounding end-fed vertical antennas (like the I-Max 2000), end fed horizontal antennas, Zepp, and J-pole antennas. All of the above antennas are actually quite similar. The J-pole is closer to the original Zepp antenna (Zeppelin antenna) than the bent antenna we commonly call a Zepp. I'll examine the most common and troublesome myth or false claim, that such antennas do not require a ground or will not have troublesome ground currents flowing over conductors into the station ground.

Some myths have been perpetuated or re-enforced by use of incomplete models. The most common modeling mistake is omitting the feedline or, if included, the coupling device (tuning or matching unit) properties are omitted. The major problem often isn't feedline radiation, it is common mode currents from the feedline. This article will explore why those currents occur, and give worse and best case examples of things affecting common mode currents.

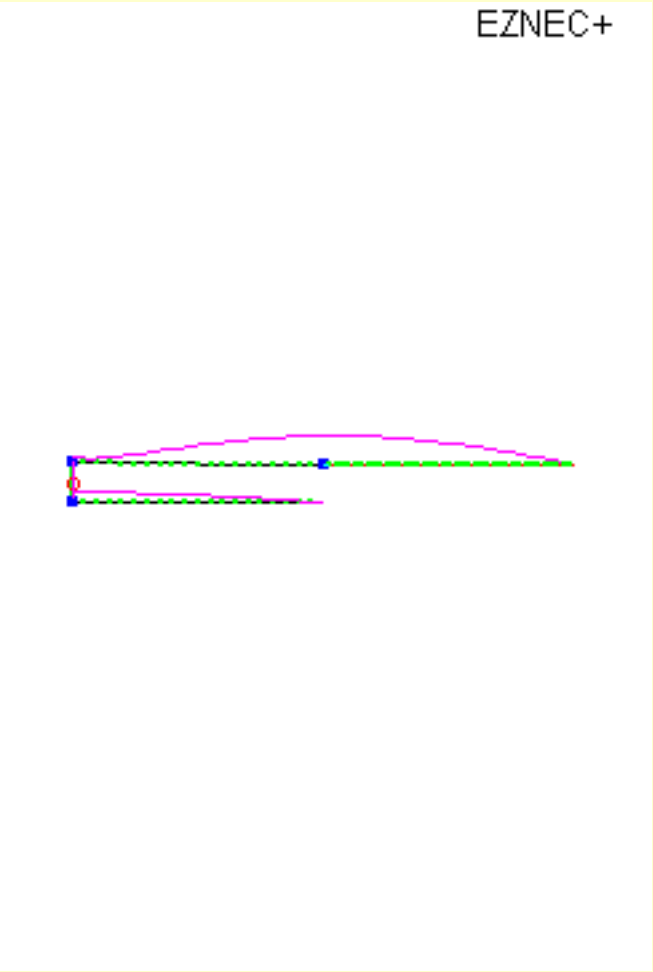
Origination of J-pole and Zepp Antenna

This form of antenna originated as a practical solution to feeding a wire antenna trailing behind a dirigible. This type of antenna is a ***Marconi antenna***, and it requires a counterpoise of some form.

(Marconi, by definition, means an antenna that is excited against a counterpoise or ground. An end-fed antenna is really a Marconi antenna, since it is impossible to force current into the end of an antenna without equal current flowing in some form of counterpoise.)

One way to create an effective ground system or counterpoise would be to use metal structural parts of the airship. This could create a problem if an RF-induced arc occurred where a mixture of hydrogen and oxygen was present. Running high RF current levels around inside a large bag of hydrogen with a pod of people hanging below was considered poor engineering.

The solution was use of a trailing counterpoise wire. With a second trailing wire was a counterpoise, the antenna system cold be floated from the airship frame. By floating the antenna and ground from the structure, most of the RF currents would be confined to the trailing wire and trailing counterpoise. The initial trailing wire antenna was 1/2 wavelength long, and the counterpoise 1/4 wl long. This set up a high impedance antenna feed working against a low-impedance counterpoise. Most of the current was in the antenna, as seen in this model:



Note the current curves in this model. Maximum current in the counterpoise wire is much less than the maximum current in the 1/2 wave section. Currents at 500 watts are:

- .71a into the 1/2 wl wire
- .71a into the counterpoise wire
- 2.32a maximum at the middle of the 1/2 wl wire

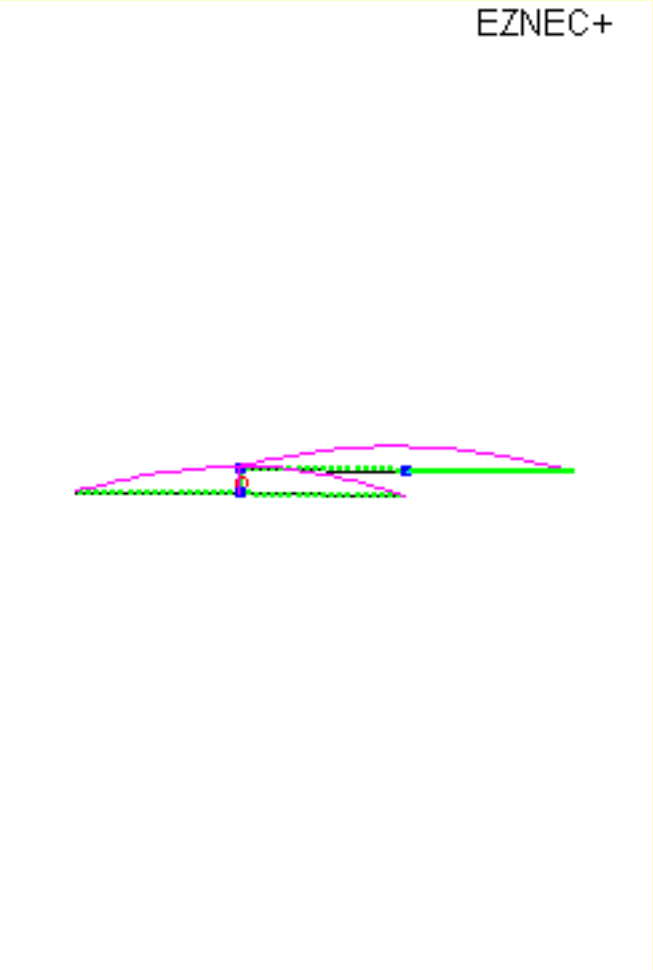
(Pattern is similar to a 1/2 wl dipole at the same height.)

Notice how currents fit the rule I mentioned at the start of this article. At the feedpoint the counterpoise wire, because there is no other path, carries exactly the same current as the antenna wire.

This model, like the models almost everyone uses, has an omission.

The flaw in this model is the same modeling omission K6STI included in his Zepp article, and the same omission repeated in "A Tiger by the Tail". The models do not include real-world effects of the antenna coupling system! All three examples feed the antenna with a ***perfect*** ground independent current source. That source that has no path to ground or to the station wiring.

When you include an imperfect source, the tiger turns around and bites you squarely on the rump. Here is what happens when a worse-case ground path is added:



In this case, I added a 1/4 wl wire to represent a low-impedance common mode path from the counterpoise side of the antenna connection. We see ground currents almost equal maximum antenna current!

In reality, most antennas will not be fed this poorly. A typical GOOD tuner has a few thousand ohms common-mode impedance. (There isn't any way around this, it is an impedance limitation inherent in the devices. You especially can't get around the problem by moving a balun to the input of a tuner!)

500-watt system currents when a typical maximum common-mode impedance is added are:

- .71a flows into end of antenna
- . 1a into ground
- .61a into antenna counterpoise

It is the .1a that causes all the problems. If you do not have a very good low-impedance RF ground on your tuner, this significant 100mA of unwanted RF current will flow into you, the power line,

the power supply, the microphone, and everything else connected to the radio and tuner! Of course the current will divide by the ratio of impedances, but this is precisely why, contrary to what other authors might claim, RF problems are common with Zepps. As a matter of fact, K9STH (a respected person on QRZ forums) uses a Zepp in an non-ideal configuration and has become a big proponent of extraordinary station RF grounds. This isn't meant to criticize anyone, but it is necessary to call attention to the problem of model sources being perfect while real-world systems have limitations.

The fact is, ***if an antenna is fed properly there is absolutely no need for a station RF ground! The station RF ground is a band-aid for poor antenna system design.***

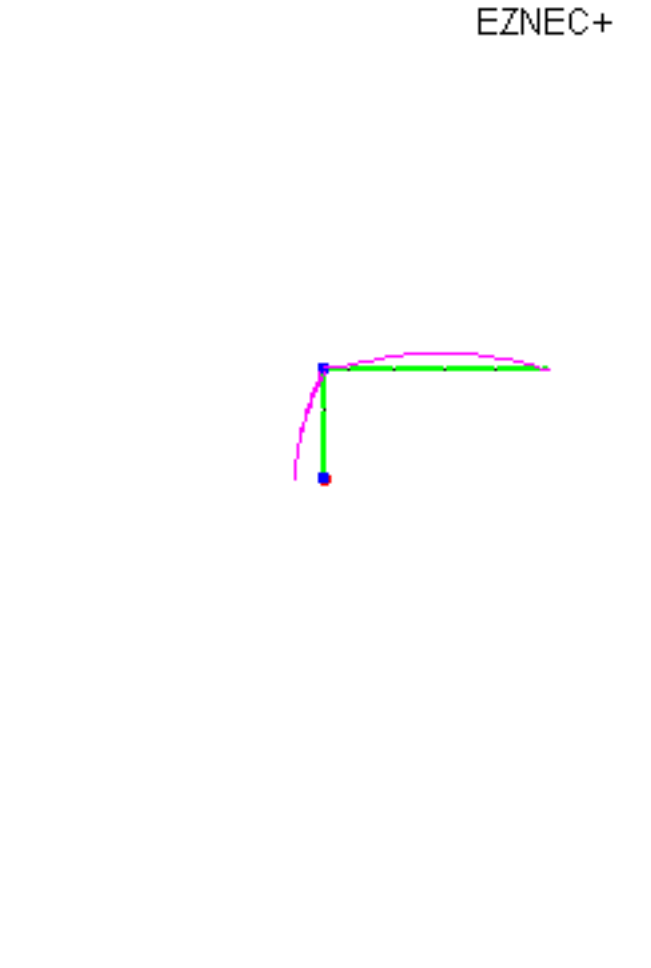
If an antenna is modeled properly to include feedlines and tuners, you will see problems that idea-source models overlook! Conclusions about system behavior change when tuners and transmission lines are included in models.

The Next Zepp Step

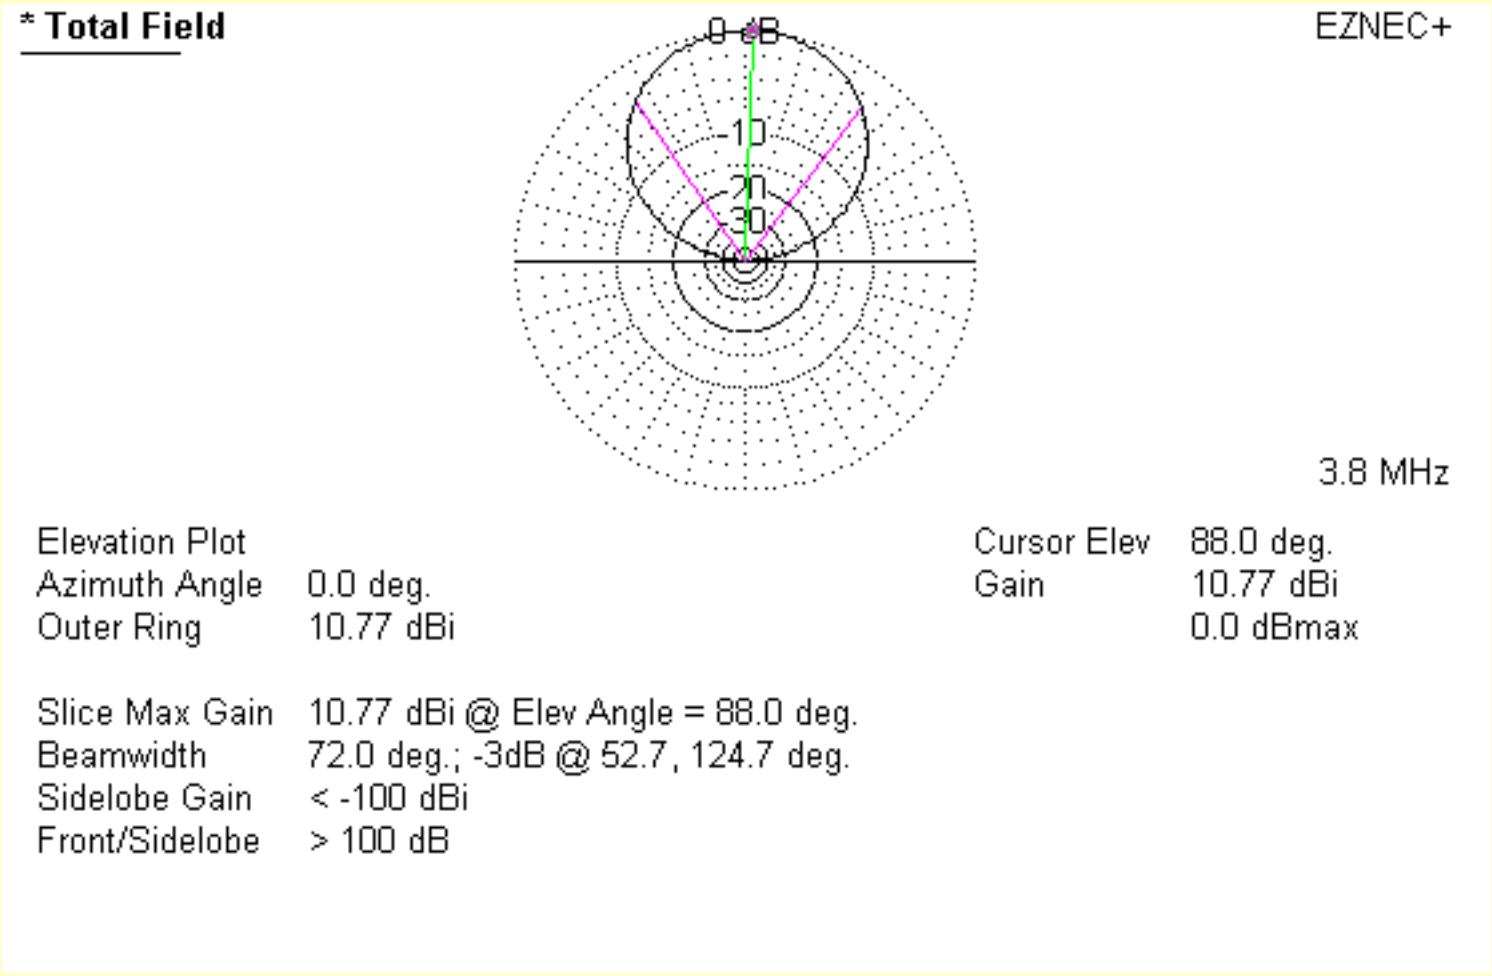
Let's look at the next evolution of the Zepp (this applies to end-fed verticals like the I-max 2000 although I will cover end-fed 5/8th wave verticals in detail at a later time). In this case we will model a 1/2 wl end-fed antenna fed with a 1/4 wl transmission line (a conventional year-2000 Zepp antenna), and see what happens when the 1/4 wl feedline is tied to ground through the common-mode impedance of a typical better-grade antenna tuner.

The ideal case for Zepp or J-pole (they are the same except for the bend in the Zepp at the feed) is when the radiator is very thin, exactly 1/2 wl long, and fed with a parallel conductor stub that is exactly 1/4 wl long.

Here is the antenna view:



Ideal antenna shows no pattern distortion:

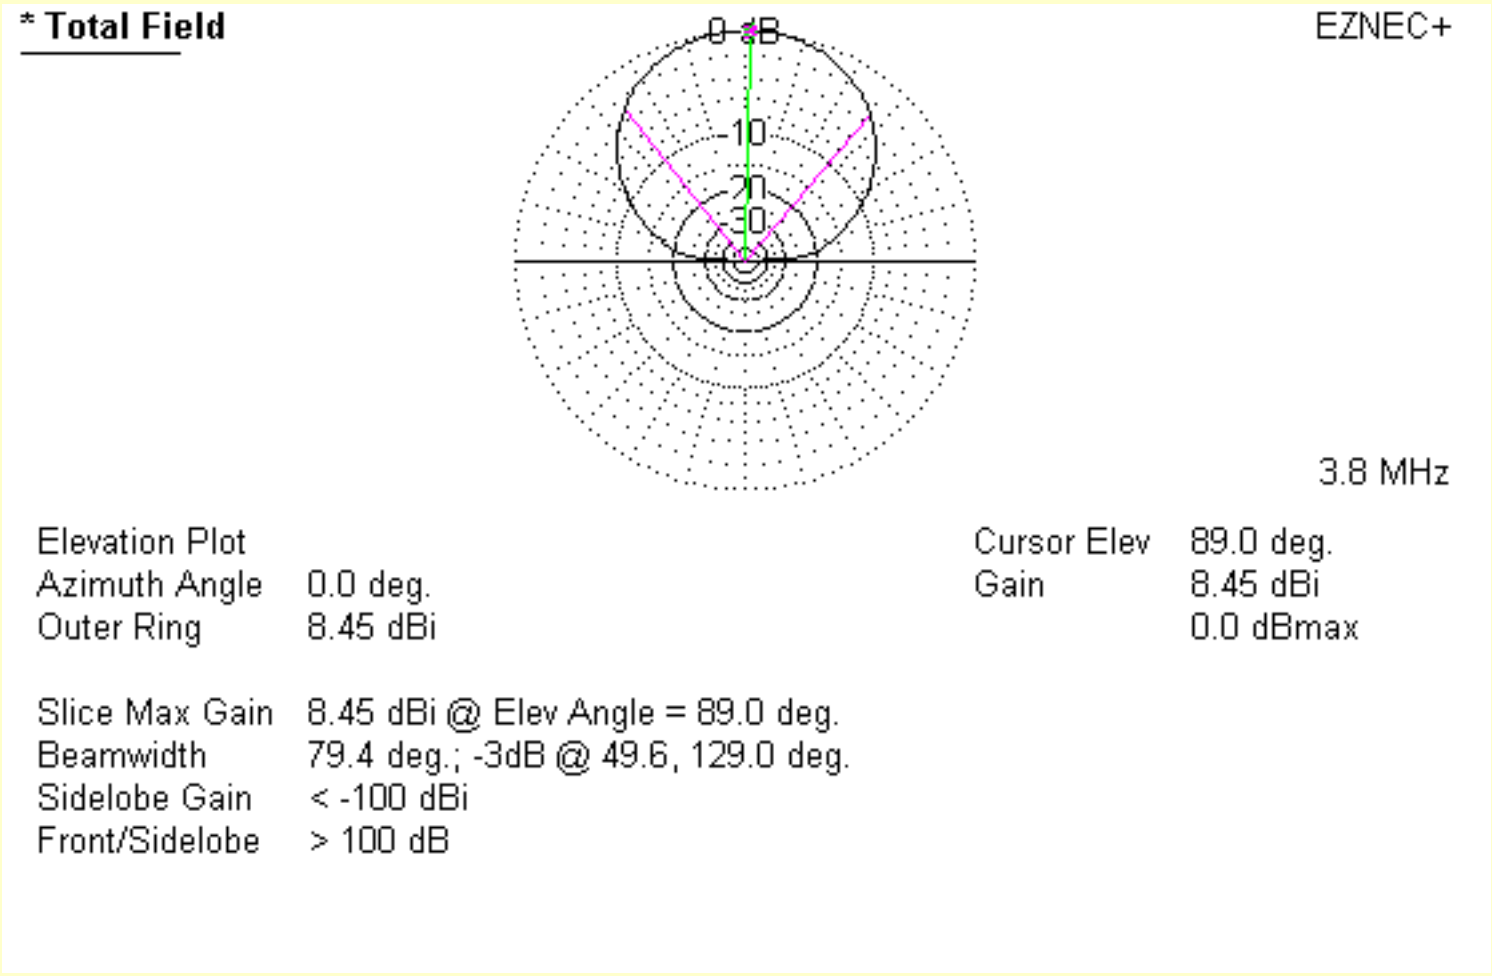


Although high feedline currents appear, they are closely balanced and out-of-phase. This is why both W4RNL and K6STI concluded feedline radiation is not a problem, and I agree ***for this specific perfect case!***

The real world adds a few variables, however. Real-world sources are not ground independent, real-world antennas are not always 1/2 wl long, and real-world feedlines are not 1/4 wl long.

Let's explore what happens when a the real world enters the perfect model!

Adding a worse-case ground path to a perfect antenna, we have:



Now we see a slight flattening of the bottom of the pattern. While the pattern does not change much, we have the following currents at 500 watts:

- 6.1 amperes feedline wire 1
- 5.35 amperes feedline wire 2
- .75 amperes ground path

Even with the small pattern error, we now has a very significant .75 amperes flowing to earth through the station equipment and perhaps eventually the operator. This is with an IDEAL antenna, and a normal worse-case antenna feed.

What is a worse case feed? The common J-pole antenna fed with coax! .75 amperes would represent the undesired shield currents and supporting pipe or mast current total when a J-pole is fed with coax.

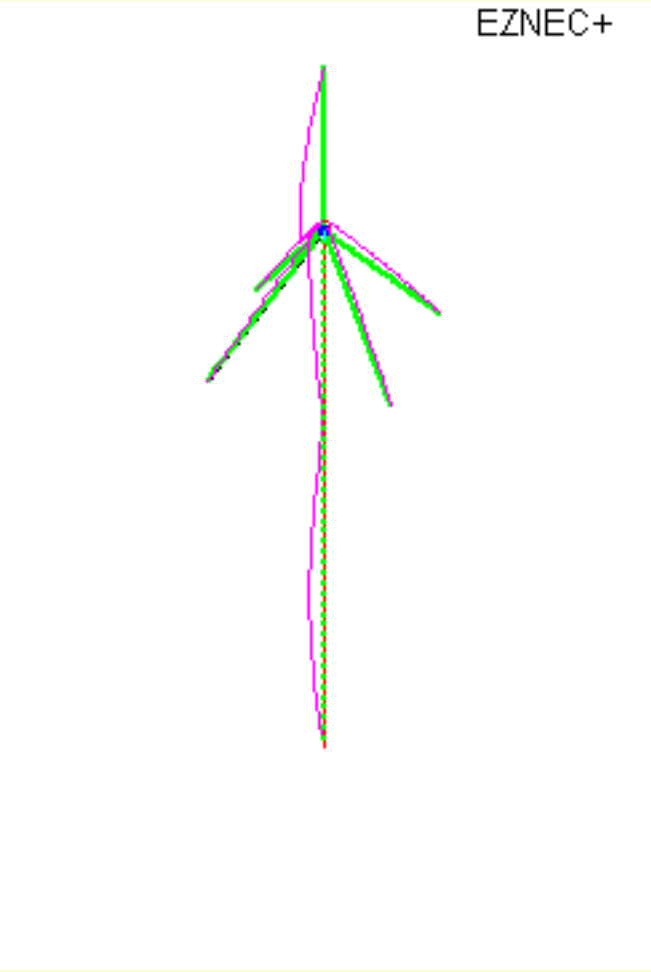
This problem gets worse when the Zepp feedline is not a 1/4 wl long, and the antenna is not 1/2 wl long. The I-MAX 2000 CB vertical is one example. The antenna has a random feedline (your coaxial feedline and mast) as a counterpoise, and is not a 1/2 wl end-fed vertical! This is why so many people complain about RF feedback with Zepp and end-fed 1/2 wl antennas.

If time permits I'll add examples of worse length combinations, but this example of a best length proves common-mode currents are an issue with a perfect Zepp connected to a real tuner. This is why people with Zepp are generally people who believe good RF grounds are required. They are correct in that belief. if you have a poor antenna design you need a good RF ground at the station!

Ground Plane and J-Pole Problems and Patterns

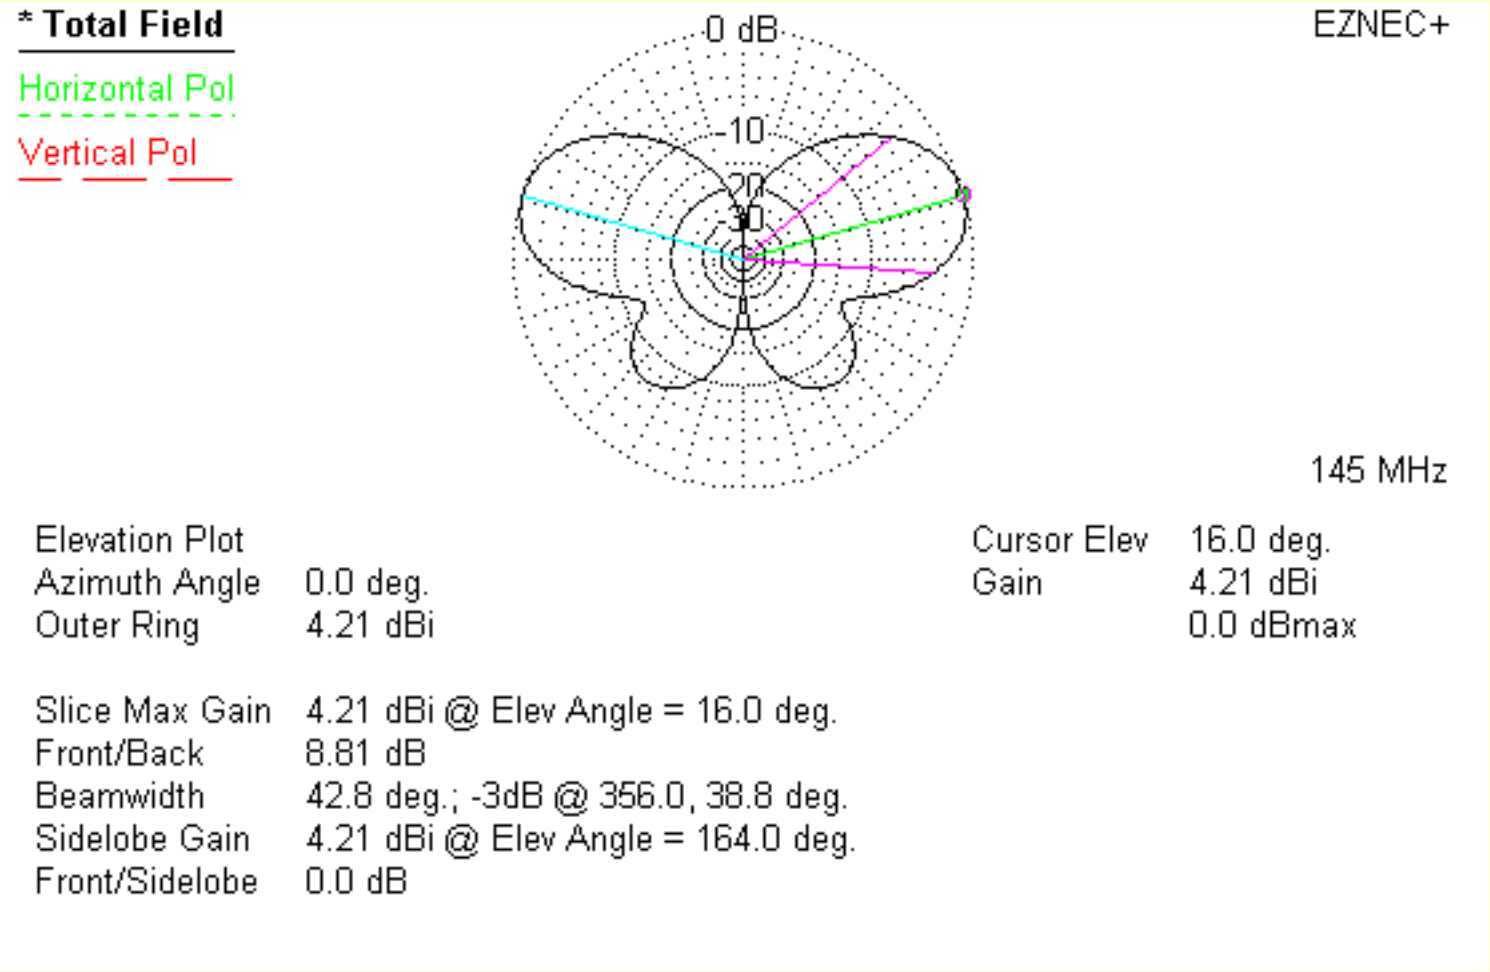
The J-pole is a worse-case situation for examining unwanted feedline radiation. In the case of the J-pole without radials, all of the common mode current created by the poor feed system flows over the coax shield and mast. The mast and coax is generally vertical and as high and clear as the actual thing we think is the antenna, and so unwanted radiation from the feedline is much more apparent than in the low-band Zepp where both feedline and antenna are near earth.

We will use this as a reference. Here is the pattern of a ***1/4 wl groundplane antenna*** without proper feedline decoupling:



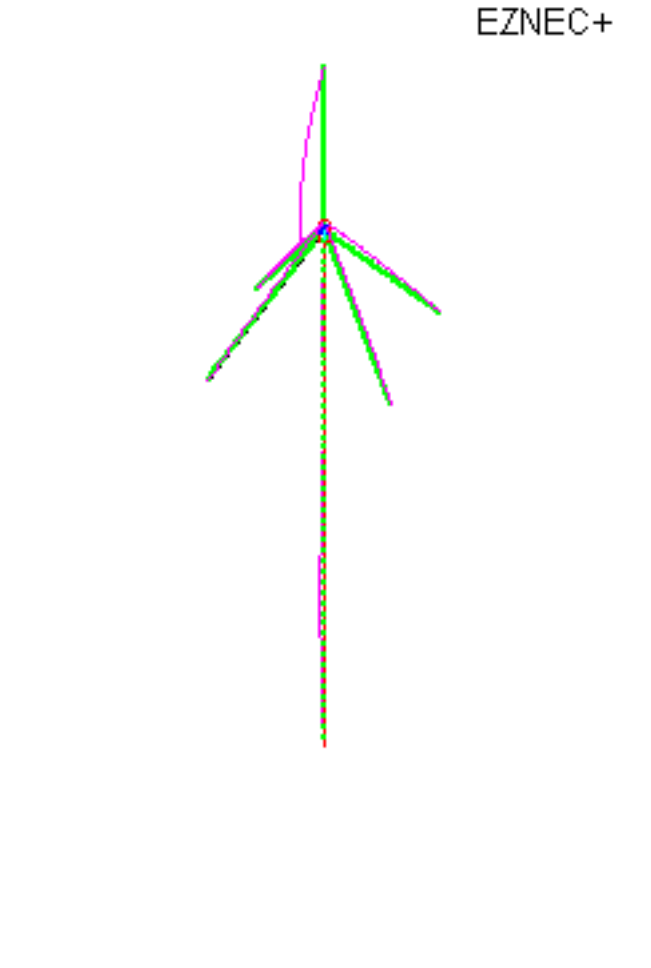
You can see some current exists on the feedline. The amount of current is actually significant, almost 1 ampere compared to 2.5 amperes in the antenna (500 watts applied)! A 1/4 wave groundplane with four radials actually needs a balun or some other form of feedline decoupling.

The pattern in freespace of this antenna is:

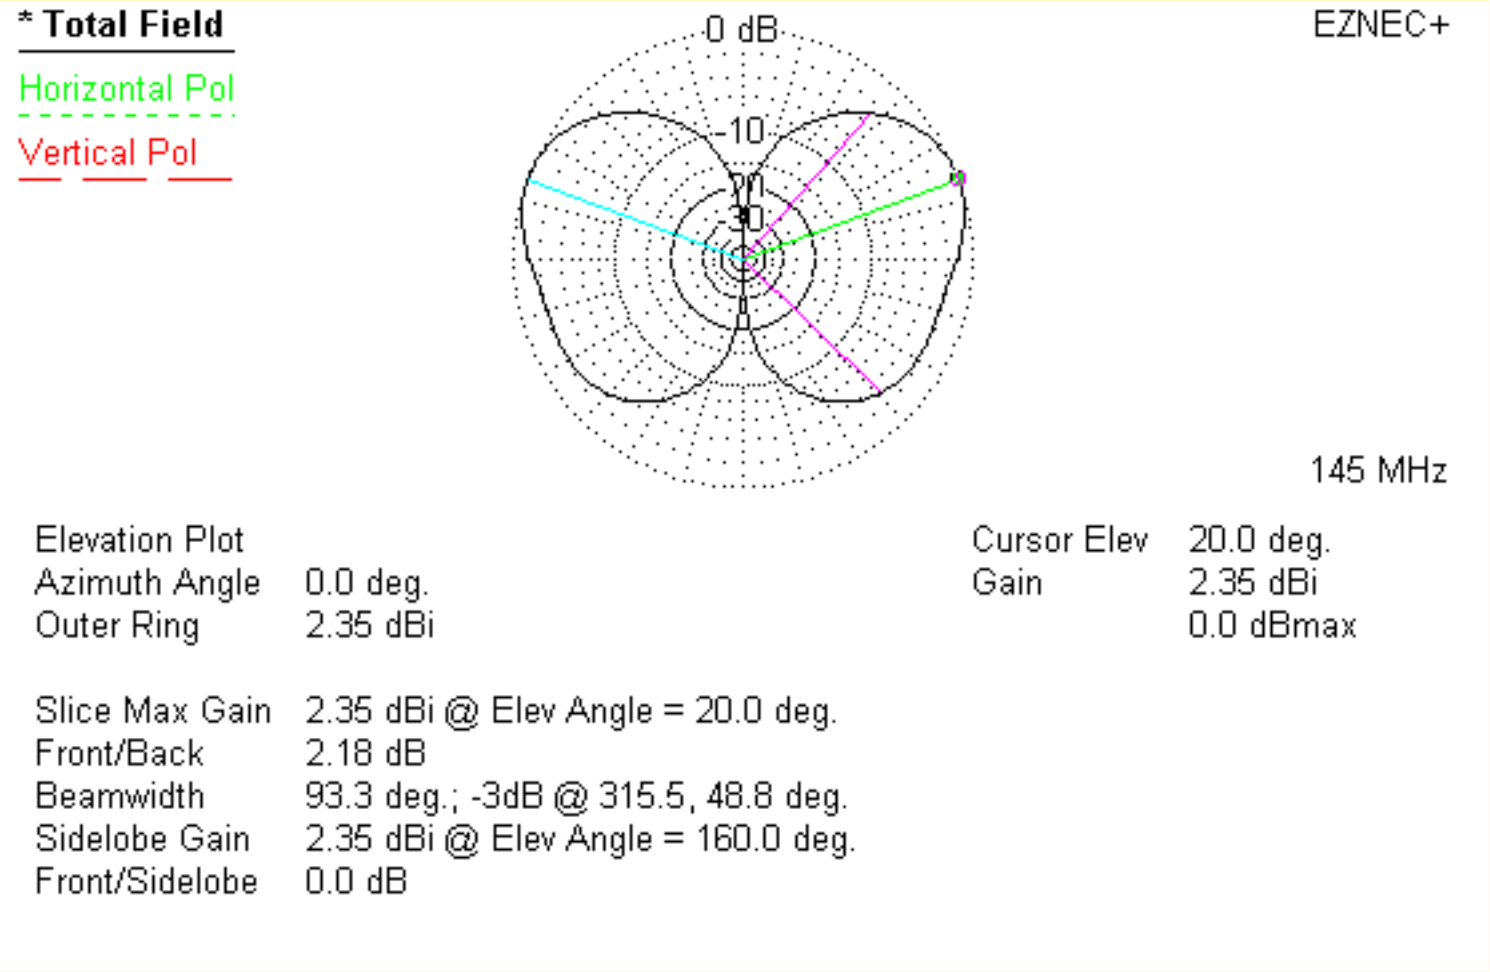


The pattern distortion is caused by feedline common-mode current. If you think this is bad, imagine what happens with an end-fed antenna (even a 1/2 wave antenna) and NO radials! In that case all of the antenna current flows over the feedline shield! Many antenna designs actually use the feedline and mast radiation that others dismiss as "insignificant" to increase antenna gain. In some cases, the antenna designers really don't even understand what they did to create a "magic" antenna.

Here is the same 1/4 wl groundplane with a feedpoint balun with a common-mode impedance of 3000 j3000:

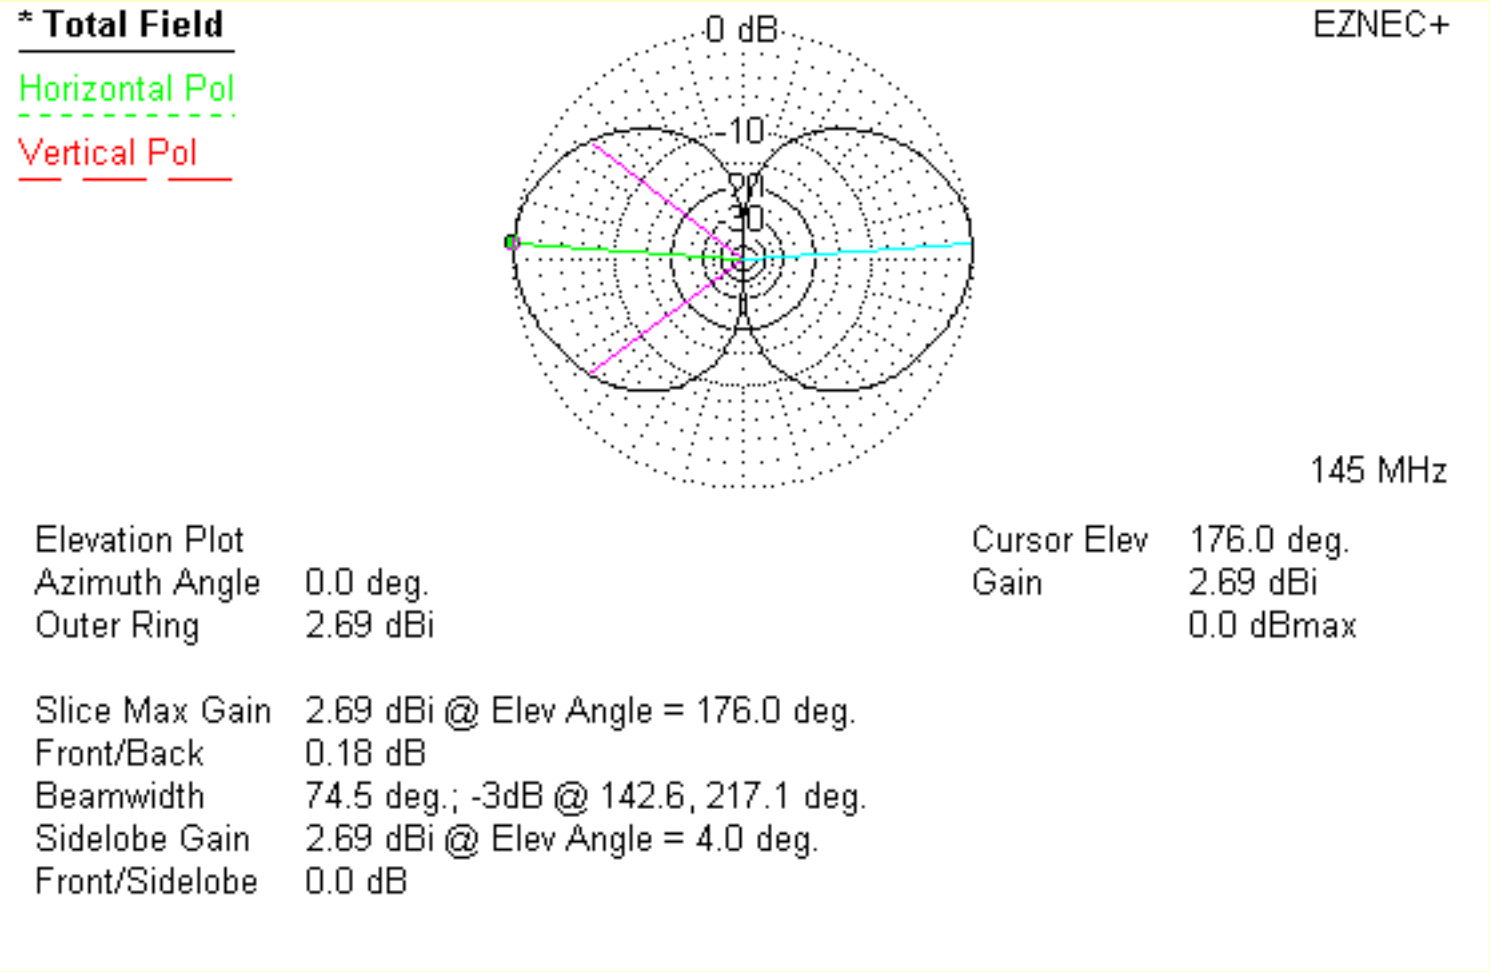


In this case feedline currents are under .4 amperes, and antenna current increases to 3 amperes. pattern is:



See how much cleaner the pattern is? The pattern is much cleaner and more like what we expect from a groundplane far above earth. We still don't have a good system, because the balun needs a ground on the "unbalanced" side to be effective. (This is why I recommend grounding the unbalanced side of baluns to antenna booms of Yagi antennas. That coil of wire hanging in the air might not be enough without a ground!)

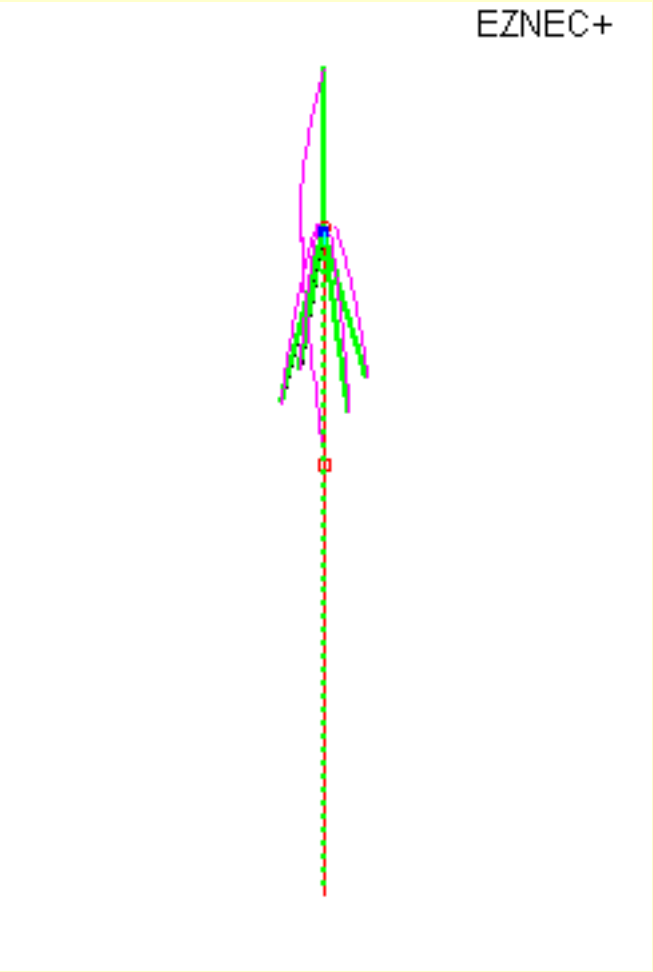
With a perfect balun and optimum de-coupling (a few extra radials below the balun or an extra-ordinary balun), the pattern looks like this:



This is the ideal pattern of a 1/4 wl groundplane, and it takes extraordinary care to obtain this pattern. Many people think they have this pattern, because they model antennas ***without*** *the feedline attached!*

To obtain this pattern I had to:

- Use a good balun just below the radial tip level
- Ground the feedline shortly below the balun to a small groundplane
- Slope the radials downwards more, to a 75 degree angle.



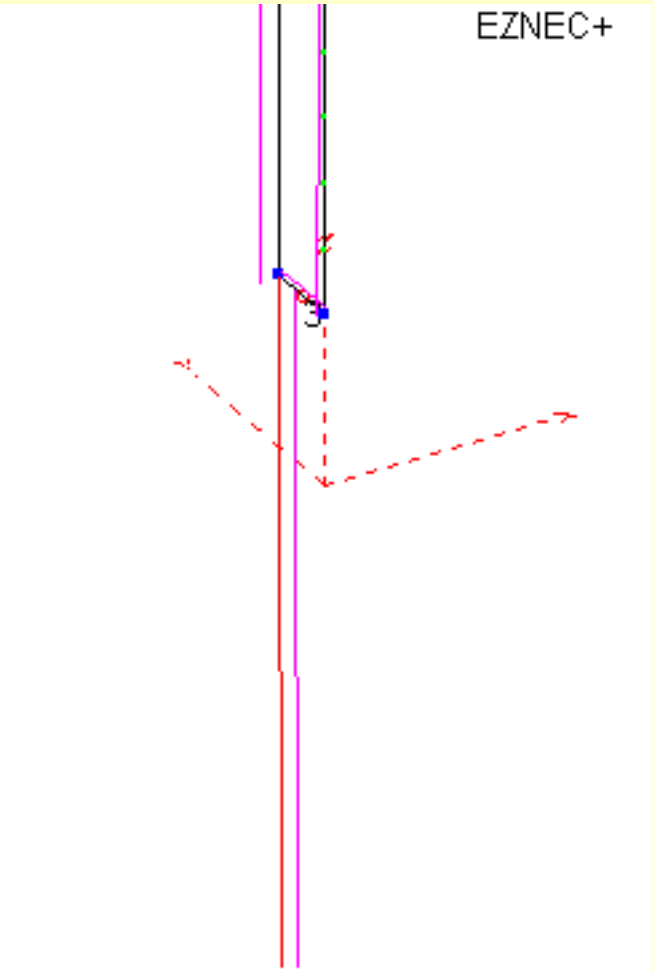
It is easily possible to do this in the real world. Instead, we have numerous articles that ignore the feedline and assume we don't have a problem with common mode current upsetting antenna pattern.

Worse yet, some articles claim the groundplane antenna only needs one or two radials!! Why does this happen? Because the person who made that assumption never modeled the mast or feedline. They eliminated the real-world problem through an omission in the model.

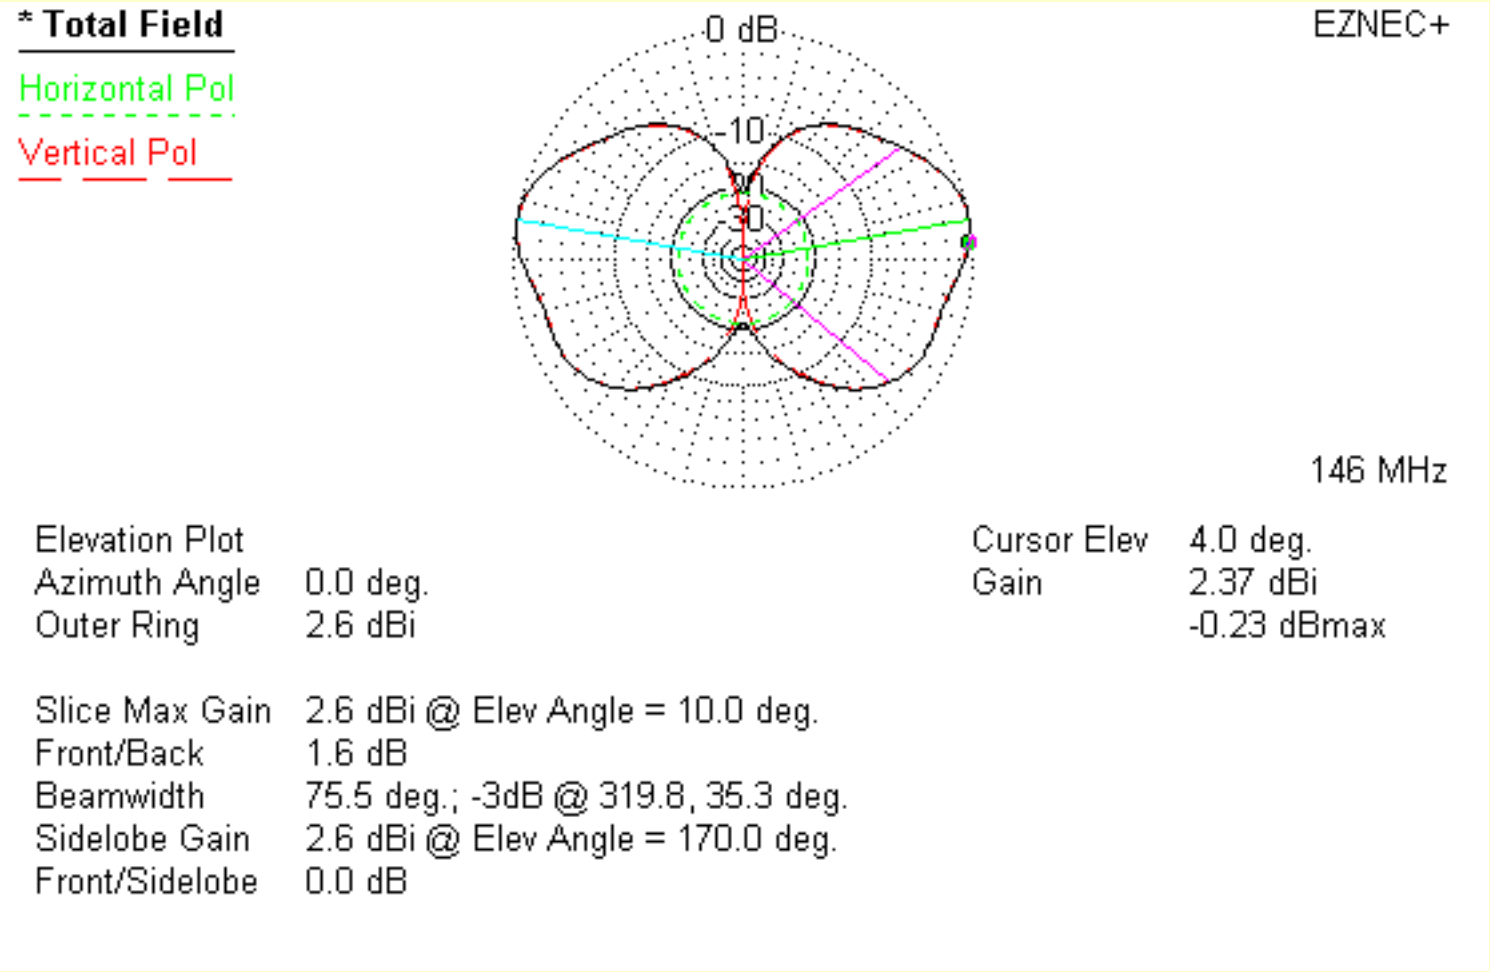
If an antenna model does not include the feedline, losses in the feedline, or imperfections in the source it much more likely than not is a flawed model. The real-world antenna often will be much different if the model ignores feedline loss and feed system source or matching system problems. Short dipoles are one example.

The J-pole and other end-fed Hertz antennas as prime examples of antenna with severe common mode current problems. The coax shield has to be at zero volts potential and have exactly equal and opposite currents flowing into and out of the load and source, otherwise the feedline radiates. Feedline length or weather changes that affect feedline moisture between the outer jacket and the support for the feedline will often change SWR. The severe common-mode feedline problems of end-fed 1/2 wave antennas is why some people swear by them, and other people swear at them.

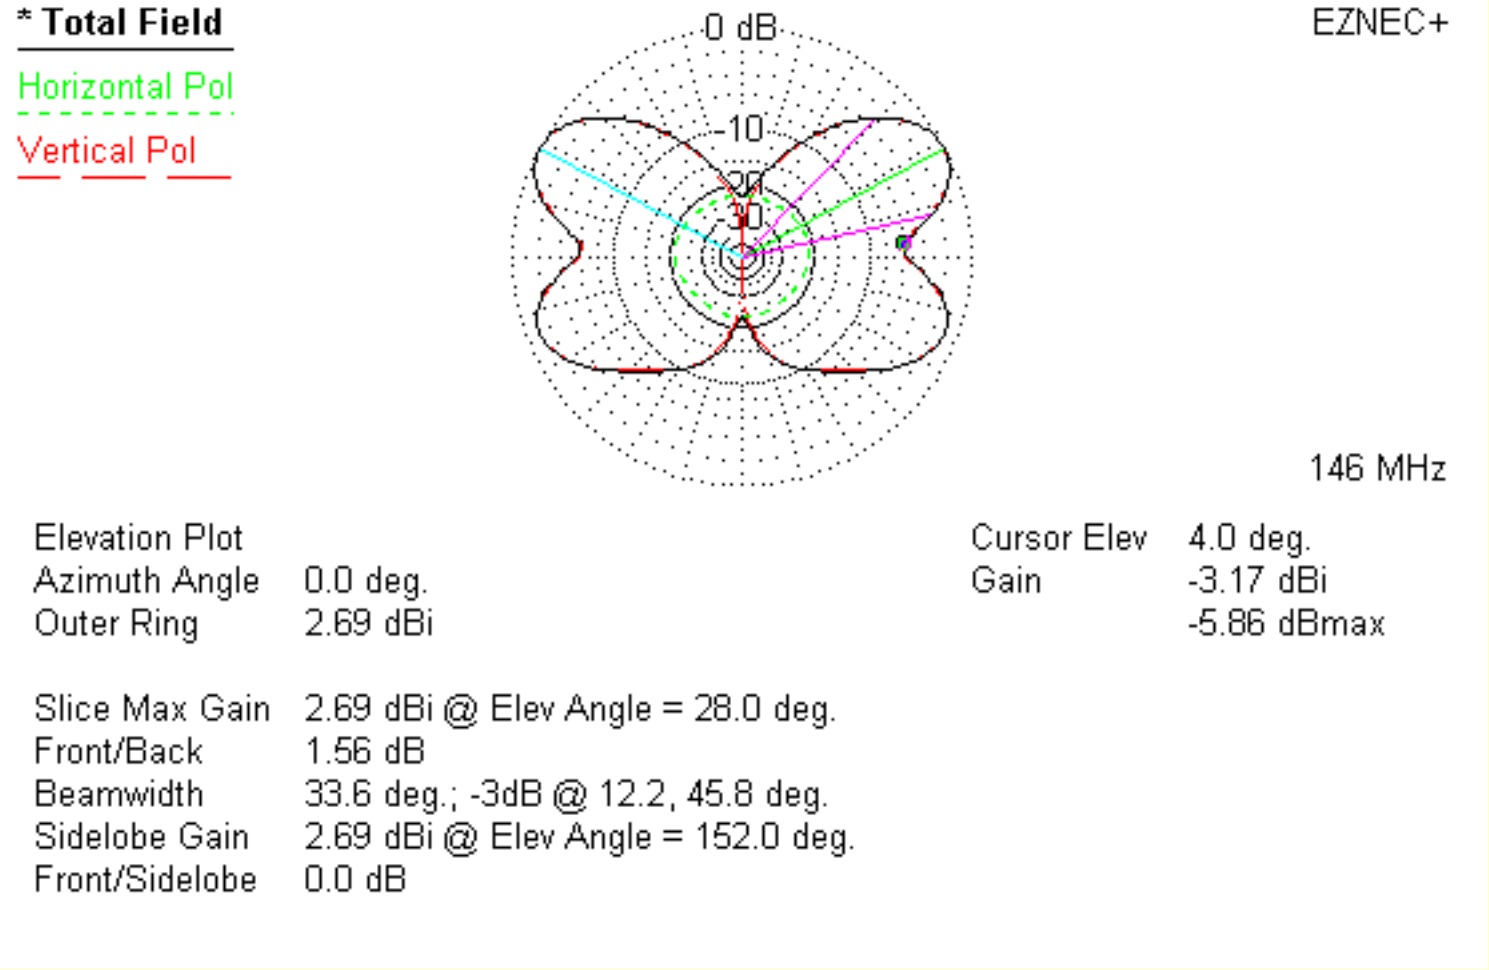
Here is a zoom of a correct model of a J-pole with a vertical feedline and/or mast attached.



You'll see the feedline or mast grounds directly to what everyone assumes is a "zero voltage" point. This is the electrical equivalent of any J-pole with the coax connected in series with the feedpoint, and the shorter leg connected to the shield. The shield can be connected to any supporting mast with any change in results. Here is the resulting pattern:

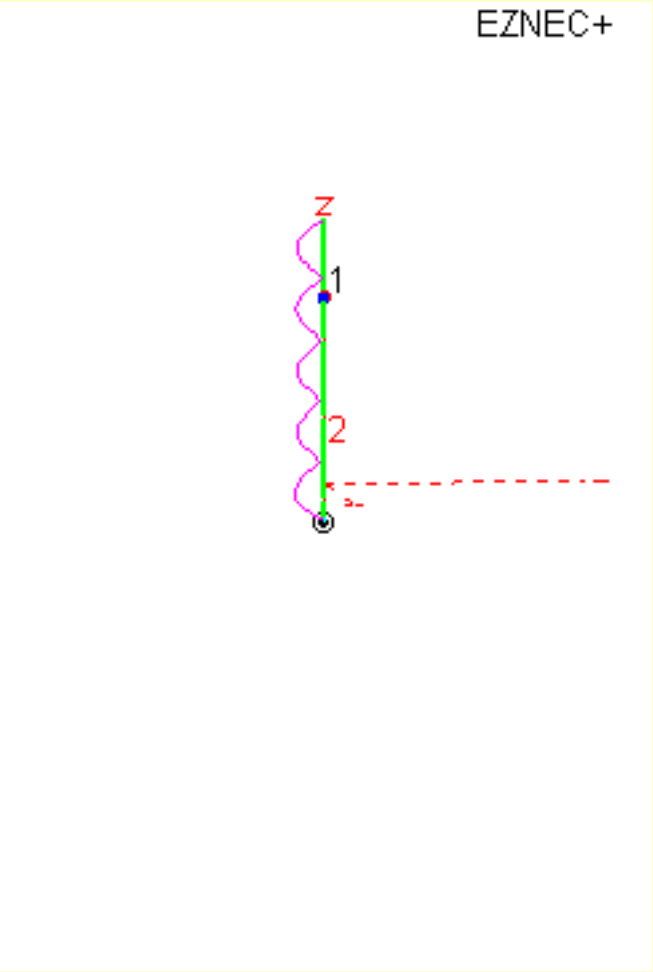


The gain is now 2.37 dB at 4 degrees elevation compared to 2.69 dB for the 1/4wl groundplane. This isn't the worse feed arrangement....it is actually the best for the J-pole! Here is the pattern with the feedpoint reversed, the shield is connected to the longer element, and the center conductor to the short element:



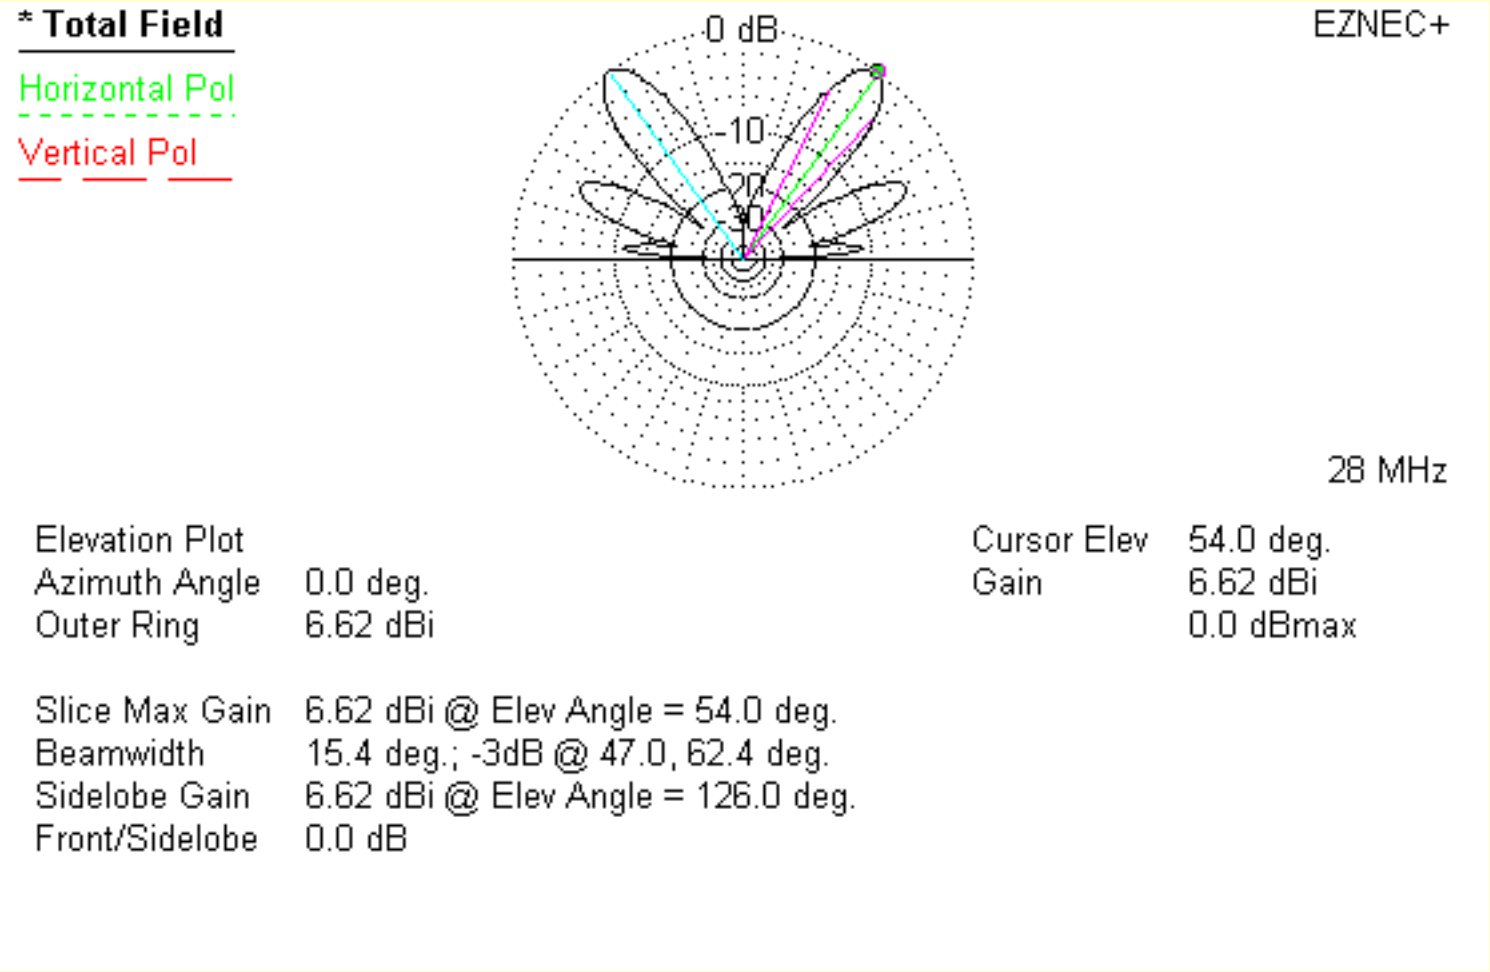
Notice the low-angle gain dropped about 5dB with just a simple reverse of feedline connections! If I didn't model the feedline, the model would never show this problem. In ALL cases, the SWR stays near 1:1, yet gain at low angles changes 5dB!

The following model is an I-Max 2000 vertical with a vertical feedline. In this case I picked the worse feedline length:



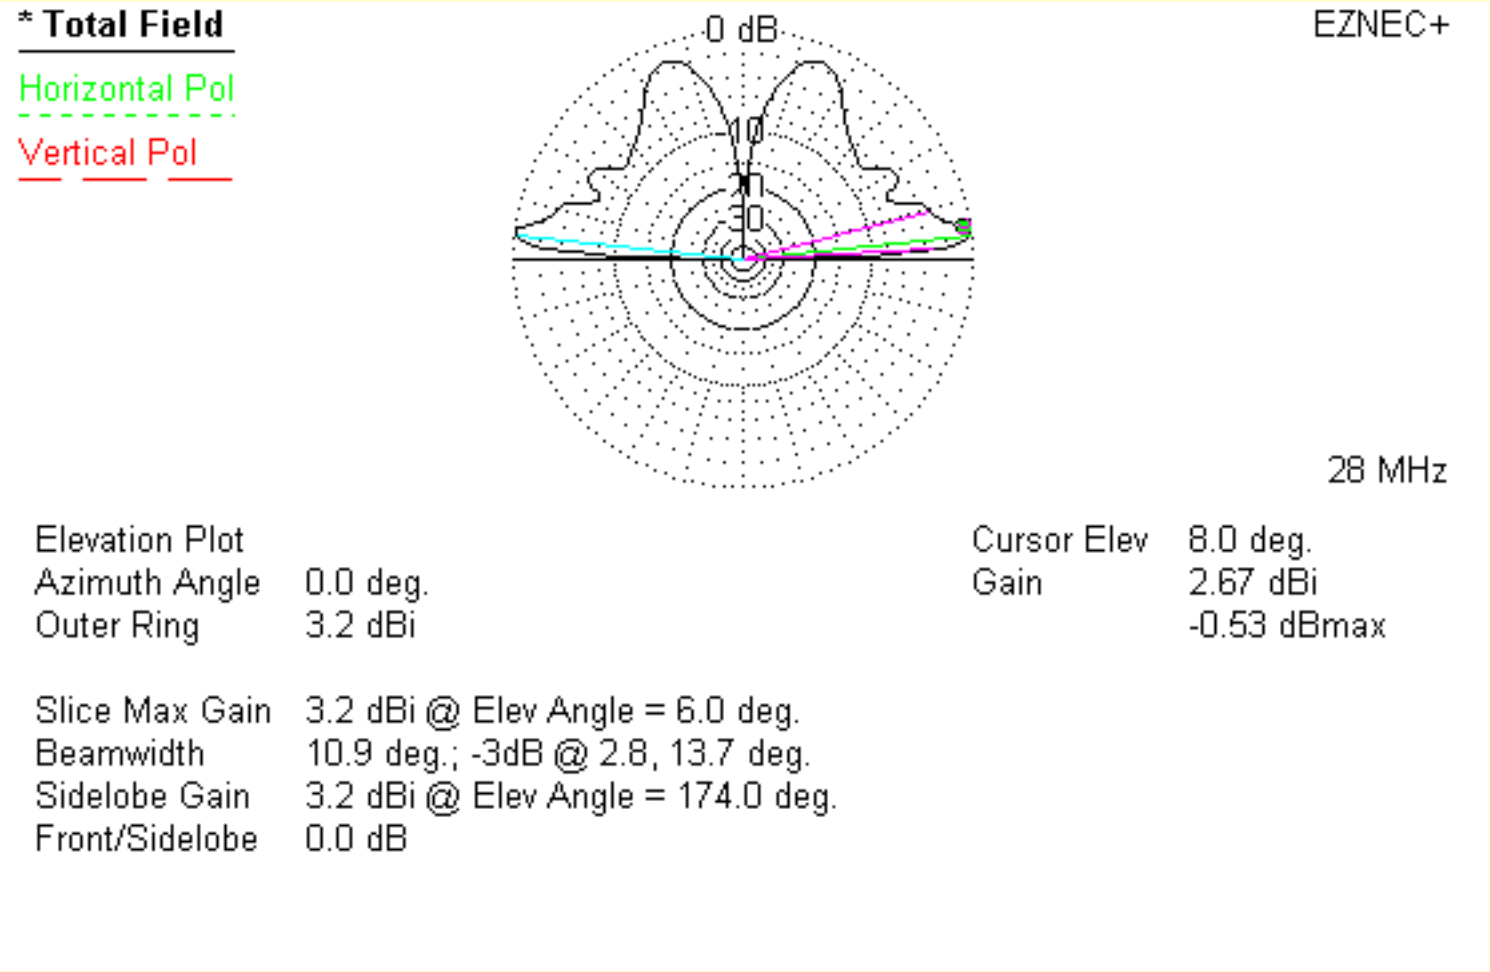
Feedline current is 100% of antenna current. This illustrates why so many people complain about SWR problems and RF in the shack with end-fed verticals like the I-MAX 2000!

Here is the pattern of an antenna that copies the I-MAX dimensions and feed system:



This is a NEGATIVE gain antenna at low angles. A 1/4wl groundplane would seriously out-talk the I-MAX 2000 or any other 5/8th wl antenna that does not have a large groundplane.

Even if we use the optimum feedline and mast length, here is the very best the end-fed antenna will do:



In this case we now have 2.67 dBi, which is actually a little less than a 1/4wl groundplane will do! The severe common-mode mast and feedline currents make "no-radial" verticals extremely sensitive to mounting height, mounting structure, feedline length, and grounding. This is NOT normal for antennas, it is a sign of a design problem.

Summary End-feds Without Grounds

ANY END-FED ANTENNA REQUIRES A LARGE GROUNDPLANE OR OTHER EXTRAORDINARY ISOLATION METHOD OR METHODS TO PREVENT FEEDLINE OR MAST COMMON MODE CURRENTS!

This is true for 5/8th waves, Zepp antennas, R7's, R5's, or even common J-poles. End-feeding antennas is bad news unless you have a large well-established ground at the feedpoint. Even 1/4wl groundplanes have common mode problems.

Some manufacturers have wised-up.

Cushcraft, in their Ringo-Ranger, eventually added a separate additional groundplane below the antenna to tame the wild common-mode currents of the Ringo. Even that solution is barely

acceptable.

The Isopole antenna used multiple sleeve sections to decouple the feedline, and it probably was one of the best antennas available for immunity to feedline coupling problems.

This problem gets worse when the element is 5/8th wave long. Think of that when you read claims of "no-radial" CB antennas with "3dB gain" and a low wave angle. They actually have negative gain at desired DX angles over a conventional 1/4-wave groundplane! Instead concentrating your signal towards the neighbor's TV set or an airplane flying overhead. They cause your entire antenna system to be critical for feedline grounding, routing and length and even allow moisture on the feedline jacket to change performance of the system!

If you find this page interesting, please pass it along. It's time to get the feedline into models!

http://www.w8ji.com/Skirt_feed.jpg

Two or even three skirts may be added to the mast as shown in Fig. 22-5*c*, but reduced excitation of the lower sections diminishes the effectiveness of each additio skirt.[6] Thus, while the multiple-skirt coaxial antenna resembles a collinear arra in-phase half-wave elements, its gain is not as great. Typical gain values are ta lated in Table 22-2, but since no test data are available for this type of antenna, values given are merely engineering estimates.

http://www.w8ji.com/Skirt_feed.jpg

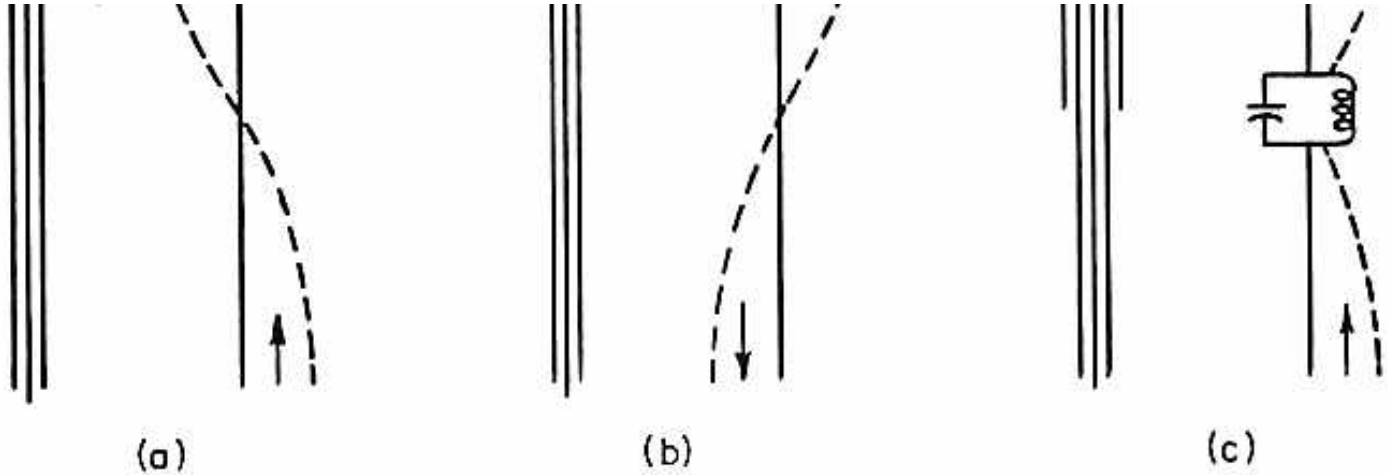

FIG. 22-5. Evolution of multiple-skirt coaxial antenna.

The relatively large diameter-to-length ratio of a practical skirt produces an effect which requires that the exterior length of the skirt be reduced by a factor of 0.8 to 0.9 and the interior length by from 0.95 to 0.98.[6] This is accomplished cutting the skirt to the proper exterior length and inserting a dielectric slug in skirt to increase its electrical length.

diversity receiver and transmission

[Home]

Diversity Receivers

We sometimes are told a quad antenna, by virtue of the vertical side and horizontal top and bottom wires, is "diversity". That just isn't true at all. Neither is an intentional mix of vertical and horizontal reception from one antenna (like a Carolina Windom), or even two separate horizontal and vertical antennas when combined into one receiver signal input. I've actually never even found it to work very well even in stereo or with a voting system, as long as the antennas are within a wavelength or two of each other.

Despite what we are sometimes told, we can't simply adjust two receivers to the same basic frequency, pipe one output into each ear, and have diversity. This is especially true with unlocked receivers that are even a fraction of a Hz different in frequency.

There are articles describing locking the dials of the FT1000D so the sub-receiver tracks the main receiver. This does work in the FT1000, because the oscillators share a common time base. The main problem with the FT1000 is the second receiver isn't a "good" receiver.

Testing For Diversity Capability

You can test your system for correct phase-lock by tuning in a carrier (like WWV) and mixing the two outputs together. When audio levels are equal, you should hear no warble or vibrato in the tone. You should hear something between a full or peak that stays perfectly locked. If your system fails this test, it will deduct greatly from possible diversity advantages. Click here for a failed test. Click here for a passed test.

Remember any warble or slow fade variation indicates the receiver is unacceptable.

True vs. Stereo Diversity

I use a loose form of diversity reception on 160 and 80 meters I call "stereo diversity". It really isn't true diversity where the receivers vote and the best S/N ratio captures the audio output, it is a system that requires your "brain" to do the voting.

I've found this system very good for substantial improvements in readability of noise-floor signals. The difference can be worth as much as a signal being nearly readability 5 (perfect) in stereo to readability 2 without. When a signal is marginal, it is all the difference in the world.

I accomplish stereo diversity by phase locking two separate receivers together so audio outputs are exactly in phase. The receivers are virtually identical, even to the point where I hand select crystal filters for equal group delay change over the filter passband. Every oscillator in the receiver is common to both receivers.

This allows me to successfully combine two antennas or antenna arrays that are several wavelengths apart into one system, a task otherwise impossible. Mixing two quiet widely-spaced antennas causes noise to appear smoother and more "hollow sounding", while the signal actually stands out more. Some of the recordings on my DX Sound Files page are in stereo. You can listen to this effect with stereo headphones by changing your computer's volume control settings to stereo or mono.

Transmitting

One common thought or claim is by transmitting both vertical and horizontal via skywave, we would have the best of two worlds. Worse yet, there is a common idea or belief we can build antennas producing two independent polarizations, and that resulting dual polarization will provide the best of two worlds and reduce transmitted signal fading. Several obvious flaws with this concept are outlined below.

Generating Two Polarizations

When speaking of polarization, we are talking about the direction of the imaginary flux lines in the electric field. When dealing with the far-field effect called EM radiation, ***the imaginary electric and magnetic flux lines are conveniently at right angles to each other***. While either could have been used for the reference standard of polarization, the electric field became the polarization reference.

The imaginary flux lines represent the force caused by any and all electric fields. They "exist" only at one angle in one small portion of space at any instant of time. We ***can not generate two polarizations at the same time at any reference point in space*** when broadcasting our signals, not with any antenna! The idea we can have dual-polarization transmissions probably comes from misunderstanding what antenna modeling programs are showing us, or a flawed or limited imagination causing an incorrect mental picture of what actually occurs with antennas.

Modeling programs only show two perfectly filtered views of the actual field. They do this out of

necessity, because the actual electric field is far too complex to display in its entirety. While we could see a slice of the field showing true polarization at any given angle and distance, I'm not aware of any commonly available programs that provide such useful information. A typical pattern display generally shows the response that would be observed through perfect vertical and horizontal filters. Modeling programs generally do not tell us the phase relationship between the intensities we see displayed, so we have no idea what the actual polarization is.

The bottom line is this....we don't know, when looking at the display, what the actual polarization is unless it is 100% vertical or 100% horizontal.

A Simple Tilted Dipole

Visualizing an actual antenna might help us picture an antenna pattern correctly, and understand what we commonly perceive incorrectly.

Imagine we have moved back a considerable distance from the center of an extremely high dipole that was installed tilted at 45-degrees. We move back from the dipole center without changing height, and observe the electric flux lines near us. To us, the distant antenna appears tilted at a 45-degree angle from our lower left to upper right. Each end of the antenna is exactly the same distance from us. In other words, this is a "side view" of a perfect sloping dipole.

If we could actually see flux lines near us representing the electric field, the lines would appear to parallel the distant antenna. Yet a view on a modeling program would show the field intensity of the electric field to be an exactly equal mix of vertical and horizontal fields!

Many of us would (incorrectly) describe this antenna as producing equal vertical and horizontal polarization in the direction where we view the antenna. The logical conclusion would probably be a vertical or a horizontal would respond equally well to that field, and that is correct for a perfect vertical or horizontal.

What we probably would fail to understand or visualize is the actual polarization. The peak response would be to a dipole antenna tilted 45-degrees in the same slope direction as the radiator, from lower left to upper right. Most important and most often missed is the simple fact that another dipole tilted 45-degrees opposite, from lower right to upper left (even though broadside towards the distant source) would have no response! It would be cross polarized, and response would be minimal.

This idea we have both polarizations is the root of the misunderstanding, and misunderstanding always seems to breed voodoo antenna claims and snake oil solutions. The most common false conclusion would be thinking sloped antennas reduce polarization related fading. The "equal-V-and-H-antenna" would be assumed to provide the best of two worlds, transmitting or receiving when either vertical or horizontal polarization or anything in between is required for an optimum signal.

Ionosphere Propagated Signals

Any distant signal arriving via the ionosphere is constantly changing in polarization. The ionosphere is a poorly aligned soup of ions, and that soup is constantly being stirred. It is not a flat perfectly aligned mirror. The ionosphere also provides multiple modes and paths for signals, particularly on frequencies well below the maximum usable frequency. The phase and level of the same signal arriving from each path constantly changes. Because of this, arriving signals tilt and rotate.

While there are some statistical odds that more time will be spent centered around one effective polarization than another, the fact remains that very little time is spent at one distinct polarization. The same effect holds true when transmitting.

Because of the random nature of polarization, the signal just as likely would be tilted 45-degrees left on on sloper as 45-degrees right. It is just as likely to fall into a cross-polarization null with the sloper as with any other angle of radiator, except one centered at the optimum tilt. We can easily see the idea sloped wires, Inverted L's, and even Windom antennas with "leaky" baluns reduce fading by providing "diversity" is pure rubbish. The same holds true for intentionally mixing two polarizations from two separate antennas, even if each is fed from separate amplifiers.

Statistically, we are actually MORE likely to have deep fades when we transmit with two very different systems than with one! The reason is simple, we excite the multiple paths better and increase multipath propagation. Since the phase delay is random and constantly changing, any attempt at circular or dual polarization would greatly increase fading when more than one path makes it to the receiver.

This is actually the reason 5/8th wavelength verticals fell out of use in broadcast work. The small high-angle lobe of the 5/8th wavelength antenna created severe deep fading and phase distortion at receivers in the fringe areas. A mix of horizontal and vertical antennas, even if properly phased to provide a rotating wave, would be even worse.

Reducing Fading

The best solution is to have two separate antennas, selecting the best antenna at any given instant of time for the path. This is true for both receiving and transmitting. Commercial sites do this by employing some form of voting, based either on signal-to-noise or absolute signal level.

Dealing with weak signals provides special problems. Good CW operators can copy code that is actually below noise floor. Because S/N ratio is near zero, noise detectors in a voting system would become overly complex and unreliable. Perhaps someone can develop a DSP system that allows

voting, but my attempts have been largely unsuccessful.

My solution is to use a stereo system with phase-locked receivers, and process the audio in my head. With antenna separations over a few wavelengths, the background "white noise" takes on a distinct hollow sound. Signals are easier to pick out, and the ability to copy CW below the noise floor is greatly enhanced. The end effect of this is reduced fading.

For transmitting, the only useful approach is having a variety of antennas available and picking the antenna generally more optimum for the particular distance, direction, and time of day. Without feedback from the receiver, it is all a guessing game. One thing I do know is that mixing my antennas directly never resulted in improved signal strengths or reduced fading in many dozens of blind tests.

How to Check Signals

[Home]

This page still under construction revised 1/8/2004!!

Related pages: Receiver tests Key Clicks Checking Transmitters

I noticed W2VJN has proposed using absolute signal level at a fixed test spacing for click measurements. While I agree with George's suggestion we establish a test method, I strongly disagree that a 15Hz BW signal level measurement of the peaks accumulated in dozens or hundreds of scans is any more useful that listening off-frequency on a known good receiver.

Some radios, like the FT-1000 series and other Yaesu radios, click on both make and break. Radios that do that are much more disruptive than radios that click only on make or break. The slope of the roll-off is also very important.

What we really need for click measurements is a peak and average power measurement on the adjacent frequency.

My local wintertime 350Hz BW noise (after preamplifier) compared to a sample of signals on one night was:

Noise -127dBm

9H1BM -122dBm

OM0WR -95dBm

DF2PY -88dBm

WA8OLN -78dBm

W3GH -60dBm

W4ZV -42dBm

The dynamic range between noise and W4ZV on one occasion was over 85dB! It also illustrates how important antennas, location, and propagation are rather than power. The dB difference between signals from the same area is profound. Many signals run at or near noise floor. This may not be typical of every night, but it shows how large the signal level variations between weak DX and strong signals are.

W8LRL and I have heard each other while running about 30 micowatts!

There are three main reasons we hear clicks and splatter off-frequency:

- The receiver is not up to the job, but it could be
- The transmitter is not up to the job, but it could be
- The signal is just too close in frequency, and reasonable use of technology won't cure the problem

Dynamic Range (IM3)

The most useful specification for receivers is called **dynamic range**. Dynamic range (DR) tells us the ratio in dB (anything described in decibels is a ratio) of the weakest signal that can be heard to the level where problems start.

Receivers

IM3 DR would be the ratio of two equal level signals (creating a third-order product by unwanted mixing) to the noise floor of the receiver.

Imagine we have two strong CW signals spaced 1kHz apart, one at 1840kHz and another at 1839 kHz. As the level is increased, the receiving system has a increasingly non-linear response. The 2nd harmonic of 1840 can mix with the fundamental of 1839, and the result would be a new signal at 2*1840-1839=1841kHz. Another signal, if the two original signals are equal strength, appears at 2*1839-1840=1838kHz.

(There are also sums, but they fall outside the filters and tuned circuits. We normally can't hear them, so we generally just ignore them.)

The response of this product is non-linear. The level of the mixing product increases faster than the level of either individual "real" signal.

When we can hear that "phantom signal" above the noise floor of the receiver, it adds interference

to other weak signals we might be trying to hear. We reference the main signal level this occurs at to the noise floor, because that is the level where it would start to be noticeable.

Always remember actual overload is the result of the vector sum of signals in the passband of the system at that point. One way to look at it is that overload is an accumulated power problem, not an absolute level problem with one signal. This means a great number of weaker signals can cause the same problem as a few strong ones.

Transmitters

Transmitters are a special case partially covered in a checking transmitters page.

Higher Order IM

We can have higher order IM products, but they are always odd sums or differences. For example the 2nd harmonic of one signal can mix with the third harmonic of another, and we have 5th order products (2*f1 minus 3*F2 called fifth because 2+3=5).

Although they can affect CW receivers, higher order products create most of our SSB problems. This occurs because higher-order products fall well outside the filter passband of a typical SSB receiver or transmitter.

Blocking

Blocking is the point where we can detect a change in sensitivity or gain from a single strong unwanted signal. Blocking "pumps" the receiver gain and can actually make false clicks. We always have to sure any click reports are given with signal levels well below the blocking point!

Blocking again is a ratio referenced to noise floor, since loss of sensitivity (either through increased noise or decreased gain) can affect readability of weak signals.

Transmitter Splatter

Under construction 1/17/2004

Transmitter Intermodulation Distortion

A common culprit behind wide SSB signals (assuming the receiver is good) is high order distortion products. Transmitters process multiple frequencies at once. Mixing between these signals caused by amplitude response non-linearity can generate new frequencies. The offending products are those with odd-orders.

In a typical SSB transmitter the ***2nd RF harmonic*** of a modulating tone from one pitch can mix with the ***third harmonic*** of the RF caused by another modulating tone. This creates a new frequency that is called the ***5th-order product*** (2*F1 minus 3*F2 is called fifth because it is 2+3=5). We also can have a lower order product called the ***third-order product*** where the 2nd harmonic of one tone mixes with the fundamental of the other. We call that the third-order product because 2*F1 minus 1*F2 makes the new signal.

A 1850kHz LSB transmitter modulated with two tones of 500Hz and 3000Hz would have main signals at 1849.5 and 1847kHz. The third-order IM products would fall at:

(1849.5*2)-1847=1852kHz

(1847*2)-1849.5= 1844.5kHz

The fifth-order would fall at:

(1849.5*3)-(1847*2)=1854.5kHz

(1847*3)-(1849.5*2)=1842kHz

You can see every increase in order spreads the signal another (F1-F2) up and down the band. In

the above case F1-F2 is 2.5kHz. The 7th order product would be 2.5kHz above and below the 5th order products. Any odd product adds bandwidth to the signal.

If the product is direct mixing or even-order mixing, mixing would be (1*F1)-(1*F2), (3*F1)-(1*F2), (2*F1)+(2*F2), etc. The "harmonic order" in the mixing would total an even number. Let's try that:

(1849.5*1)-(1847*1)=2.5kHz outside the passband of the transmitter and antenna!

(1849.5*1)+(1847*1)=3696.5 outside TX passband.

(1849.5*3)-(1847*1)=3701.5 kHz again outside the passband of the antenna and transmitter's RF section. This was the fourth order.

Even-order isn't a problem in RF transmitters. This is why push-pull RF amplifiers don't help audible distortion and don't help bandwidth. They do cut down on harmonic distortion making band-filter requirements less.

Keep these rules in mind:

- ***Any increase in frequency difference between the highest and lowest modulation frequency increases BW greatly.***
- ***An increase in level increases the strength of the IM product in even greater proportion than we might expect.***

Higher odd-order products create most of our SSB problems. This occurs because high odd-order products fall well outside the normal passband of a typical SSB transmitter, spreading wasted energy to adjacent voice channels.

Three Greatest Sins

The three greatest sins creating unnecessary bandwidth are:

1. ***Turning up a radio's internal power or "drive limit" pot.***
2. ***Enhancing Bass and Treble at the same time***
3. ***Under-loading an amplifier***

Radios

Some modern radios are especially poor, even when operated at rated power levels. For example,

the TS-2000 and IC-756 series radios are particularly bad on 160 meters. I can hear some of these radios, when signals are strong, producing weak spurious emissions (splatter) 10-20kHz away from the operating frequency. If you look at ARRL test reports of transmitters, you will see many radios are just a bit above class-C performance levels. (Remember the ARRL uses dB below PEP, which improves results by 6dB compared to commercial test methods.)

IM3 levels of -30dB are really very poor. An old KWM2 I tested was -47dB using ARRL standards. Compared to something like an IC-756, the Collins had about ***50 times LESS power*** in total adjacent channel distortion products!

Compression and Processing

Any type of speech processing or compression (even ALC) makes the IM problem worse, because the average level of F1 and F2 increase. It is the multiple tones in our voices that create the "original" tones that mix, so the more we put in the more that come out!

Processing is a double-edged sword, however, because it also limits the level of peaks. Decreasing the level of peaks compared to average power loads bias and power supplies more steadily, and can keep stages after filtering out of limiting or distortion. While it might bring the level of "low-level nasties" up, it also decreases the likelihood of high-level overdrive problems.

Light or modest processing is actually beneficial in reducing splatter!

ALC

ALC is normally slow and plagued with inherent problems. Filters in radios add group delay (the signal takes noticeable time to move through filters), and the ALC loop adds a time-delay of its own. The result is leading edge signal overshoot, which often shows up as an adjacent channel "spit" or "pop" on leading or rising edges of voice or CW.

Some rigs like the early 775DSP and IC706 are plagued with very high levels of overshoot. A new 775DSP I had actually overshot to around 300 watts on leading edges for a few milliseconds. Kenwoods and other radios also have this problem. This problem is not only harmful for bandwidth, it also can damage amplifiers. The problem often gets *WORSE* as power level is turned down!

Gain should be set so ALC just starts to take effect, if a drive control is available. Rigs like the FT1000D include a "Drive" adjustment.

WideFi or Enhanced Audio

Enhanced audio is a generally bad idea, since it adds and boosts unnecessary lows and highs. The audio processing brings the level of the extreme low and high frequencies up to abnormal strength. Since the frequency spread of the lows and highs is wider and the level is stronger, IM products also are wider and stronger. Enhanced or Hi-fi audio, even with perfect "brick wall" filtering, is wider than communications audio for a given RF amplifier quality.

Many of the radios popular with the HiFi crowd are among poorer radios for IM performance! My own opinion is HIFi is OK on emptier bands, but we should do all we can to discourage enhanced audio on crowded bands or near weak signal areas.

Transmitter Tests

The standard transmitter test is IM3 or higher order products. The general test uses two tones of equal level. If it is a radio, the two tones are fed into the audio port. If it is an amplifier, the tones must generally be from two separate transmitters generating steady carriers. The carriers are mixed through a combiner and used to drive the amplifier. The reason we use two separate transmitters in the test is most amplifiers, especially cathode driven triodes, are far cleaner than most modern radios. The test radio's two-tone IM would establish the IM distortion limit (not the amplifier, in most cases.

Confusing Conflicting Standards

In most commercial tests, we find the maximum power of one tone and compare that level to the level of third-order spurious signals created in the transmitter. The ARRL, for some reason, adopted a different reference. They compare the PEAK power of both tones to the spurious, rather than the level of one test tone. This inflates transmitter IM results, making everything appear 6dB better than it really is in the standard test used commercially.

If you look at Eimac data sheets, the IM specs are dB-below-one-tone of the two tones. If you look at data sheets from other sources, they might use dB below PEP. One manufacturer's US importer of Russian tetrodes used dB below PEP to compare the quality of their product to Eimac.

Unfortunately Eimac used dB below one tone, while the other tetrode test used dB below one tone, so the tetrode manufacturer wrongly proclaimed their tetrodes "cleaner" when in fact they were not. If you look at QST tests of ETO, QRO, and Ameritron amps you will see the 3CX800's in the AL800H greatly surpass the 4CX800's in the other amps for IM3 and IM5. This confusion is a clear example of how mixed standards gets us in trouble.

It's a Poor Test Anyway

Two-tone IM3 (or higher orders, like IM5) transmitter tests generally show us the very ***BEST*** a

transmitter will do. In general, two-tone tests are pretty poor tests for system designed to process speech. The two-tone test uses two steady signals (normally with wide spacing), but actual modulation has many frequencies that vary at syllabic rates.

In two-tone tests, the test spacing is generally a few kHz. The varying load on power and bias supplies is at the separation of the two frequencies. Small capacitors filter the time-varying load, while the long term dynamic load remains constant. Two-tone tests do ***NOT*** show power supply deficiencies.

Slow variations in speech level load and unload power and bias supplies. This causes supplies to "wobble around". The conclusion of some is that screen or bias regulation is "unimportant", but that conclusion is mostly rooted in the fact they use a very poor test method that does not show low frequency dynamic regulation problems.

A Better Test

There are two tests that are better. One test is an adjacent channel power tests, with normal voice modulation of the transmitter, another test I developed uses a three-tone signal.

The three tone test injects a third low-frequency tone into the system. Is anything from a warble to a low-pitched hum variation in power levels of the two major tones. The analyzer reads the peak amplitudes of mixing in higher frequency tones while the level is varied at a syllabic to low pitched audio rate. The low pitch amplitude modulation is varied in frequency until the worse case IM is produced.

The variation causes the power to change at a speech rate, testing supply regulation effects on wide spaced distortion at all important frequencies for speech.

The adjacent channel power test simply uses normal voice operation and compares the long term peak power in an adjacent channel to the peak power in the desired channel.

Either test gives a much more reliable indication of transmitter bandwidth than a two-tone test.

Remember, a two-tone test is generally a "best case" scenario.

Summary

A normal two-tone test is not really very effective in measuring a SSB signal, because there is no slow dynamic change typical of a voice. Voltage regulation problems are masked and do not show up when a two-tone test is used, because load currents all average the same amount. Filter capacitors and other energy storage components mask any voltage regulation problems. We can, as

a general rule, be confident the actual SSB voice performance is LESS than a two-tone test indicates.

A large improvement occurs with a three-tone test, when levels are varied at syllabic rates as well as higher frequencies in the voice range. This tests voltage regulation problems otherwise hid in a two-tone test, because all speech frequencies ranges are included. The most accurate test, of course, is with actual speech. The FCC now requires some commercial radios used on congested bands to be tested with actual speech.

We can help ease spectrum pollution by:

- **Strongly discouraging use of enhanced bass and treble on crowded bands. It has no place on crowded band or near weak signals. Wide-Fi is selfish and inconsiderate even when it uses a 3kHz filter because of the increase in level and frequency spread of IM products.**

- **Discouraging and chastising people would turn the power limit or drive limit control inside radios up. This is CB behavior! There isn't a radio made that will tolerate a user-increase in power limit without a serious degradation in IM performance. If you have a friend who peaks up the power control inside a radio, tell him why it is bad. Radios are bad enough without removing even more headroom. Even the best transistors cannot be driven more than about half of saturated power before IM becomes unacceptable.**

- **Making sure we use processing and ALC, but only at modest levels. We should just see the needles start to show compression.**

- **Making sure we tune amplifiers correctly, and avoiding 12 volt transistor amplifiers or grid-driven tetrode amplifiers whenever possible.**

MFJ-259B Calibration

[Home]

©2003-2004 W8JI

Revised 8/24/03

History:

I worked with another contract engineer (my friend JB) in designing the MFJ 259 and 269. No one else outside of MFJ was involved, and certainly no one named Ted Hart.

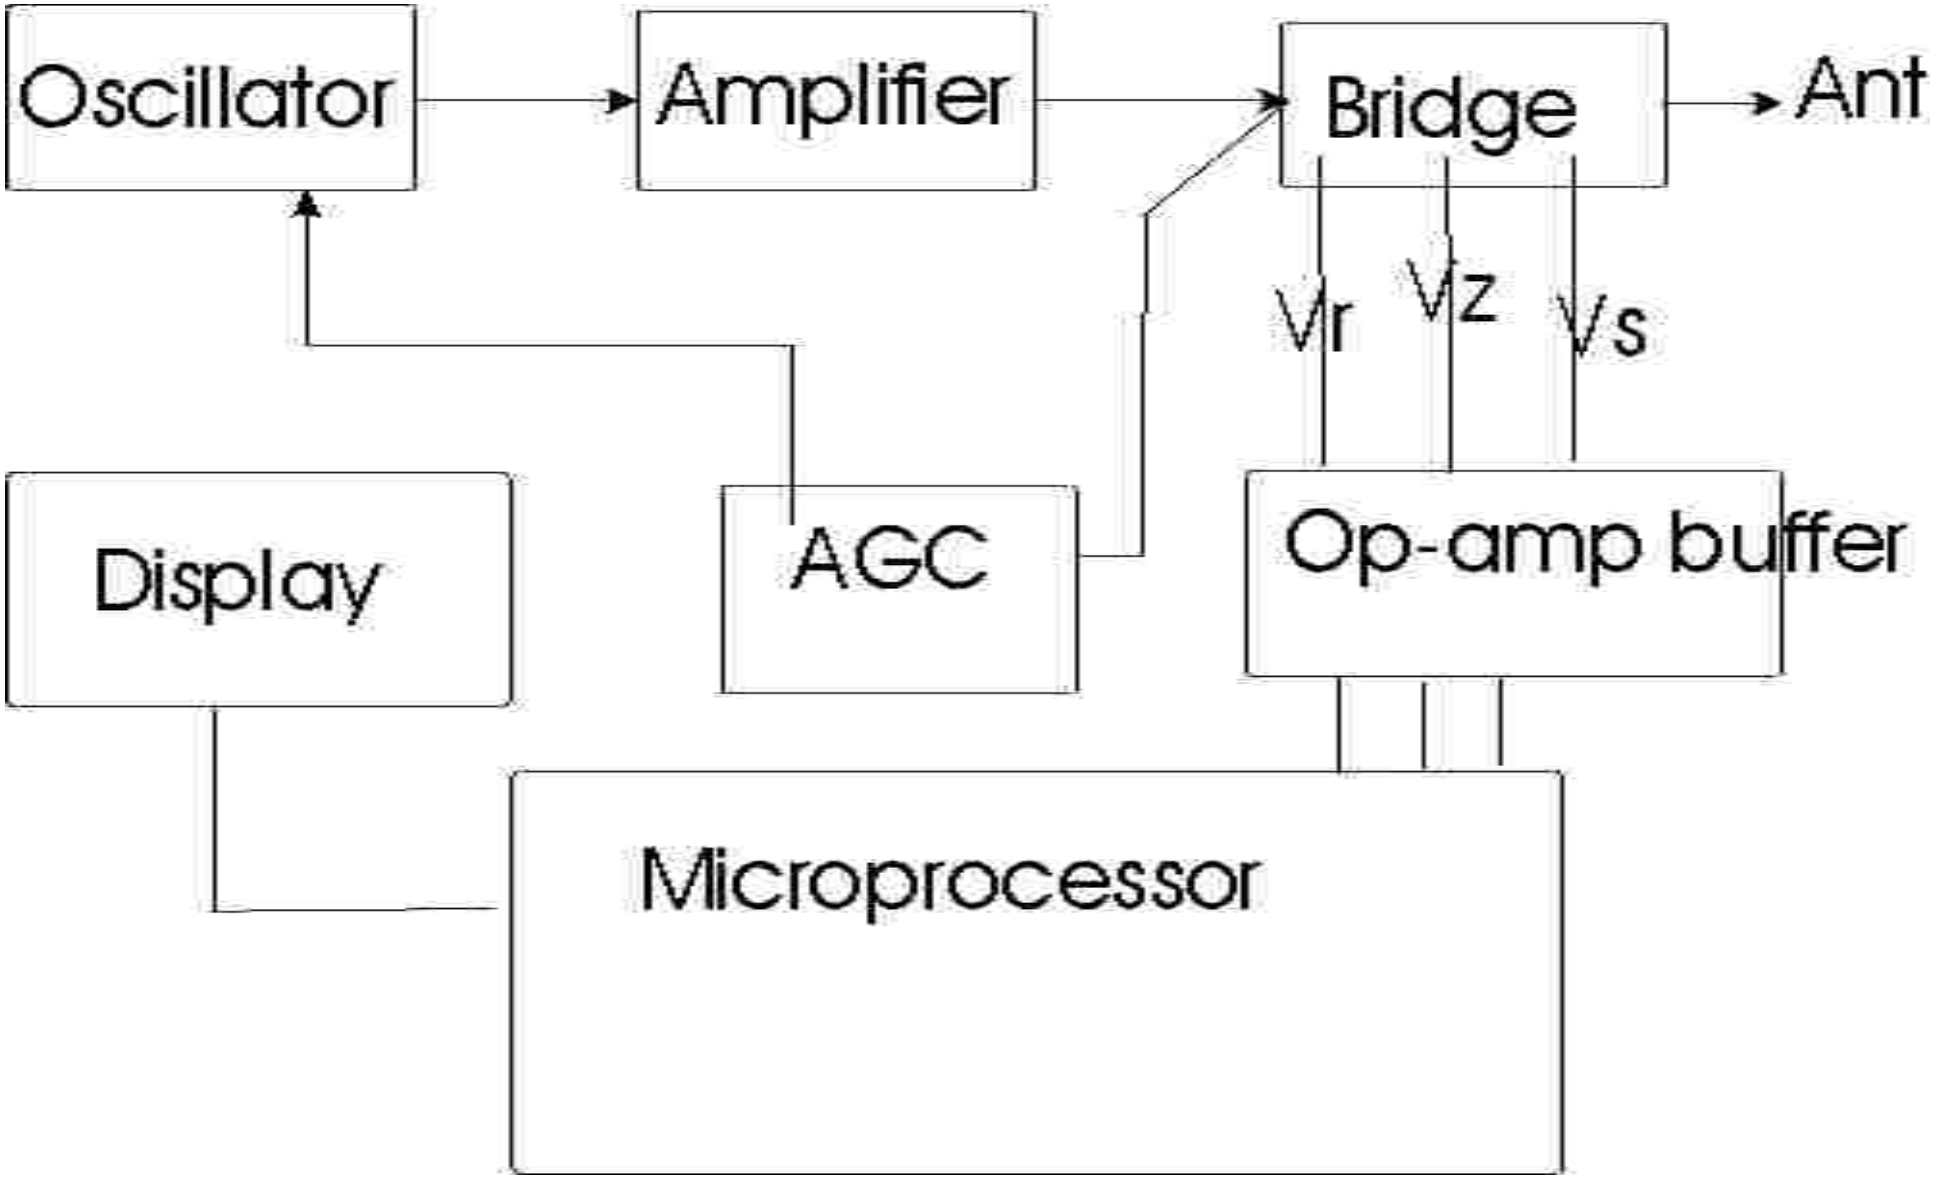
This information is here because it is the correct way to calibrate the MFJ-259B analyzer. This work is all donated. K1BQT took an instruction set supplied by MFJ and re-wrote it. I modified, expanded and edited that work. This page is the result.

It is best that no one copy this, and start handing it out in mass. The only reason for this request is there must be a point of control of information, so it can be corrected or expanded as errors or omissions are found.

I am not aware of any other source that gives correct calibration procedures. It is important that the 259 be calibrated by these steps, even if they sound complex. If you don't do it right, don't do it. Without following these steps, many special functions may not work correctly even if the unit tests properly on calibration loads!

How This Type of Device Works

This type of analyzer contains an RF oscillator, a linear amplifier to increase power, and an internal resistor bridge in a conventional Whetstone bridge configuration.



Since it is designed to be inexpensive, there are a few shortfalls with this system.

The bridge is dc-coupled from an internal resistor bridge to the antenna port. The bridge detectors are NOT frequency selective, and respond to anything from minor dc offsets through microwave signals. This causes a potential problem if there is ***any*** voltage appearing across the antenna port, from dc through microwave. (This is also true for competing analyzers from other manufacturers.) There are multiple reasons why, at the time of design, these units were dc coupled with broadband detectors. Hopefully someday a higher cost-design with selective detectors will become available, but for right now

this is all that is available for amateur use from any manufacturer.

The second shortfall is the internal amplifier must be linear and have very low total harmonic content. Total harmonic power, at the lowest load impedance, must be down at least 25dB and preferably 35dB. This is true for ***ANY*** antenna analyzer, since you do not want the analyzer to measure the load at two frequencies!

Because the detector is broadband and because it is dc coupled to the antenna, any external voltage across the input port causes measurement errors. It is the **accumulated voltage of multiple sources** that is most important, not the strength of any individual signal. Because of that, large antennas should be tested at times when propagated signals in the range of the antenna's response are at minimum strength.

A definite RFI improvement occurs with a bandpass filter, but multiple-section bandpass filters cause impedance measurement problems. Multiple-section filters behave like transmission lines of random line impedances, loss, and lengths as frequency is varied. The best solution is to use a single-stage bandpass filter and dc isolation on large arrays or with long feedlines. I often use a good 1:1 isolation transformer for measurements, and often find a parallel L/C filter (like the MFJ-731 Filter) useful.

Most Likely Failures

Other than manufacturing errors, the **detector diodes clearly stand out as the most common problem. They are the most easily damaged devices in the analyzer.** If you have a sudden problem, it is most likely a defective detector diode. Diode damage almost always comes from accidentally applying voltage on the antenna port.

Why are the diodes so sensitive? In order for the detectors to be accurate within a fraction of a percent (one bit), detector diodes must have very low capacitance and a very low threshold voltage. This means the diodes, through necessity, must be low-power zero-bias Schottky microwave detector diodes. The same characteristics that make them accurate and linear cause the diodes to be especially sensitive to damage from small voltage spikes. ***ALWAYS discharge large antennas before connecting them to the analyzer! Never apply external voltages greater than 3 volts to the antenna port!***

Technical Support

From time to time MFJ gives incorrect advice on the 259B and other analyzers. One bad piece of advice that has come to my attention concerns measuring stubs. Someone in MFJ support has been telling customers that the manual is wrong, but the manual is actually correct! The person in support is wrong.

A problem with measuring stubs and cable lengths occurs if the harmonics are high in the 259 or 269, or if you do not tune for lowest X and minimum impedance and store that impedance, and then move to the VERY NEXT minimum X and lowest impedance. Whatever anyone tells you at MFJ, that is how it has to be done.

How This Unit Works

This is a rough outline of how this unit works:

The MFJ-259B, and other digitized MFJ antenna analyzers, compare three major voltages in a 50-ohm bridge circuit. They are:

Vz= Voltage across the load. This voltage is called Z in the alignment display menu

Vr= Voltage indicating bridge balance. This voltage is called R in the alignment display menu

Vs= Voltage across a 50-ohm resistor between the RF source and the load. This voltage is called S in the alignment display menu

All voltages are converted through an eight-bit A-D converter to a 256-bit digitized output with a test-display range of 0-255 bits. By knowing the ratio of these voltages, as compared to the regulated RF source voltage, many different load parameters can be calculated. An antenna analyzer could calculate everything (except sign of reactance) from measuring only Vs and Vz, but at certain impedances any small error in either Vs and Vz becomes critical. This is especially true when voltage is digitized into a 256-bit format (~0.4% steps). At certain impedances, an almost immeasurable voltage change will cause a sudden large jump in the measured impedance parameters.

To reduce display impedance jumps, SWR is weighed into the calculation of reactance and resistance at low SWR values. (An SWR bridge is most accurate when the load is closest to 50 ohms, which is a primary measurement area where impedance measurements through Vz and Vs become critical.) By factoring in a direct SWR measurement from an internal bridge, the analyzer can check and "correct" any small level errors in Vs or Vz. This reduces the impedance jump that would occur with a one-bit jump in voltage. This also why bits must be calibrated for near-perfect accuracy. a one-bit error can cause a resistive load to appear reactive (the total of Vs and Vz must always be 255 bits or less for a load to be considered resistive).

Calibrating the MFJ-259B Antenna Analyzer

This calibration procedure is the correct procedure for later MFJ-259B's. Disregard any other information. Since MFJ-259B firmware has several versions under the same model number, you may find some final performance verification steps not valid. These steps will involve parameters that do not appear on the display.

Be sure you have printed a copy of the board layout showing adjustment points, have read all this, and have suitable loads before proceeding.

Adjustments

This unit has tracking and gain adjustments for Vz, Vs, and Vr. Tracking is set at low voltages (low bits). Gain is set at high voltages or bits. Together they make the detector voltage output closely track the actual RF voltage.

This unit also has meter calibration adjustments. The analog meters almost certainly suffer from some scale linearity problems, they will be somewhat less accurate than the digital display. These adjustments only affect analog meter readings. The meter adjustments do not affect the display.

Quiescent current (bias) in the RF amplifier section is adjustable. This adjustment directly affects output signal harmonic content. Harmonics are worse with low supply voltages, and with low impedance loads. ***Be sure you check the harmonics as outlined below, with a 1/4 wl open-circuit stub!!***

Excessive harmonics can cause severe errors in measurement of frequency-selective loads, even when dummy-load SWR tests appear perfect. Loads most sensitive to harmonic-induced errors include, but are not limited to, antenna tuners, tank circuits, very short resonant antennas, and distance to fault and stub length measurements. If you notice something "funny" going on with a stub measurement, it may be a fault of incorrect bias.

Warning: Never calibrate around a sudden "problem" that appears. If a detector suddenly shifts voltage, the problem is almost certainly a defective detector diode. If the meter is recalibrated with a defective (leaky) diode, the meter will probably NOT track correctly with frequency.

Alignment

Tools and Equipment:

[ ] #2 and #1 Phillips-head screwdrivers

[ ] Digital meter or accurate analog meter for checking supply voltage

[ ] Small set of non-metallic alignment wands for coils, or small jeweler's screwdrivers for controls

[ ] Power supply, regulated to 12-volts + - 5%

[ ] General-coverage receiver with level meter or Spectrum Analyzer (these are optional with additional work and use of a stub)

[ ] ~10 MHz 1/4wl open-stub, for example 15’ good-quality solid-dielectric RG-8, UHF connector at on end, open on other (not needed with analyzer or receiver)

[ ] 2.2-ohm 1/4 or 1/2 watt film resistor (not needed with stub)

[ ] Accurate load set to include:

A. Short

B. 12.5-Ω load

C. 50-Ω load

D. 75-Ω load

E. 100-Ω load

F. 200-Ω load

Note 1: Loads must be constructed using physically small 1% carbon-film resistors.

- **DO NOT use large resistors. Acceptable results will be obtained when load resistors are mounted in the very bottom of a UHF-male connector.**
- **The ideal load resistors are surface-mount precision-resistors, but other styles will work. It is acceptable to parallel multiple resistors to obtain low resistances, but don't series connect more than two resistors!**
- **Never use physically large resistors, such as 1-watt or larger resistors, unless you are absolutely positive they are composition-types (very rare).**
- **Since the loads are used to set the number of bits in critical calculations, the maximum reactance error will always be worse than the percentage of resistive load error. *A one bit error in calibration (~ .4%) can cause a purely resistive load to read reactive.***

Quick-connect loads can be made with surface mount resistors on a BNC male chassis mount connector with the bayonet removed. This makes a "quick connect" connector that will slide directly into a type-N female. In this case, use a good UHF to BNC female adaptor for the 259 units. With a 269, the load will plug directly in to the N female.

Note 2: The power source should be the LOWEST expected operating voltage. DO NOT use a standard "wall-wart" or batteries! You can reduce voltage from a conventional 13.8v regulated supply by adding a few series diodes. Silicon diodes will normally drop about 0.6volts or so per diode. Three or four diodes will reduce place the voltage below 12 volts.

WARNING: The MFJ-1315 AC adapter or other "wall-warts" should NOT be used to power the unit for most alignment steps.

Step 1

Visual Inspection: Before, during, and after calibration, be mindful of physical condition. Watch for missing or loose hardware. Do not tug, stress, or repeatedly flex leads, or carelessly flop or toss things about. Keep your bench clean. Follow these rules the entire time you have the unit apart!

Step 2

Battery Tray Removal: This step provides access to trim-pots and most inductor adjustments.

[ ] Remove last two batteries at each end of the tray.

[ ] Remove two screws (right side) and extract the tray.

[ ] Always position the battery tray to minimize strain on wires.

Refer to the board layout pictorial for specific control locations.

Step 3

Band Overlapping: Each band should overlap the next by a small amount to ensure gap-free coverage from 1.8 MHz to 170 MHz. While viewing the *LCD Frequency Display*, wiggle the bandswitch from side-to-side gently. Watch for any display or meter dropout. Check each band as follows:

[ ] **114-170 MHz:** Oscillator tunes from below 114.0 MHz to above 170.0 MHz. Check tune for dead spots.

[ ] **70-114 MHz:** Oscillator tunes from below 70.0 MHz to above 114.0 MHz

[ ] **27-70 MHz:** Oscillator tunes from below 27.0 MHz to above 70.0 MHz.

[ ] **10-27 MHz:** Oscillator tunes from below 10.0 MHz to above 27.0 MHz.

[ ] **4-10 MHz:** Oscillator tunes from below 4.0 MHz to above 10.0 MHz.

[ ] **1.8-4 MHz:** Oscillator tunes from below 1.8 MHz to above 4.0 MHz. Check tune for dead spots.

*While verifying overlap, at least check the lowest and highest bands carefully for dead spots. The LCD Display will indicate 000.000MHz if a dead spot occurs. Dead spots generally indicate a defective tuning capacitor (**TUNE**).*

If you find wiggling the switch causes a dropout, the switch may have dry or dirty contacts. Less likely are poor solder joints, but check solder joints first. If you must clean and lubricate the switch, be aware it is a difficult task. The entire board needs to be lifted from the case front. Dirty band-switch contacts may be restored with spray tuner cleaners. The best place to spray the switch is from the front side (shaft side), right below the nut. You must remove the switch indexing tab retainer nut and the metal switch retainer (stop) under the nut. Be sure the stop goes back exactly as removed.

To correct overlap problems, locate and retune the appropriate VFO coil (see Pictorial for coil locations). Note that L1-L4 are slug-tuned and require an insulated hex-head tuning wand. If you use the wrong size wand or a worn wand, it will break a slug!

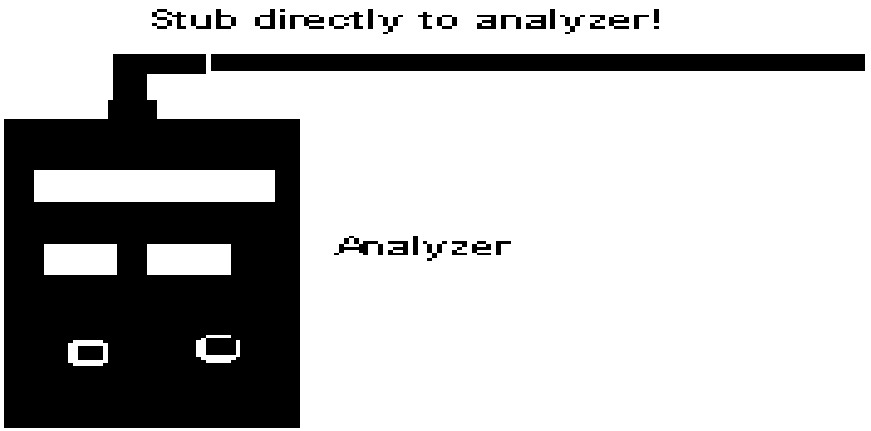
Inductors L5 and L6 are located on the component side of the board and are compression-tuned (press turns closer together to lower frequency or spread apart to raise frequency). Make only very small corrections--*especially to L5 or L6*--and recheck the band you are adjusting. You should also check the *next lower band* after each adjustment to ensure that the lower band hasn't moved excessively.

Important Warning: VFO coils MUST be aligned from highest frequency to lowest frequency. The next higher range affects next lower band the greatest amount. Do not attempt VFO coil adjustment unless you are experienced working with VHF-LC circuitry or complex alignment procedures.

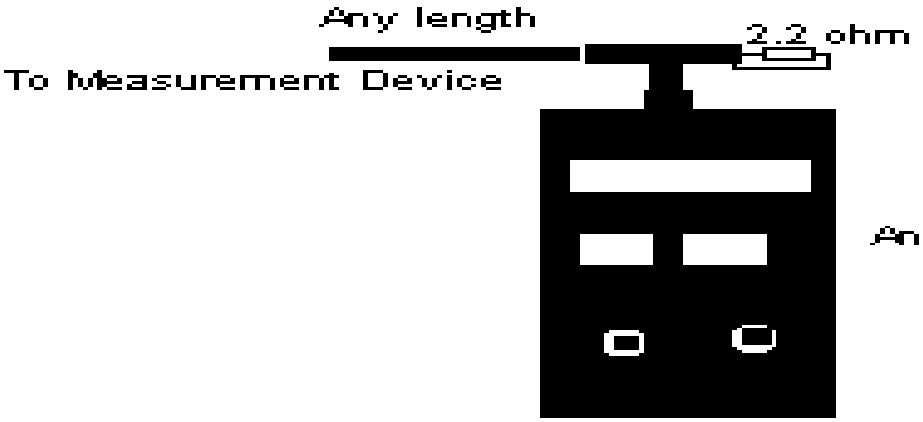
Step 4

Harmonic Suppression/ Bias: Connect the analyzer ***exactly*** as shown below.

- The impedance of the cable to the measurement device should match the impedance of the measurement device.
- The "T" must be connected either directly to or placed within a few inches of the analyzer.
- The power source must be the lowest expected operating voltage.
- The measurement device must be well-shielded, and not pick up any substantial signal from the analyzer when the "T" is disconnected from the analyzer.



Test Setup Using Internal V2 for Harmonics



Test Setup using External Analyzer and resistor for Harmonics

Step 5

Harmonic Suppression (bias R89): This adjustment reduces oscillator harmonics. Harmonics will cause incorrect readings under some load conditions.

WARNING: ***Incorrect adjustment of R89 will NOT show when checking with resistive dummy loads!!! The unit will appear to calibrate correctly, but will produce errors in stub length, distance-to-fault, and other frequency selective functions.***

When R89 is set properly, harmonic suppression of –30 to –35dBc should be possible across most of the analyzer's tuning range. This particular

adjustment must be made at the lowest expected operating voltage. Proper alignment requires a 12.0-volt regulated supply as a power source. NEVER use an AC adapter or any supply voltage higher than 12-volts when making this adjustment. A calibrated spectrum analyzer works best for monitoring harmonic output, but a well-shielded general-coverage receiver with signal-level meter will also work. The receiver MUST be "T'd" into the analyzer just as the spectrum analyzer is, and the Tee and resistor must be located at the analyzer connector. If you do not have a good-quality receiver or spectrum analyzer, use the test mode of the analyzer with a stub. Watch MFJ analyzer test-mode Vz. Test-mode Vz will roughly indicate total harmonic voltage when the analyzer is set at the stub's exact resonant frequency. Entering the test mode is described in Detector Calibration (Step 6).

[ ] **a.** Install either a 15' RG-8 open stub, or resistor and measurement device, and tune analyzer to approximately **10 MHz**.

[ ] **b. (stub and internal Vz use only)** Observing Vz on the data display (analyzer test mode), adjust frequency until the *lowest* fundamental output reading (or lowest impedance) is obtained. You should clearly see the MFJ analyzer's fundamental frequency output voltage (Vz) go through a deep null.

[ ] **c.** Observe the analyzer frequency reading. This is the approximate resonant frequency of the stub, and the test frequency.

[ ] **d.** Without changing the analyzer test frequency setting, observe the second harmonic level. This harmonic will be at twice the MFJ analyzer frequency counter reading..

[ ] **e.** Adjust **R89** for **lowest 2nd harmonic meter reading** on the receiver, lowest Vz test-menu reading, or lowest harmonic level on the spectrum analyzer. Be SURE the fundamental frequency level remains nulled in the analyzer.

WARNING: Always repeat steps (b) through (e) at least one extra time when relying on display Vz. The original null point of any stub will shift if there is a substantial reduction in harmonics after R89 is adjusted. The original stub frequency, as observed at (c), will probably change slightly. It is NOT necessary to recheck when doing a resistor load test with a good-quality spectrum analyzer or receiver. With a resistor, exact test frequency is NOT critical.

NOTE: If you have a poorly performing spectrum analyzer or receiver with limited dynamic range, use a stub with the spectrum analyzer or receiver instead of a 2.2 ohm resistor. If you have a reasonable quality spectrum analyzer or receiver (at least 50dB dynamic range) use a 2.2-ohm non-inductive resistor in lieu of the stub, resistor adjustment is easier and more accurate.

Detector Calibration

Step 6:

This critical sequence calibrates A-D conversion for various load conditions. If you know your unit has been tampered with, preset trim pots **R88**, **R89**, and **R90** to their center positions before continuing. If you find any control bottoms-out in adjustment, you almost certainly have installed an incorrect load or the analyzer has a defective detector diode.

To prepare for detector tracking alignment, place the analyzer in *Test Mode*. Entering test mode may be tricky with some units, and it may take practice. To enter *Test Mode*:

[ ] Turn power off.

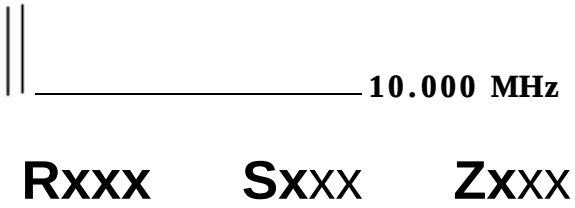
[ ] Hold down ***MODE*** and ***GATE*** buttons while restoring power.

[ ] As display comes up, slowly (about 1 second period) rock between pushing the **MODE** and **GATE** switches alternately (the best method is to use two fingers, and rock your hand from side to side between the two buttons)

[ ] Confirm analyzer has entered test mode (it may take more than one try).

[ ] Using the **MODE** button, advance display to the **R-S-Z** screen (shown below).

Note: If you go past the R-S-Z screen, you can still see R-S-Z by pushing and holding the MODE button.



[ ] Tune analyzer operating frequency to approximately **10.000 MHz**

[ ] Leave antenna connector **Open**

[ ] Set **R72** for **Z=255**

[ ] Install the **Short**

[ ] Set **R73** for **S=255**

[ ] Install **12.5-Ω** load

[ ] Set **R90** for **Z=051**

[ ] Set **R53** for **R=153**

[ ] Install **200-Ω** load

[ ] Set **R88** for **S=051**

[ ] Set **R72** for **Z=204**

[ ] Install **75-Ω** load

[ ] Set **R89** for **R=051**

[ ] Install **12.5-Ω** load

[ ] Reset **R90** for **Z=051**

[ ] Set **R73** for **S=204**

[ ] Reset **R53** for **R=153**

[ ] Install **200-Ω** load

[ ] Reset **R88** for **S=051**

[ ] Verify or set **Z=204**

[ ] Install **75-Ω** load

[ ] Reset **R89** for **R=051**

Important Note: **Small single-turn trimpots are touchy to adjust and tracking settings are somewhat interactive. If specified readings aren't obtained on the run-through, repeat the sequence a second time (accuracy counts). When the sequence is complete, turn power off to remove the analyzer from *Test Mode*.**

Be particularly mindful of the total bits of Vz and Vs. If the sum of these bits ever exceeds 255 with a resistive load, the analyzer

will indicate reactance.

Display Test and Analog Meter Calibration

Step 7:

This step sequence checks meter calibration and verifies accuracy of the *LCD Display* information.

Remove and re-apply power and enter the *Real-Imaginary* impedance mode **R-X**. Readings + or - 10% of reading or + or - 5 ohms of display, whichever is larger, are considered within design specifications. Typically digital readings are almost perfect with proper detector calibration. Analog meter readings may be outside that range, and as much as 20% off with some load values.

[ ] Install **75-Ω** load

[ ] Verify reading of **R= 75 X=0** on *LCD Display* (±10%)

[ ] Install **50-Ω** load

[ ] Verify reading of **R=50 X=0** on *LCD Display* (±10%)

[ ] Set **R67** for reading of **50** on the *Impedance Meter*.

[ ] Verify reading of **1.0** *SWR Meter* (no deflection).

[ ] Install **Open** load

[ ] Verify reading above **400** on *Impedance Meter*

[ ] Install **100-Ω** load

[ ] Verify reading of **R=100 X=0** on *LCD Display* (±10%)

[ ] Verify reading of **100** on *Impedance meter* (approximate).

[ ] Set **R56** for a reading of **2** (2:1) on the *SWR Meter*

[ ] Install **12.5-Ω** load

[ ] Verify a reading of **4:1** SWR on *LCD display* (3.8-4.2 good)

[ ] Verify reading of **>3** (greater than 3:1) on *SWR Meter*

[ ] Install **200-Ω** load

[ ] Verify reading of **4:1** SWR on *LCD display* (3.8-4.2 good)

[ ] Verify reading of **>3** (greater than 3:1) on *SWR Meter*

Capacitance Mode Check

Step 8:

If you have a few precision capacitors, you can verify the calibration between the ranges of 100 and 5000 pF. Read the analyzer manual for details of capacitor measurement.

[ ] Install no load

[ ] Set *Mode* to *Capacitance*

[ ] Set VFO to **70 MHz**

[ ] Verify **4-6 pF** reading on LCD Display

Frequency Counter Check

Step 9:

These steps verify accuracy of the counter. Note that the counter's clock isn't user-accessible, so no adjustments will be made. To conduct this test, use a general-coverage receiver in AM mode.

[ ] Tune in **WWV** on 5.0,10.0,15.0, or 20.0 MHz (frequency with best reception).

[ ] Install a short clip lead or wire in the analyzer's *Antenna* jack.

[ ] Turn on the analyzer and **zero-beat the WWV signal** as closely as possible.

[ ] Compare *LCD Display* reading to the WWV frequency being used.

[ ] Verify agreement is within ±**5 kHz.**

Advanced Modes Check

Step 10:

This sequence verifies operation of the analyzer's advanced features. To enter *Advanced Mode* menu:

[ ] Turn unit off.

[ ] Hold down the MODE and GATE switches while turning power on.

[ ] Verify "*Advanced"* appears on the *LCD Display*.

[ ] Install **Open** load

[ ] Tune VFO to **>170 MHz** (top end of coverage range)

[ ] Verify **Z** = **<650 Ω** with (about) **90**° phase shift

[ ] Install RG-8 open stub

[ ] Tune VFO for minimum **Z** reading (around 10 MHz)

[ ] Verify **Z-min = 0** to **2 Ω**

[ ] Install **50-Ω** load

[ ] Set VFO to **1.8 MHz**

[ ] Verify **Z = 50** Ω, θ = **0**°, and **SWR = 1** (±10%)

[ ] Enter **RL** *Mode* (return loss)

[ ] Verify **RL = >42 dB**, ρ = **0**, **SWR = 1**

[ ] Enter *Match Efficiency Mode* (skipping *DTF Mode*)

[ ] Verify **ME ≅ 100%** (approximate)

[ ] Press and hold MODE and GATE buttons to restore *Main Modes*

[ ] Remove load and verify **Z = >650** on *LCD Display*

Conclusion:

Step 11:

[ ] Reinstall battery tray

[ ] Confirm charger jumper is set for type of batteries used (disable for alkaline).

[ ] Reinstall cover

This completes calibration.

MFJ-259B Calibration Checklist

Make a copy and check each box as you proceed down the calibration list.

Physical Condition

[ ] Hardware, batteries okay

Harmonic Check

[ ] Suppression -35 dBc or better

Overlapping

[ ] All bands have sufficient overlap

Check Digital Calibration at 10 MHz in test mode.

[ ] **Open**

[ ] R72 for Z=255

[ ] **Short**

[ ] R73 for S=255

[ ] **12.5-Ω**

[ ] R90 for Z=051

[ ] R53 for R=153

[ ] **200-Ω**

[ ] R88 for S=051

[ ] R72 for Z=204

[ ] **75-Ω**

[ ] R89 for R=051

[ ] **12.5-Ω**

[ ] R90 for Z=051

[ ] R73 for S=204

[ ] R53 for R=153

[ ] **200-Ω**

[ ] R88 for S=051

[ ] Verify Z=204

[ ] **75-Ω**

[ ] R89 for R=051

Analog Calibration: 10 MHz, values approximate

[ ] 75-Ω

[ ] Verify R= 75 X=0

[ ] **50-Ω**

[ ] Verify R=50 X=0

[ ] Set R67 for 50 on Imp Meter.

[ ] Verify 1.0 on SWR Meter

[ ] **Open**

[ ] Verify >400 on Imp Meter

[ ] **100-Ω**

[ ] Verify **R=100 X=0**

[ ] Verify 100 on Imp Meter

[ ] R56 for 2 (2:1) on SWR Meter

[ ] **12.5-Ω**

[ ] Verify 4:1 on LCD (3.8-4.2)

[ ] Verify >3 on SWR Meter

[ ] **200-Ω**

[ ] Verify 4:1 on LCD (3.8-4.2)

[ ] Verify >3 on SWR Meter

Capacitance Mode Check

[ ] **Open**

[ ] Set VFO to 70 MHz

[ ] Set Mode to *Capacitance*

[ ] Verify C≅4-pF

Counter Check

[ ] Counter Okay

Advanced Modes

[ ] Tune to 170 MHz

[ ] **Open**

[ ] Verify <650, Phase ≅ 90°

[ ] **3' RG-58**

[ ] Tune for Z-min (≅150 MHz)

[ ] Verify Z= 0-2 Ω

[ ] **50-Ω**

[ ] Tune to 1.8 MHz

[ ] Verify Z=50 Ω, θ=0°, SWR=1

[ ] Advance to Return Loss

[ ] Verify RL=>42dB, ρ=0, SWR=1

[ ] Advance to Match Efficiency

[ ] Verify ME ≅ 100%

[ ] Restore Main Modes

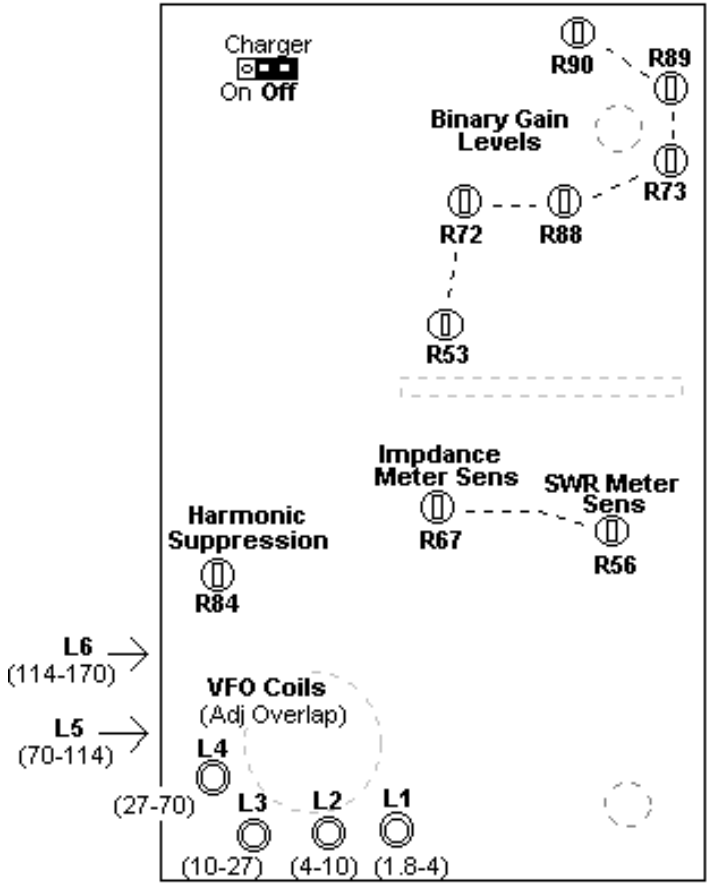
[ ] **Open**

[ ] Verify Z=>650

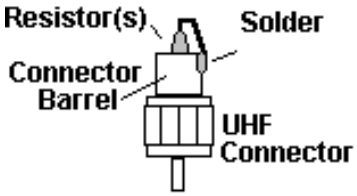
End of Procedure

Pictorial Diagram of Analyzer Board

Locations for trimpots and inductors



Loads Using Standard-Value Resistors



- Install resistors all the way down in the connector, the goal is zero lead length

.

- Use precision 1% carbon or metal film 1/8th-1/4 watt resistors

12.5Ω = (4) 50-ohm or a single 15Ω and 82Ω 1% in parallel

50Ω = 49.9-ohm or 100Ω and 100Ω in parallel

75Ω = 75-ohm or 150Ω and 150Ω in parallel

100Ω = 100Ω

200Ω = 200-ohm or 100Ω + 100Ω in series

Important Note: *These simple HF loads will not always be accurate for SWR checks above 30 MHz. Only precision terminations should be used in the VHF region, and even then there can be some errors. The MFJ-259B does not correct for connector impedance bumps or the electrical length between an external load and the bridge inside the unit.*

RF Noise Powerstroke Diesel

[Home]

Related pages:

mobile antennas Loading coils Field Strength Measurements

RFI measurements showed HF noise at a distance of 5 meters from my 2003 Power Stroke was 15-20dB less than my 1995 F-250. I never could get all the noise out of my 7.3L 1995 F-250 HD PSD. The measurements of noise field a small distance from the truck gave me great hope I could have a better HF mobile with minimal work.

I am delighted to report my 2003 F-250HD PowerStroke diesel has virtually no RFI with only very simple and fast corrections. Be aware this is for my antenna mounting location, and my style of truck. This is a new old-stock truck I found at a small rural dealer for a *very* good price!

Antenna Mounting Location

I mounted the antenna in the stake hole of the bed that is located just behind the cab on the driver's side. I use this location because:

1. I do not want to drill holes in a new truck
2. I have no topper or camper shell to mount the antenna to
3. I want maximum performance
4. I would like to remove the mount if necessary

Antenna Mount

My antenna mount is home made. It is formed from a scrap sheet of stainless steel that looks to be about 7 gauge. In order to make the mount, I went though the following process:

1. bent two angle-sticks of metal that match the rectangular dimensions of the stake hole
2. TIG welded a 3/4inch nut inside one L to match the height of the existing Ford bolt hole
3. TIG welded the L's into a rectangular tube
4. TIG welded a few sharp points on the tube near the bolt hole to break the paint for a ground connection
5. bent a wide long plate into an L that matched the size of a Tarheel mount
6. added holes to match the Tarheel plate
7. TIG welded the bent plate to the end of the tube
8. added gussets to brace the bend, since that was a weak area that allowed the antenna to flop around too much
9. cut a 4" square load spreader out of 3/16 inch thick scrap stainless
10. drilled a hole in the load spreader plate
11. cut square of rubber as a buffer to prevent damage to the trick's bed rail top

You can see where I get my shield ground connection. I feed the antenna with the single wire to the lug normally used to mount the impedance correction coil. I mount my impedance correction coils on PL-259 plugs so I can change them easily. I screw them into the SO-239 connector normally used as a feed!

Noise Noise Noise

When the antenna was installed, I had S-7 injector noise on my IC-706. I cured it with the following:

I removed the Tarheel motor line choke bead because it was far too low an impedance. I was receiving on that lead, and it was bringing RF back into the cab, I use my own jumbo size 44 mix bead.

You will probably find most frame-type vehicles mount passenger compartments on rubber mounts to reduce noise and vibration. The cab is only grounded at the front. The bed is bolted solidly to the frame, and this means all RF currents must travel down the bed to the frame, follow the frame forward to the front of the cab, flow back along the cab towards the antenna. This actually makes a very short thick antenna out of the truck frame and cab of the truck! The common mode currents excite all the wiring under the vehicle, increase ground losses under the truck, and increase noise ingress from truck wiring into the antenna.

To cure the common mode current problems, I added a ground strap between the bed and the cab.

You can make the connection UNDER the chassis at the locations shown in the following picture:

Note that I heavily tin the edges of the 1" braid. I do this insure all of the braided wires stay fully in contact all of the time. The flex area must remain solder free.

I use stainless thread cutting screws, and stainless external tooth star washers under the braid in the tinned area to cut through the paint.

Adding this single strap made the following changes:

The base resistance of the antenna dropped from 45 ohms to 25 ohms on 7 MHz. This mean I greatly reduced radiation from the truck body or frame.

Noise level dropped 2-3 S units

RF in truck wiring dropped substantially

Remaining Noise

A small amount of noise remained audible after the grounding. I traced this noise to radiation from the exhaust system. The engine block was

hot with RF, the injector control modules are mounted on the block and have leads that leave to other wiring in the truck. This lets the injector modules "push" against the wiring in the truck, making the poorly grounded engine block pump up and down with pulse voltages. Since the exhaust system bolts to the engine with a direct conductive path through the turbocharger, the tailpipe is actually excited just like an antenna.

I cured ALL of the remaining noise with the addition of one more ground strap between the exhaust and the frame just ahead of the muffler.

You can see the widening of the pipe as it expands into the muffler, with the fuel tank and transfer case in the background. The strap grounds under a nut used for the exhaust hanger. As before, I tin the leads and use stainless star washers to help maintain connections. Notice I clamped the strap under the factory exhaust joint clamp.

I now have absolutely no noise at all from the diesel engine on any band.

Skin depth and Conductors

[Home]

The following short article is about Litz wire, braid, and skin depth. It is still being expanded.

The best explanation of skin depth I have seen is in Circuits and Networks (by Koehler) on page 196:

conductor with return path at a distance equal to several times the diameter of the conductor. Assume that an emf is applied between the two ends of the conductor and further assume that the conductor is divided into many concentric cylinders of equal cross-sectional area. Now if the current density were uniform over the entire cross section, the total current in each cylindrical shell would be the same. The magnetic flux encircling the innermost cylinder would be larger than that of the outermost cylinder. Since the voltage drop along each of the cylinders is made up of a resistance drop (IR) plus a reactance drop (jIX), the reactance drop along the innermost cylinder would be higher than that of the outermost cylinder because of the greater flux. Obviously this cannot be true because the voltage drop across all cylinders must be the same, i.e., the impressed voltage. Consequently, the current density changes in such a manner as to equalize all voltage drops. This results in a higher current density toward the outside surface of the conductor. This effect, called skin effect, is a function of the frequency, permeability, conductivity, and diameter of the conductor. It causes the conductor to have a higher ac resistance than dc resistance because it effectively reduces the size of the conductor by virtue of the decrease in current density from the outside to the inside portion of the conductor. The current not only decreases in magnitude but also changes in phase with reference to the current at the surface. At high frequencies, dependent upon the size of the conductor and its electrical properties, most of the current may flow only in a very thin outer cylinder.

An exact mathematical analysis of current distribution in a cylindrical conductor shows that the current density is given in terms of Bessel functions of a complex argument that involves the distance from the center divided by δ where $\delta = 1/\sqrt{\pi f \mu \sigma}$; μ is the permeability and σ is the conductivity. When δ is very small compared to the radius of the conductor the ac resistance of the conductor is substantially the same

the conductivity. When δ is very small compared to the radius of the conductor the ac resistance of the conductor is substantially the same as the dc resistance of a conductor with a cross-sectional area equal to $2\pi r\delta$, where r is the radius of the conductor.

When δ is not small compared to r, it cannot be assumed that the entire current flows in a cylinder of radius r and thickness δ. For large values of δ/r, an exact solution* for the current distribution results in the curve of Fig. 8-3, where R_{ac}/R_{dc} is shown as a function of r/δ. This curve indicates that when $r/\delta \leq 1$, the ac and dc resistances are substantially equal. Thus if it desired to have the resistance of a conductor

So we see, skin effect occurs because the outer areas of a conductor have less magnetic flux surrounding them than the inner layers. While we often consider the effect on materials without weaves, think about how this affects woven conductors like braiding or Litz wire. Any individual conductor has HIGHER impedance when it moves into the center areas, and if current finds an alternate path it moves out to the lower-impedance outer layer.

If strands touch with high resistance connections, it effectively adds unnecessary resistance to the path. The fact the surface is rough also DECREASES effective surface area for current for a given occupied physical area, because there are non-conductive air gaps in the occupied area!

The increased resistance (and impedance) is why braiding should never be used for high frequency high current applications unless it is oversized to compensate for increased impedance and dissipation. Parallel stranding decreases effective current carrying surface area at high frequencies, but at least avoids the weave problems.

As a matter of fact the weave is what causes most of the loss increase when typical coaxial cables are contaminated by water. The problem occurs, even after the cable is dry, because the hundreds of weave contact points corrode and make poor connections, increasing the resistance. Something similar happens when we "unpack" a braid from a jacket. The pressure between weaves decreases, and series resistance (and impedance) increases!

We could insulate strands, and once we establish a basic loss in conductivity caused by replacing useful conductor area with insulation we would find the impedance slope much flatter with frequency. If the strands are insulated (Litz wire) and frequency is increased, eventually we reach a point where the conductor resistance increases and we are much worse off than we would be with braided or stranded wire. The upper limit point is generally around 1 MHz for Litz wire.

From Radio Engineering by Terman:

Litz Wire.—The effective alternating-current resistance of a conductor can be made to approach the direct-current resistance at low and moderate radio frequencies, by forming the conductor from a number of strands of small enameled wires connected in parallel at their ends, but insulated throughout the rest of their length, and thoroughly interwoven. If the stranding is properly done, each wire will, on the average, link with the same number of flux lines as every other wire, and the current will divide evenly among the strands. If at the same time each strand is of small diameter, it will have relatively little skin effect over its cross section, so all of the material is equally effective in carrying the current. Such a stranded cable is called a *litz* conductor.

Practical litz conductors are very effective at frequencies below about 1000 kc, but as the frequency becomes higher the benefits disappear. This is because irregularities of stranding, and capacitance between the strands, cause a failure to realize the ideal condition at very high frequencies.

In reality, the real advantage of Litz wire is NOT reduced resistance per unit length for a given diameter. The advantage is less slope in resistance with frequency and reduced eddy current when the conductor is in a multi-layer coil or transformer. The individual strands are like laminations in a transformer core, and below a certain frequency they greatly reduce eddy currents by decreasing the "short circuit" path distance for magnetic flux induced currents that are not in the normal current flow direction.

My own measurements have shown noticeably lower ESR (equivalent series resistance) for a given conductor size when using a ***SOLID*** wire as compared to any Litz wire sample I have tried above 300kHz (the lower limit of my main vector network analyzers).

For a given wire diameter and form factor, I've always been able to achieve higher Q with solid round or ribbon conductors.

stacking broadside collinear

[Home]

Popular rumor is gain doubles each time elements are doubled. In other words, adding a second vertical above another vertical would add 3dB gain. Adding two more after that (total of four) produces 6dB gain over a single element.

The same concept is often applied to stacked Yagi or dipole antennas.

In neither case is it true. Gain comes from forcing nulls in areas of high radiation. This removes energy from the null areas, and that energy moves to enhance gain in other directions. This effect is sometimes called ***pattern multiplication***.

Before antenna modeling software was commonly available, we often used pattern multiplication to estimate patterns and gain. It still is a useful tool.

The graphs below, from Jasik's Antenna Engineering Handbook, shows the gain of various couplets or elements when placed either end-to-end (Collinear) or parallel above each other (stacked broadside).

Collinear Gain

First we have the end-to-end element placement gain.

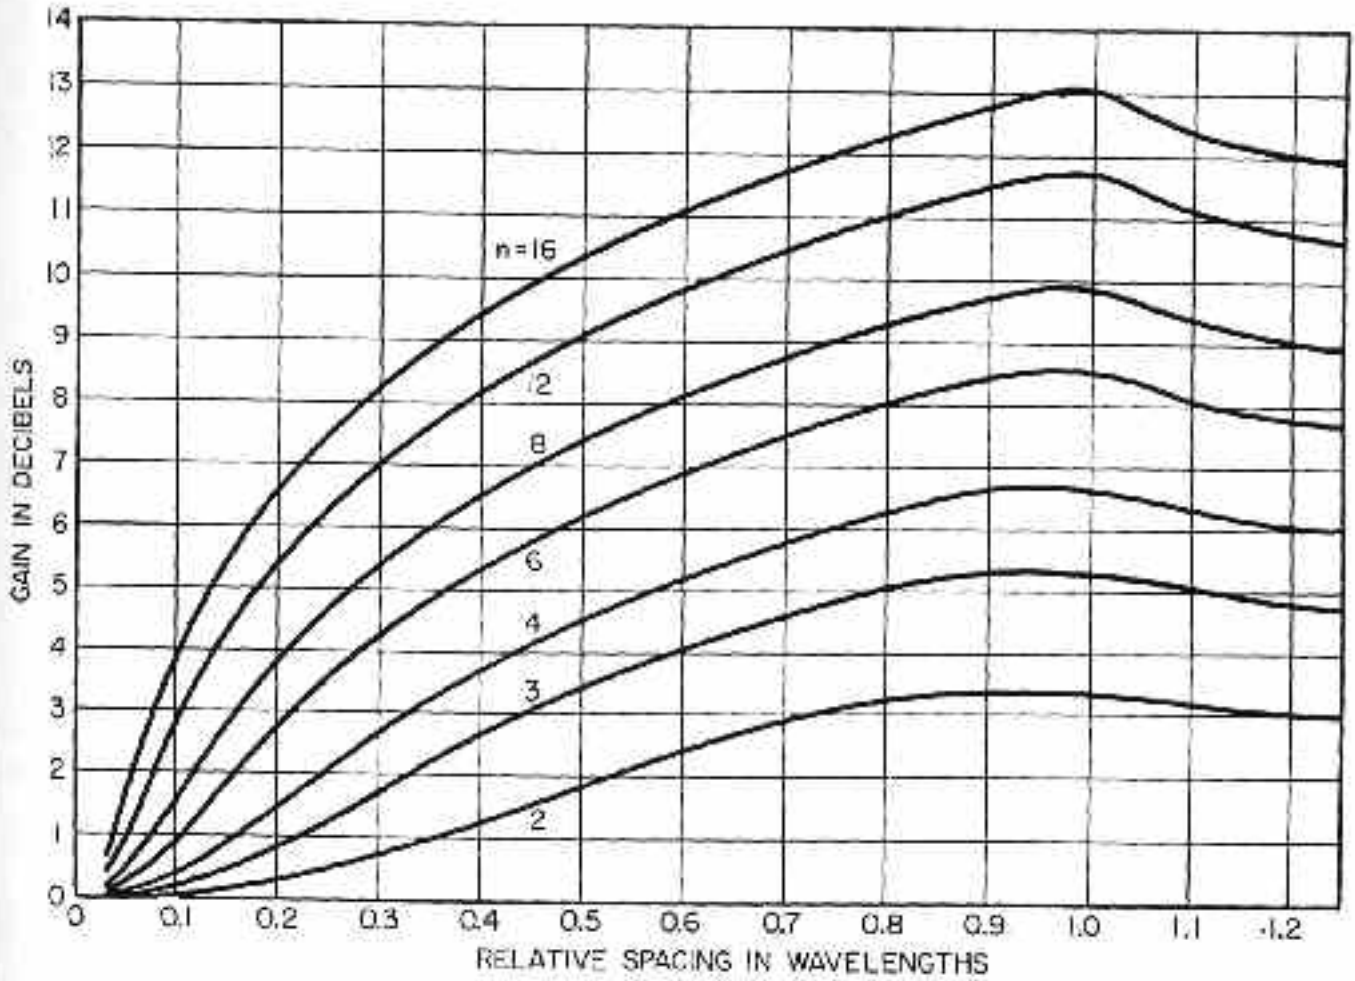

FIG. 5-22. Gains to be expected from a collinear (omnidirectional) array of short-dipole elements. The gain is relative to that of a single element.

We can see the gain for two elements peaks at .9 wavelength spacing. This spacing is the current maximum spacing of the elements, NOT the end spacing. With a 1/2 wl dipole in each element, the end-to-end spacing would be .9 - .25 -.25 = .4 wavelengths. The overall array length would be .9 + .25 + .25 = 1.4wl

With two dipoles end-to-end the center-to-center spacing of current maximums would be .25+.25=.5wl. The absolute maximum gain would be found on the graph above at the crossing of the vertical .5 relative spacing line and intersection of curve 2 (two elements). The gain would be less than 1.9dB in ANY collinear antenna.

We would achieve 3dB at about .71-.25-.25= .21wl tip-to-tip spacing, or 1.21wl total collinear element array length.

To double gain again (adding 3dB more) the array would have to be four elements with .75wl center-to-center spacing in elements! The array would be 3*.75=2.25wl (this is number of elements minus 1 multiplied by required spacing) for the total spacing of four elements). The end-elements would extend .25 wl each from the current maximum, so the array length from end-to-end would be

2.25+.25+.25=2.75wl.

To go from three to six dB requires we change antenna length from 1.21wl to 2.75wl!

We cannot simply double length to double gain! That concept is wrong.

Note we can get more than 6dB gain by using more than .75wl element center-to- element center spacing. We really should have .95wl element center-to element center spacing, making the array N-1*S + El = L where N=number of elements, S=spacing, El = element length. The result is an array of four elements would have optimum gain of 6.7dB with a length of 3.35wl.

The longer the array is, the wider the individual elements should be spaced for optimum gain.

Broadside

Broadside gain applies to elements that are parallel and one above the other. This could be Yagis or dipoles. This is the ***OPTIMUM or maximum gain***, not the actually gain you might have.

Optimum broadside stacking distance increases with more directive elements, so a pair of three-element Yagis stacked requires wider spacing than a pair of dipoles, and less maximum stacking gain is possible.

Here is the optimum gain graph for dipoles:

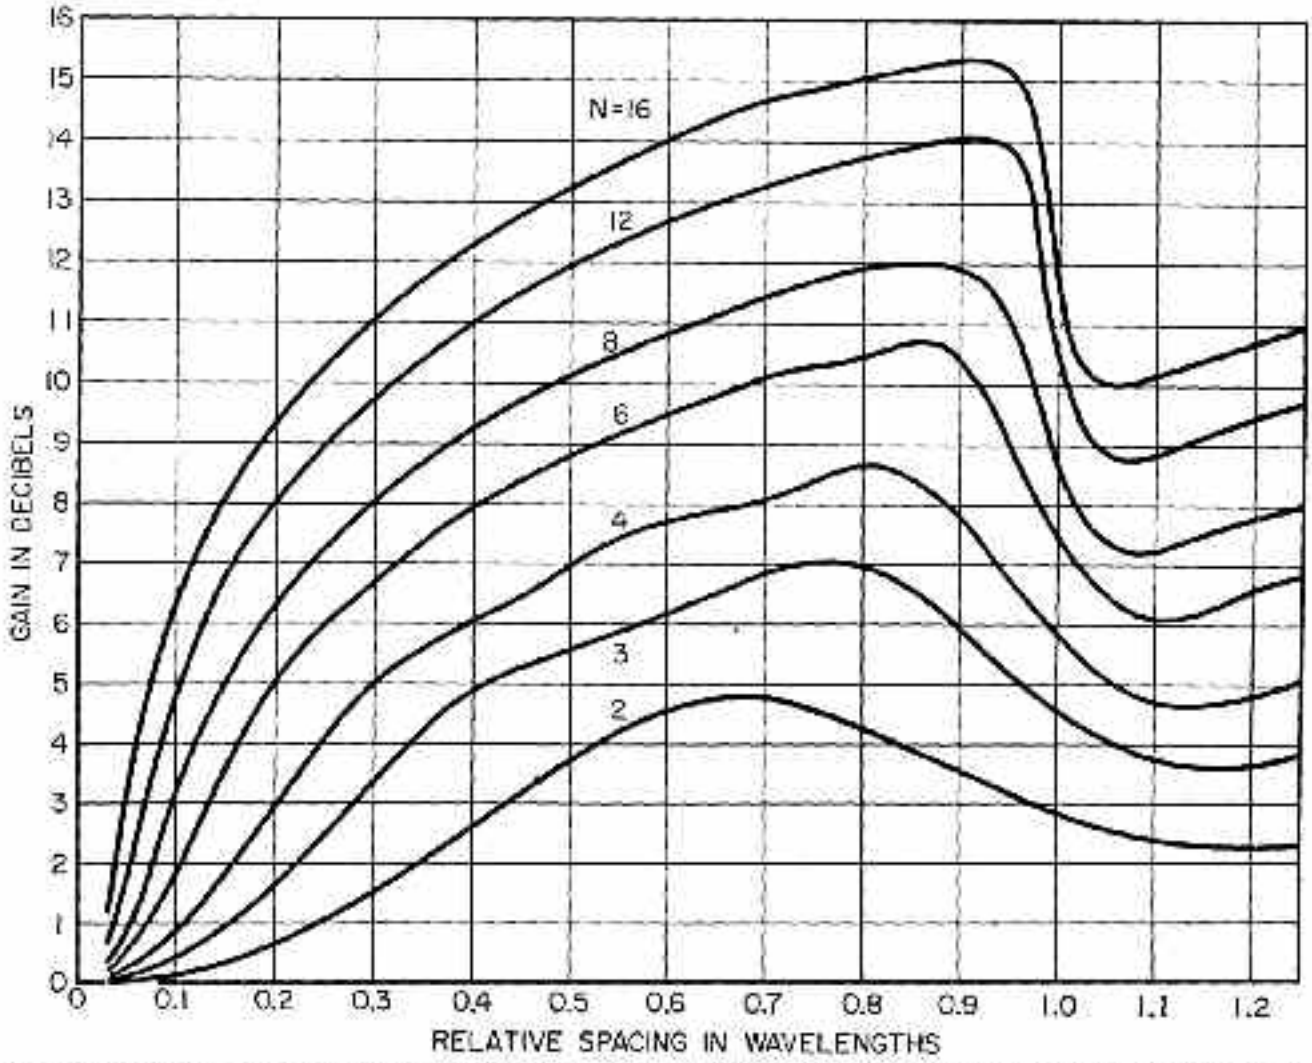

FIG. 5-10. Gains* to be expected from a single array (no reflector) of broadside elements.

You can see maximum gain occurs at .675wl stacking height. The stacking gain is 4.8db, not 3dB as we see claimed claim. Again the more elements, the wider the stack spacing must be between elements.

I hope these graphs help dispel the myth that doubling element numbers doubles gain! It just doesn't work that way.

A Practical Application?

Combination Broadside/Collinear/ End-fire

If all goes as planned, a new 3.5-10MHz array will be installed later this year in the SE USA using four 80-meter 1/2wl elements fed with open wire line with optimum spacing in broadside-endfire. This array will be 300ft tall and 400 feet wide. A reflector grid of wires will be spaced 1/8th wl behind the array.

The 80 meter gain is 4.8dB broadside + 3.2dB collinear for a total of 8dBd. A screen reflector adds 3dB gain, for a total of 11dBd gain on 80 meters. This is 11dB over a dipole at the same mean height! With ground reflection gain the total dBi gain is about 18dBi.

On 40 meters, the same array will produce 21dBi (or 14dB gain over a dipole at the same mean height). In contrast, a typical 3-element full size Yagi on 80 meters would have about 7dBd gain. The curtain is roughly like four stacked three-element Yagis on 80, and eight stacked on 40.

Curtain pattern can be slewed in both E and H planes to focus on the target. Such arrays are actually practical, and have been used for years in SW BC work.

Trust Fund Information

There have been many information requests for the trust fund for Graeme and Erik, Bill and Dana's sons. The family is overwhelmed by the outpouring of kind words by fellow amateurs. If you would like to contribute to the W4AN Memorial Fund for Bill and Dana's children, the trust fund account information is:

Account number 20005913

W4AN Memorial Account for Graeme and Erik Fisher

North Atlanta National Bank

10500 Old Alabama Road Connector

Alpharetta, GA 30022

Bank Phone (678-277-8400)

If you wish to make a contribution, any amount will help. Make checks payable to:

W4AN Memorial Account.

You can include the account number "**20005913**" or "**Graeme and Erik Fisher**" in the "for" line.

I will post more information after the Dayton Hamvention rush is over and I recover. Briefly, the basic plan is that Graeme and Erik will be able to draw from this fund for worthwhile activities like school, a first home, or some valid emergency. Having a headache, buying new mag wheels or a dirt bike would not be a good reason. College tuition, books, or housing would be. It will be a 50/50 split unless one doesn't require funds. If neither requires funds, then it will go to some other similar circumstance involving an amateurs young children.

The fund is administered by several well-known members of the amateur community. All of this will be released in final form with more detail a short while after Dayton. Sorry, but anyone who works in the industry knows what a huge time-sink Dayton is!

Spectral Analysis of a CW keying pulse

Kevin Schmidt, W9CF
6510 S. Roosevelt St.
Tempe, AZ 85283

October 6, 2001

1 Introduction

This problem was brought to my attention by Tom Rauch, W8JI, who, in his note to me, had described his experience and correctly pointed out all the main features that govern the bandwith. These notes are an expanded version of my reply giving the mathematical explanation.

To fit the most CW signals into the available spectrum, we need to limit the bandwidth taken up by the signals. It is therefore useful to see how the energy in a dot or dash pulse is distributed around the carrier frequency. Here I give some notes on how to make this analysis. The main result is that the spectrum for many keying shapes is given by the product of the spectrum of a square pulse times the spectrum of the slope of the rise and fall behavior of the pulse.

It seems from my experience reading morse, that the rise time should be the main factor in producing code that can be read by ear comfortably. Since the rise time dominates the bandwidth for the usual CW signal, the analysis shows that to get a nearly optimal bandwidth to rise time, the keying pulse shape should have a gaussian slope.

In the next section I review basic Fourier analysis of amplitude modulation. I then calculate the spectrum of a pulse with an exponentially shaped rise and fall as would be produced by simple RC networks. The results suggest the more general analysis in the following section, with the conclusion that a pulse with gaussian slope, i.e. error function rise and fall shapes, will have an optimal bandwidth and rise time.

It seems likely that all of this would have been worked out by radio engineers in the early 1900s when CW signals were first employed.

2 Fourier analysis for amplitude modulation

To analyze the spectrum generated by keying a transmitter let's look at a single ``dot.'' If we imagine we have a

carrier with angular frequency ω_0, and we amplitude modulate it with an envelop A(t), we get the amplitude of the signal from the transmitter is

$$f(t) = A(t)\cos(\omega_0 t) \tag{1}$$

To calculate the energy spectrum we Fourier transform this to get

$$\tilde{f}(\omega) = \int_{-\infty}^{\infty} dt A(t)\cos(\omega_0 t)e^{i\omega t} = \frac{1}{2}\left[\tilde{A}(\omega-\omega_0)+\tilde{A}(\omega+\omega_0)\right] \tag{2}$$

where

$$\tilde{A}(\omega) = \int_{-\infty}^{\infty} dt A(t)e^{i\omega t}. \tag{3}$$

In the usual case, the modulation $A(t)$ contains frequency components much smaller than the carrier frequency. Therefore the $\tilde{A}(\omega+\omega_0)$ is negligible and can be ignored. The energy spectrum of the amplitude modulated signal is therefore given by

$$P_0(\omega) = \frac{1}{4\pi}|\tilde{A}(\omega-\omega_0)|^2 \tag{4}$$

and since $A(t)$ is real, $\tilde{A}(\omega) = \tilde{A}^*(-\omega)$, and the sidebands are symmetric around the carrier frequency.

It is convenient to write

$$P(\omega) = P_0(\omega+\omega_0) \tag{5}$$

so that ω here is the frequency difference from the carrier, so that $P(\omega)$ gives the energy distribution for an

angular frequency of ω from the carrier angular frequency. I will call $P(\omega)$ the sideband energy density.

3 Application to Keying Bandwidth

To get an explicit result, I'll assume an explicit form for a keying waveform. A simple form where the Fourier transforms can be calculated analytically is the case where the wave builds up exponentially (as in the usual RC circuit) to the carrier value when the key is pressed, and then decays exponetially to zero when the key is released. That is

$$A(t) = \begin{cases} 0 & t < 0 \\ 1 - e^{-t/\tau} & 0 < t < T \\ (1 - e^{-T/\tau})e^{-(t-T)/\tau} & t > T \end{cases} \tag{6}$$

where T is the keying pulse width and τ is its time constant. A plot of this waveform is shown in figure 1 for the cases where τ is 4 milliseconds, and T is 20 and 50 milliseconds.

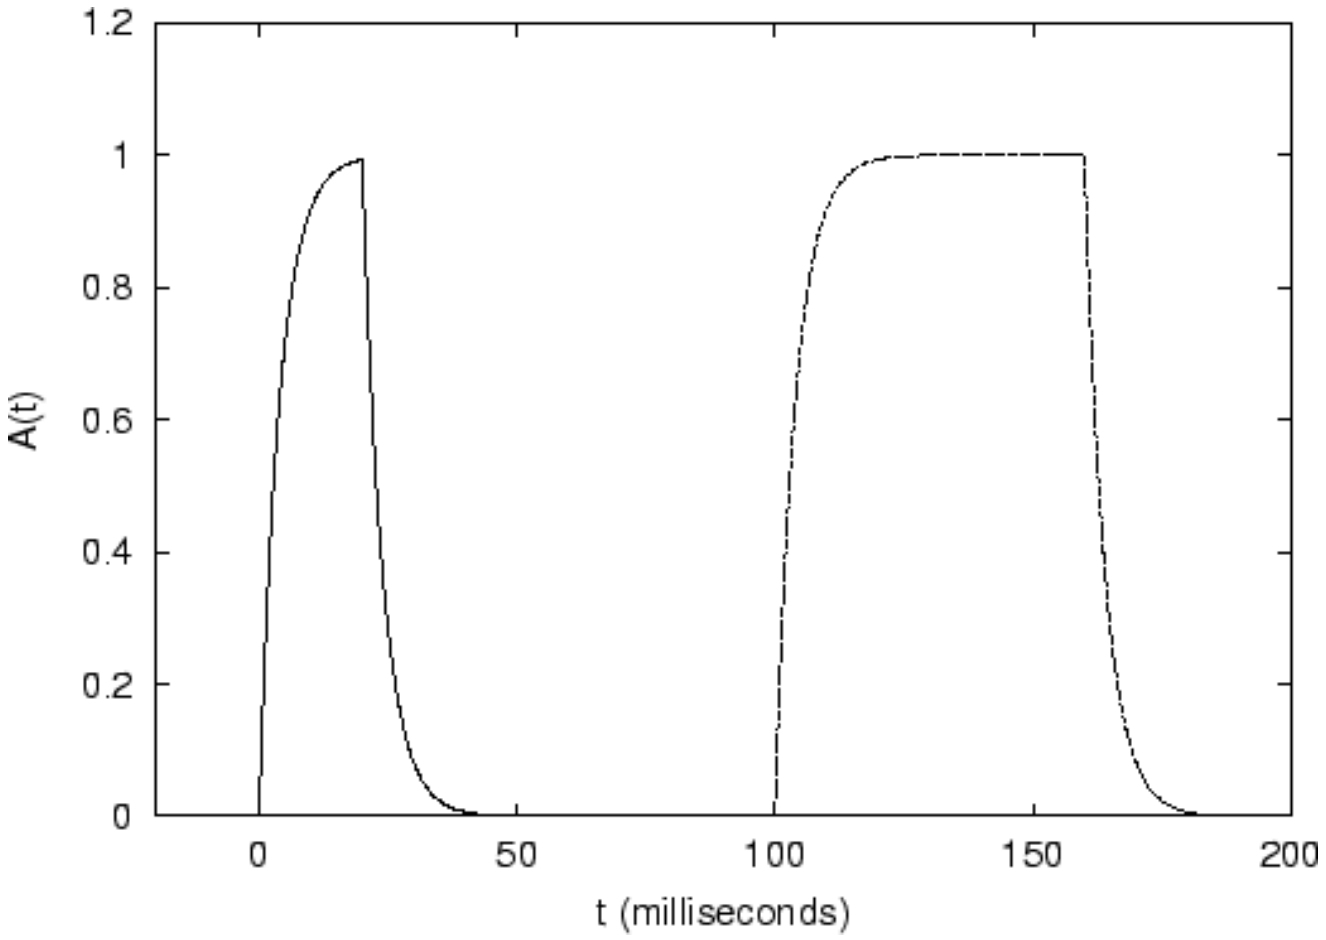

Figure 1: The exponential keying waveforms for a time constant τ of 4 milliseconds and durations of 20 and 50 milliseconds. The 50 millisecond pulse begins at $t = 100$ milliseconds to separate it from the 20 millisecond pulse.

The fourier transform integral of the amplitude is straightforward and gives

$$\tilde{A}(\omega) = -\left[e^{i\omega T} - 1\right] \frac{1}{i\omega(i\omega\tau - 1)} \tag{7}$$

so that the sideband energy density) becomes

$$P(\omega) = \frac{1}{\pi} \frac{\sin^2\left(\frac{\omega T}{2}\right)}{\omega^2} \frac{1}{(1 + \omega^2\tau^2)} \,. \tag{8}$$

So the sideband energy density has two factors. If we measure it in dB relative to some fixed value, we add the logarithms of the factors. The only dependence on T comes from the first factor. The $\sin^2$ function is always less than or equal to 1, so this will subtract from the other factor which only depends on τ the time constant which determines the rise time.

The main features of the sidebands will therefore be given by the rise time, while the length of the pulse will modify those features somewhat.

Figures 2 and 3 show the energy density in dB referenced to the carrier energy density for T of 20 milliseconds. The curves are plotted together in figure 4. Each curve is plotted versus frequency $f = \omega/2\pi$.

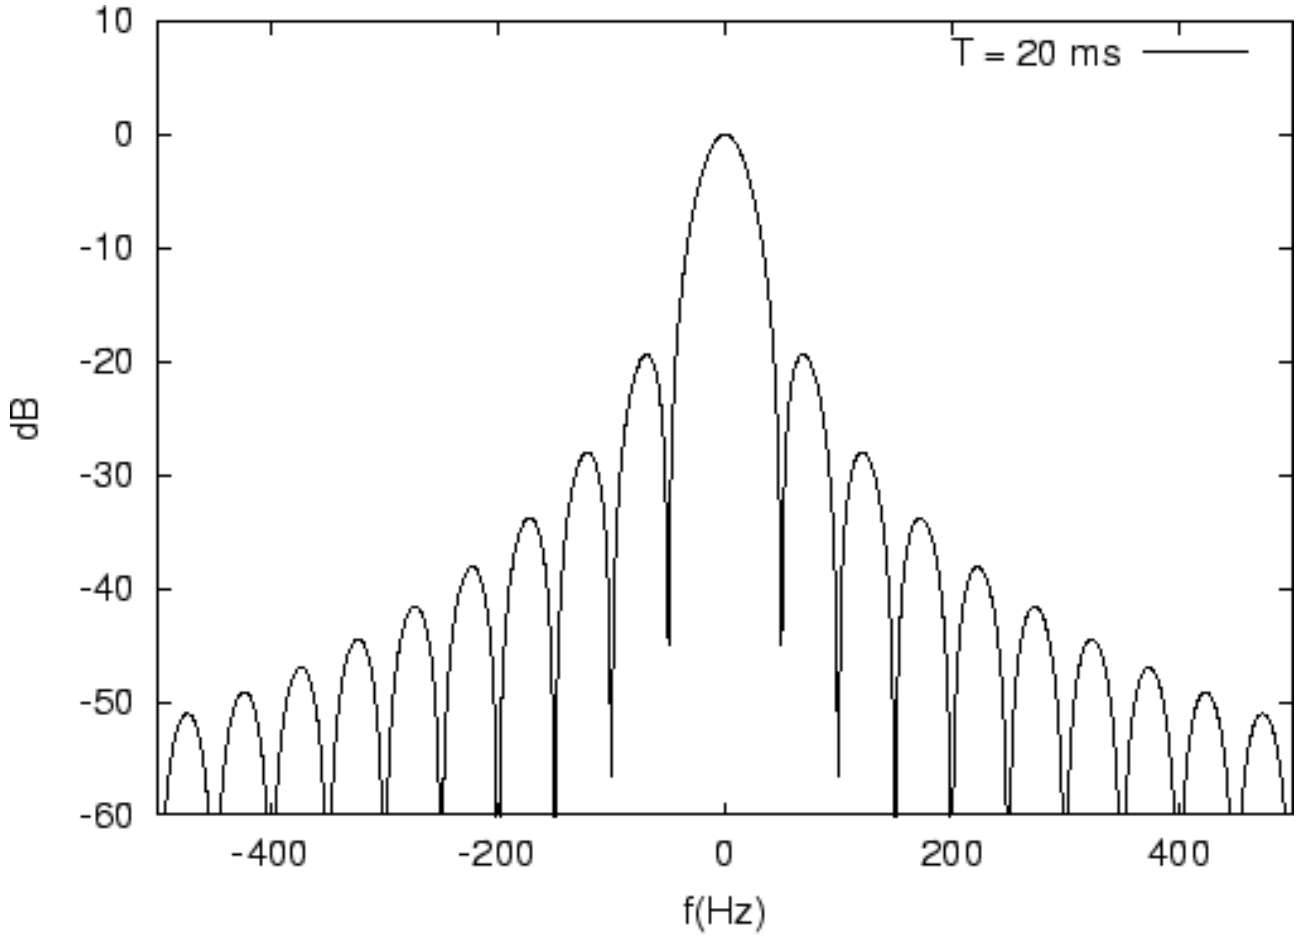

Figure 2: The sideband energy density for an exponential keying wave form with $\tau = 4$ milliseconds and T of 20 milliseconds. The carrier energy density is set to 0 dB.

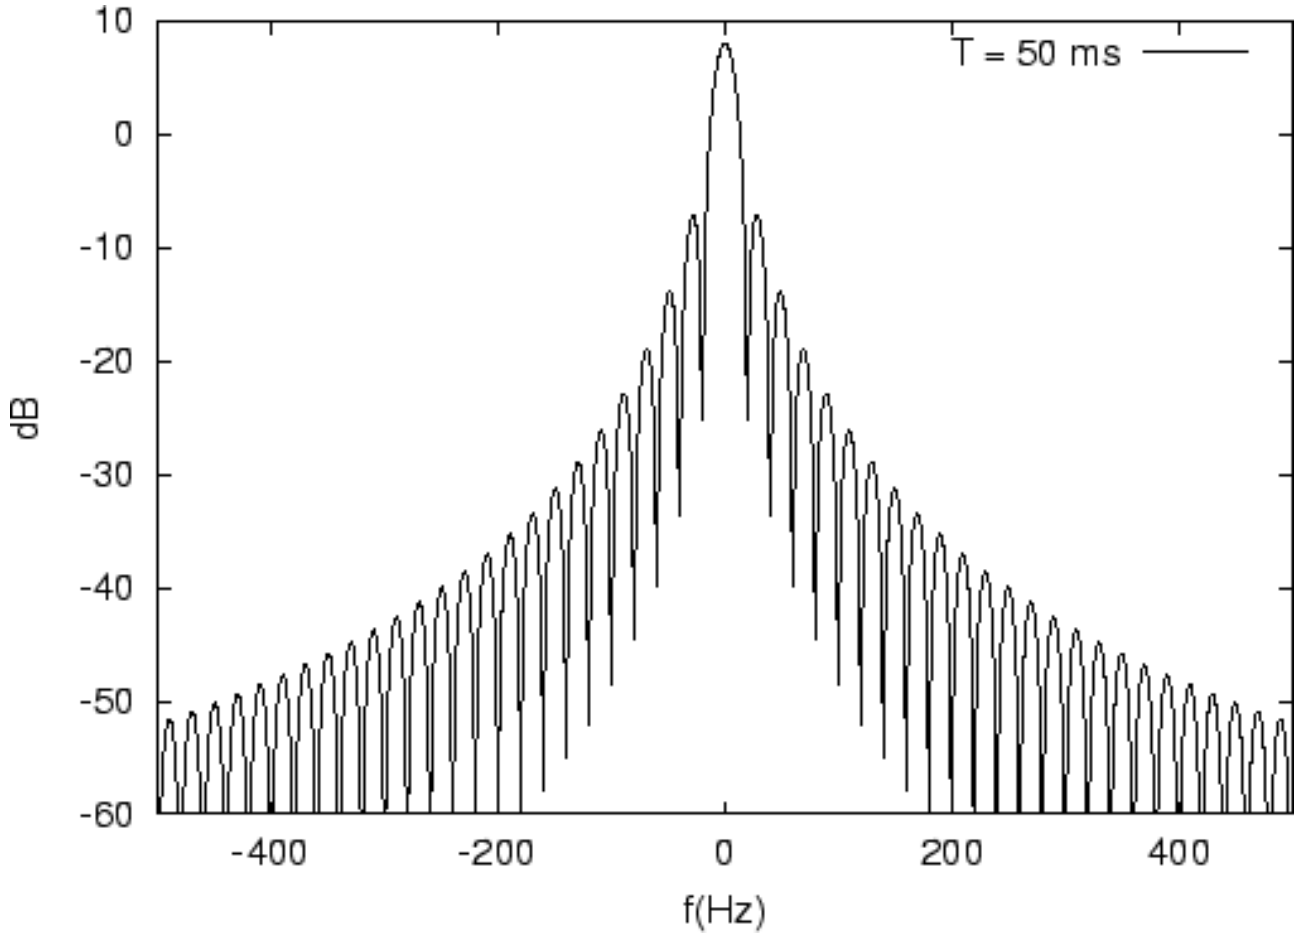

Figure 3: The sideband energy density for an exponential keying wave form with $\tau = 4$ milliseconds and T of 50 milliseconds. The scale is the same as figure 2.

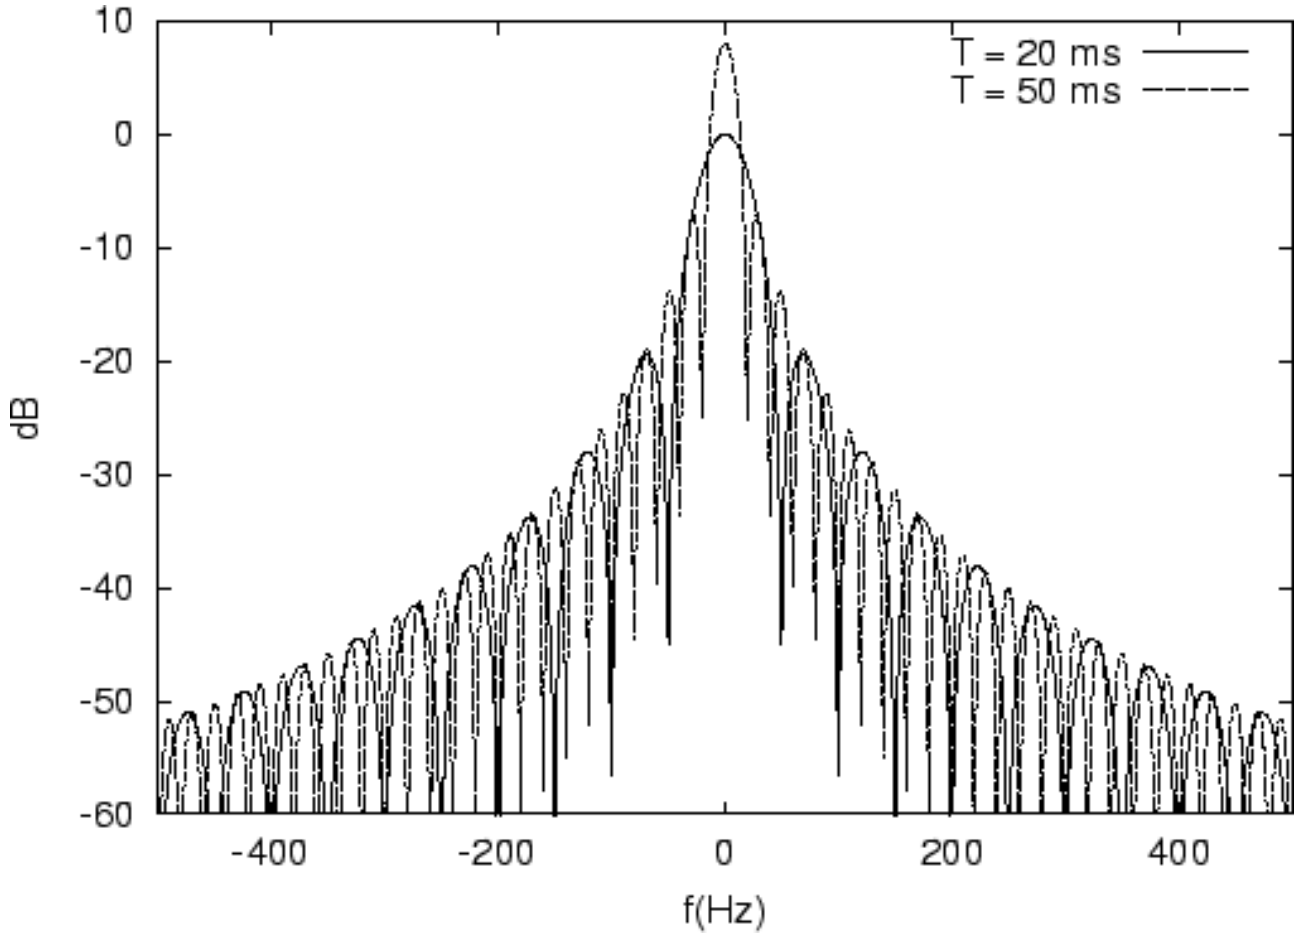

Figure 4: The plots of figures 2and 3combined.

Notice that the differences between the 20 millisecond and 50 millisecond pulses are first the energy near the carrier frequency is larger for the longer pulse as needed since it has about 2.5 times as much energy, and second the ``ringing" has more oscillations for the longer pulse as expected. The sidebands fall off 12 dB per octave once we are at frequencies beyond about $1/\tau$.

The effect of the keying speed on the bandwidth as long as the rise time is small compared to pulse length is the change in shape of the central peak. It does get narrower for slower keying and wider for faster keying, however, the keying speed does not effect the overall bandwidth.

4 General Pulse Shape

I can write a general pulse shape as

$$A(t) = E_r(t+T/2) - E_f(t-T/2) \tag{9}$$

where E_r and E_f describe the rising and falling edges of a pulse and are positive functions that go to zero at

large negative t and to 1 at large positive t. The Fourier transform of A is the sum of the transforms of the two terms. If the rising and falling edges have the same form, we can write

$$A(t) = E(t+T/2)-E(t-T/2) = \int_{-\infty}^{\infty} dt'[\delta(t+T/2-t')-\delta(t-T/2-t')]E(t') \quad (10)$$

and integrating by parts gives the result

$$A(t) = -\int_{-\infty}^{\infty} dt' S(t-t')\frac{dE(t')}{dt'} \equiv -\int_{-\infty}^{\infty} dt' S(t-t')E'(t') \quad (11)$$

where $S(t)$ is a square pulse of width T,

$$S(t) = \begin{cases} 1 & |t| < \frac{T}{2} \\ 0 & |t| > \frac{T}{2} \end{cases} \quad (12)$$

and I have defined E' to be the derivative of E.

Since $A(t)$ is written as a convolution, its Fourier transform is now the product

$$\tilde{A}(\omega) = \tilde{S}(\omega)\tilde{E}'(\omega)\,. \quad (13)$$

For keying wave forms this has the nice interpretation that the spectrum is given by the spectrum of a square pulse of length T multiplied by a factor that is the Fourier transform of the slope of the rise and fall wave form.

Except for an unimportant change of the zero of time, the exponential case calculated above can be written as

$$E(t) = \begin{cases} 0 & t < 0 \\ 1 - e^{-t/\tau} & t > 0 \end{cases} \quad (14)$$

The Fourier transforms of these are

$$\begin{aligned} \tilde{S}(\omega) &= \frac{2\sin\left(\frac{\omega T}{2}\right)}{\omega} \\ \tilde{E}'(\omega) &= -\frac{i}{1+i\omega\tau} \end{aligned} \tag{15}$$

and the sideband energy density is exactly as before.

As we saw for the exponential case, the bandwidth is dominated by the rise and fall time. Therefore it seems reasonable to try to optimize the rise and fall waveform of the keying pulse. In terms of the function $E'(t)$ whose integral is the rising and falling wave form, we want to simultaneously make its width in real time and in frequency small. One measure of this is the product of $\Delta\omega$ and Δt where they are defined as the variances in frequency and time

$$\begin{aligned} (\Delta t)^2 &= \int_{-\infty}^{\infty} dt\, t^2 E'(t) - \left[\int_{-\infty}^{\infty} dt\, t E'(t)\right]^2 \\ (\Delta\omega)^2 &= \int_{-\infty}^{\infty} d\omega\, \omega^2 \tilde{E}'(\omega) - \left[\int_{-\infty}^{\infty} d\omega\, \omega \tilde{E}'(\omega)\right]^2 . \end{aligned} \tag{16}$$

This problem is well known in optics and quantum mechanics where it goes by the name of the minimum uncertainty wave-packet[1] . The solution is a gaussian

$$E'(t) = \frac{1}{\sqrt{\pi\tau^2}} e^{-\frac{t^2}{\tau^2}} . \tag{17}$$

The Fourier transform of this gaussian is

$$\tilde{E}'(\omega) = e^{-\frac{\omega^2\tau^2}{4.}} \tag{18}$$

and the keying wave form with this $g(t)$ has $E(t) = 1/2[1 + \mathrm{erf}(t/\tau)]$

$$A(t) = \frac{1}{2}\left[\mathrm{erf}\left(\frac{t+T/2}{\tau}\right) - \mathrm{erf}\left(\frac{t-T/2}{\tau}\right)\right] \tag{19}$$

where $\mathrm{erf}(x)$ is the error function[2] defined to be

$$\mathrm{erf}(x) = \frac{2}{\sqrt{\pi}}\int_0^x du e^{-u^2}. \tag{20}$$

The differences in the keying wave form are shown by the turn on shape of the keying pulses in figure 5.

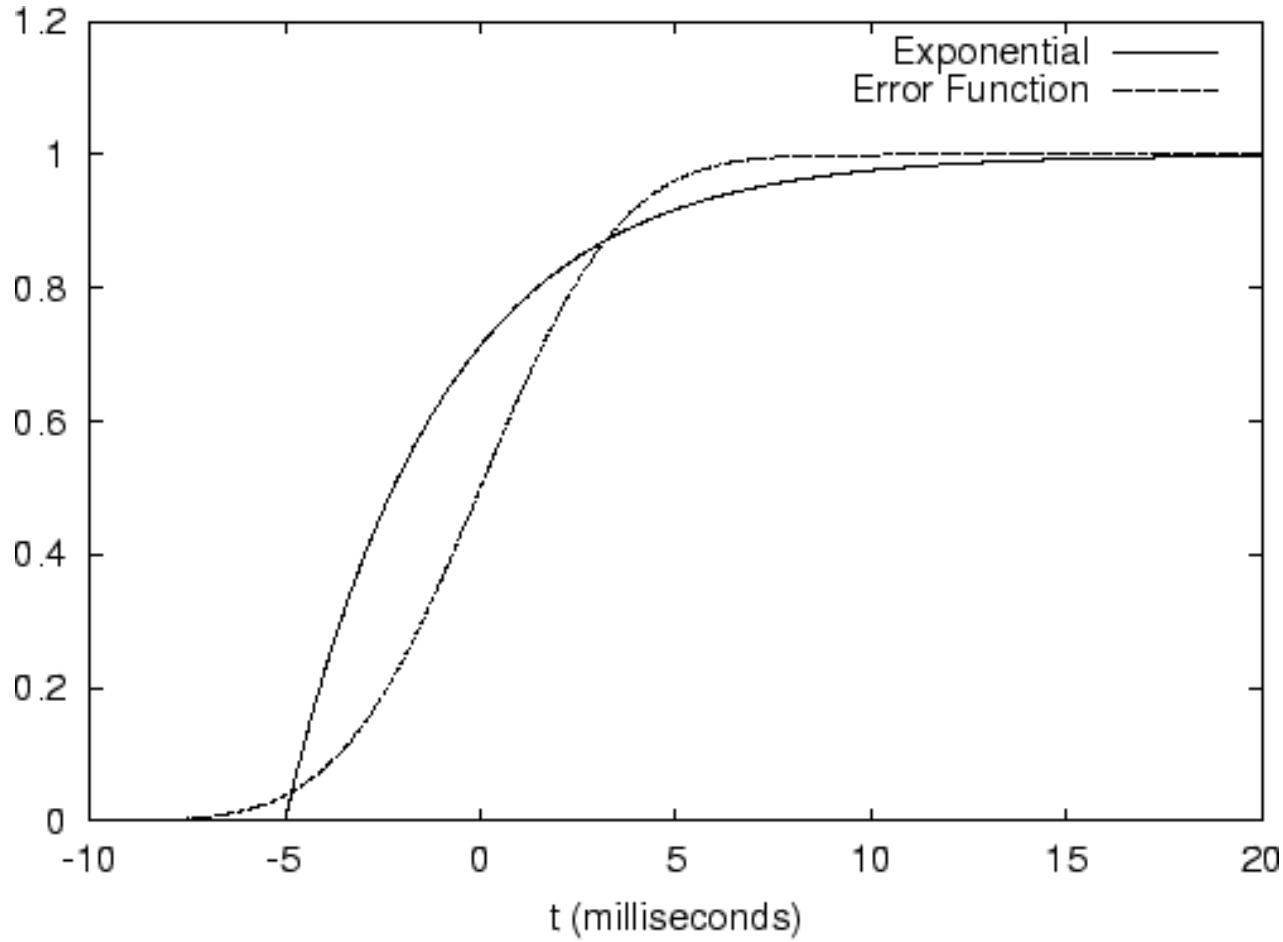

Figure 5: A comparison of the error function turn on with the exponential turn on, both for their respective τ values of 4 milliseconds.

In figure 6 I show the keying wave form for $\tau = 4$ milliseconds and $T = 20$ and 50 milliseconds as in figure 1 for both the exponential and optimized wave form. Notice that the abrupt changes in the exponential form are absent from the error function form.

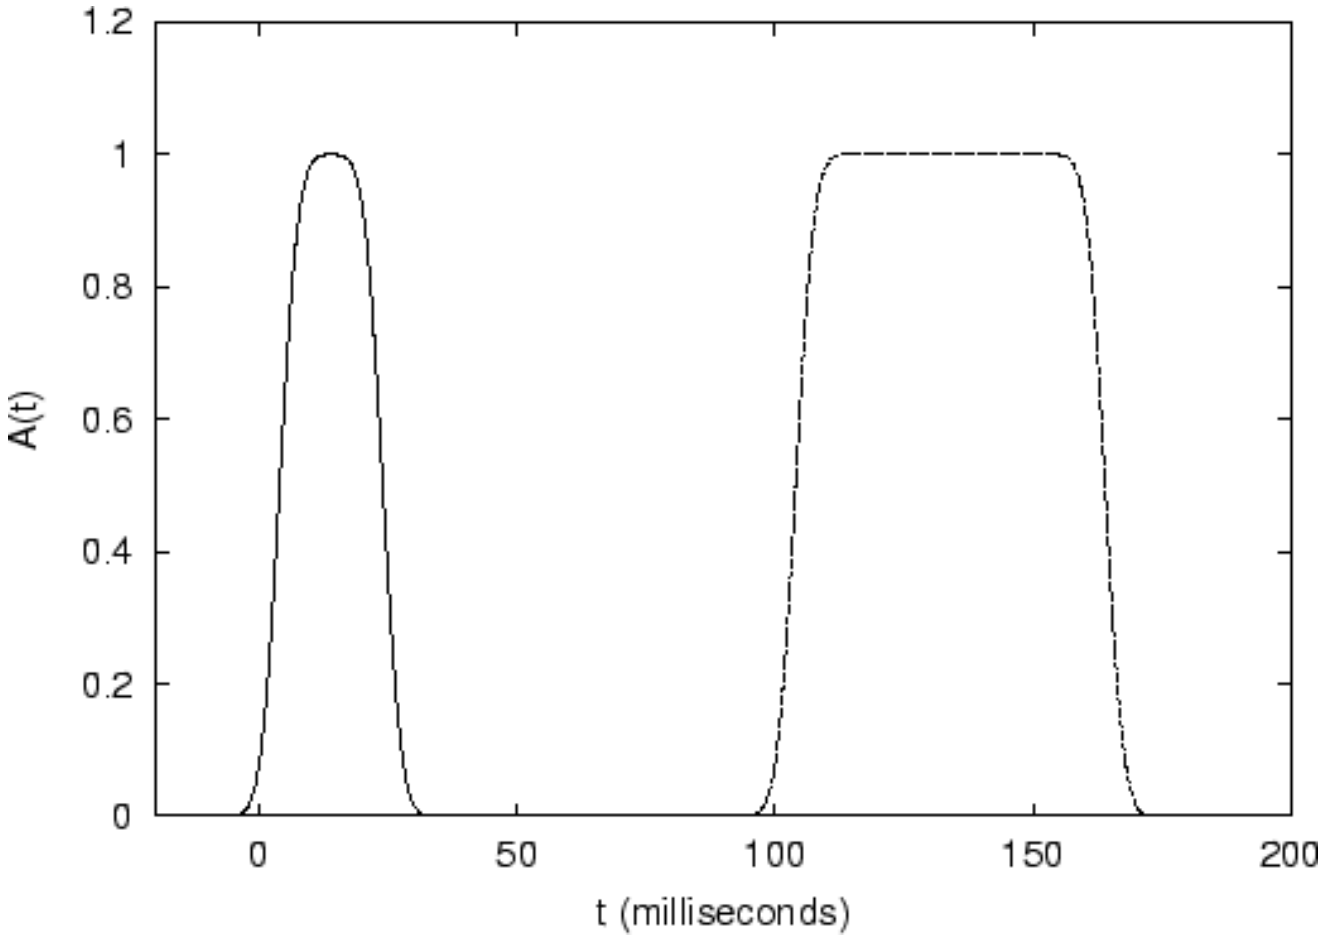

Figure 6: The error function keying waveforms for τ of 4 milliseconds and durations of 20 and 50 milliseconds. The 50 millisecond pulse begins at $t = 100$ milliseconds to separate it from the 20 millisecond pulse.

Figures 7 and 8 show the sideband energy density.

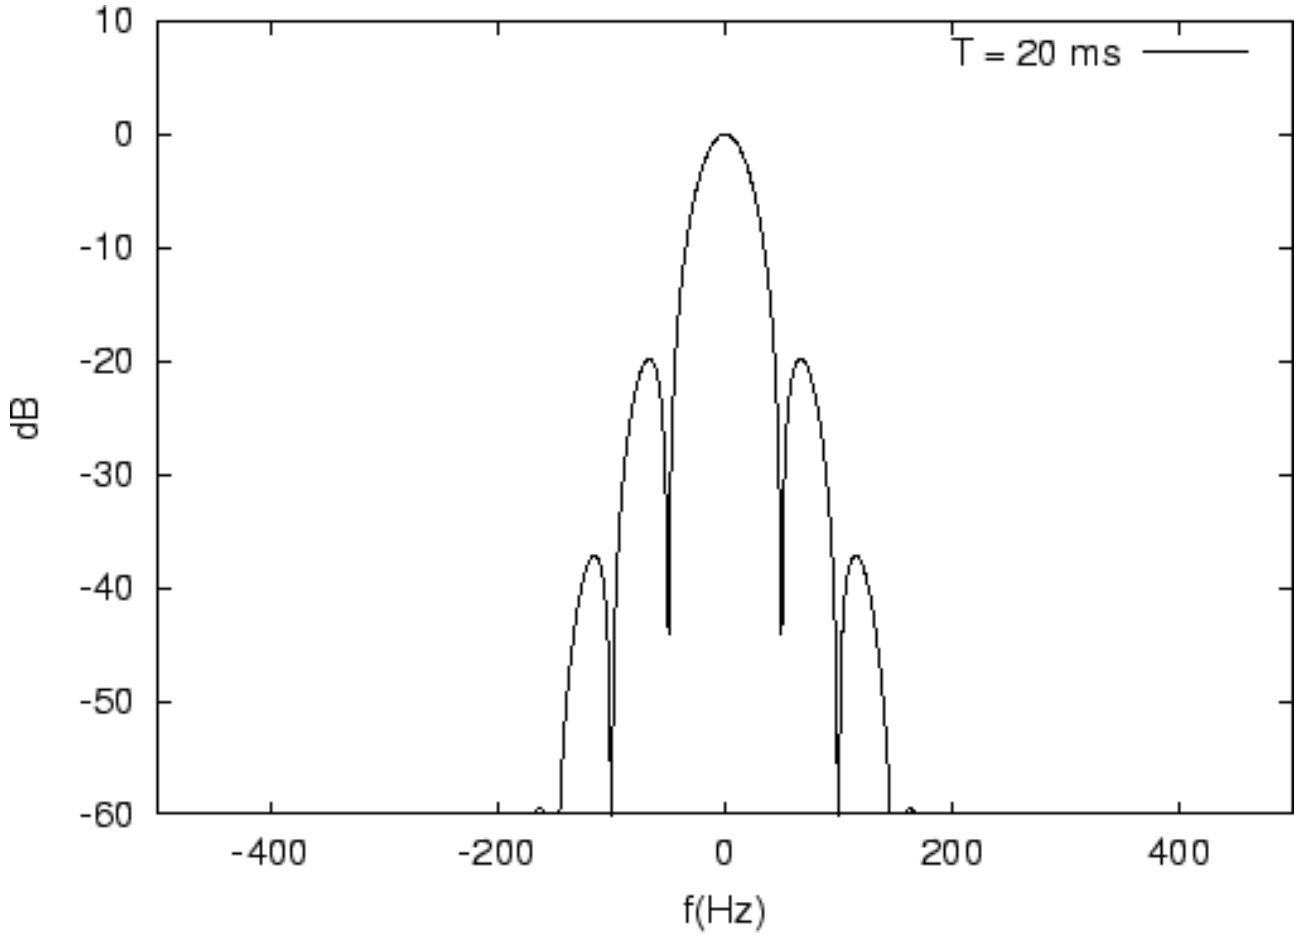

Figure 7: The sideband energy density for an error function keying wave form with $\tau = 4$ milliseconds and T of 20 milliseconds. The carrier energy density is set to 0 dB.

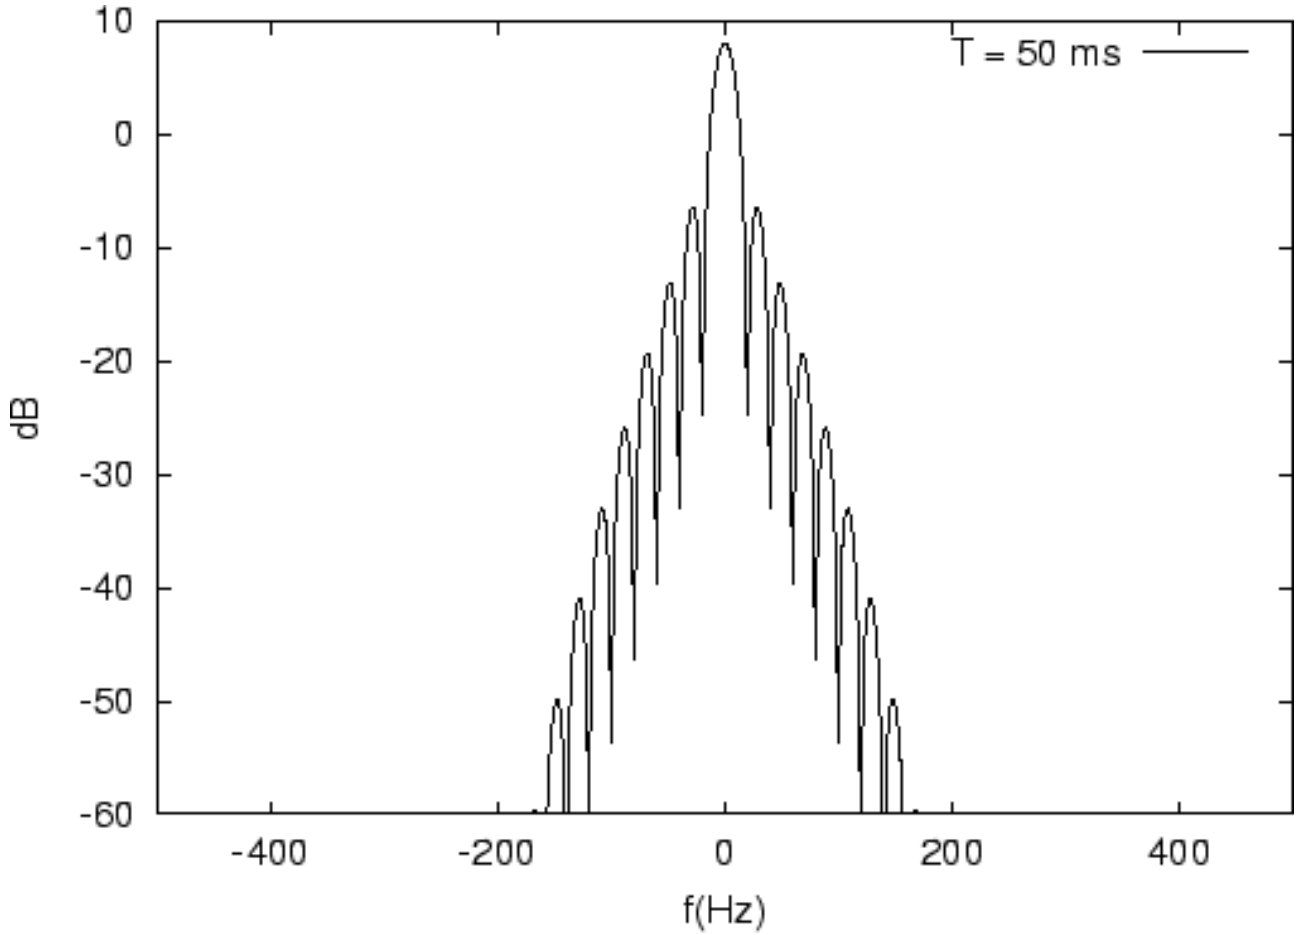

Figure 8: The sideband energy density for an error function keying wave form with $\tau = 4$ milliseconds and T of 50 milliseconds. The scale is the same as figure 7.

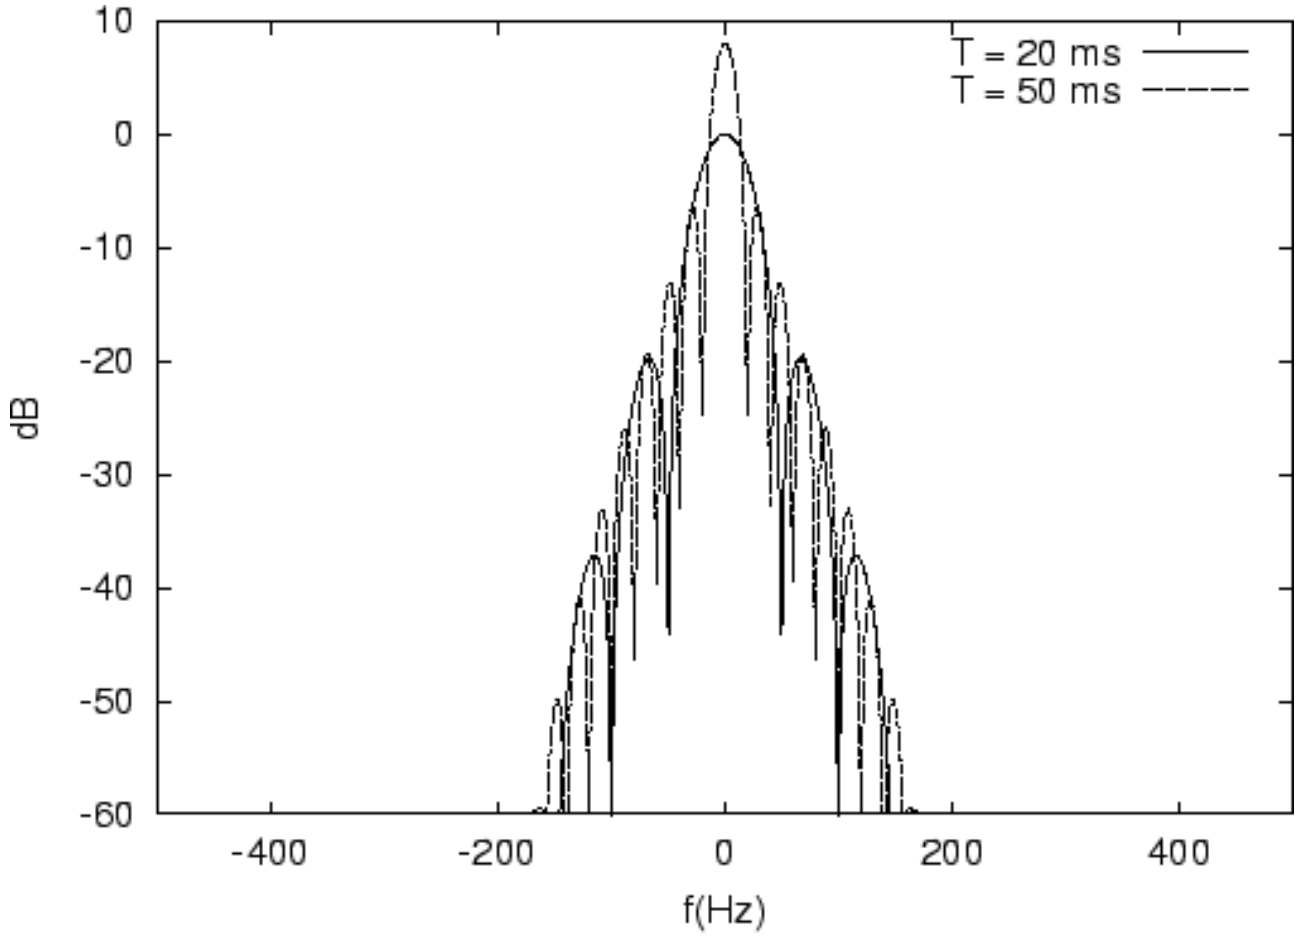

Figure 9: The plots of figures 7and 8combined.

5 Extensions and Conclusions

The sideband energy density for many pulse shapes factorizes. The first of the two factors is proportional to the Fourier transform squared of the square pulse and the second by the Fourier transform squared of the slope of the rise and fall. The analysis can be easily generalized to an arbitrary sequence of pulses. The Fourier transform of the single square pulse simply needs to be changed to the Fourier transform of the sequence of square pulses. For a given rise time, the error function shape for the rise and fall will attenuate unnecessary interference away from the carrier frequency much better than exponential keying.

Welcome to the International Radio Web Site!

http://www.inrad.net

About key clicks

At International Radio we get a lot of questions about the FT-1000MP series key clicks and the effect of the Inrad mod. There is a lot of data out there, some of it taken with spectrum analyzers and some taken with second radios. There is no standard for comparison in the spectrum analyzer data, so it is difficult to draw any conclusions from it. Data taken with a second radio is very subjective at best and is essentially meaningless for comparison purposes.

We have taken data on unmodified FT-1000MPs (original version) and also on radios modified with the Inrad circuitry. There have been no changes made in the keying circuitry in the Mark V or the Field versions. The data was taken on the same spectrum analyzer, with the same settings and with the analyzer settings clearly shown on the plots. In order to compare the MP performance with some other radios, we also are showing data taken under the same conditions, with the analyzer set the same way, etc. on several other radios. We will post data on our site on any one radio of a type which we can get for testing.

Here is the technical explanation for the measurements. The radios are being keyed at 40 WPM by an external keyer. The spectrum generated by a CW transmitter is similar to amplitude modulation where the modulating frequency is the keying rate. Sidebands are produced on both sides of the carrier. If the modulating source were a perfect sinewave, there would be only one sideband on each side of the carrier. However, the modulating source is nearly a square wave and is very rich in harmonics. So the sidebands created are spaced by the modulating frequency and have an envelope which is a function of the waveshape of the keying source. Note that the envelope does not change for different keying speeds. The number of sidebands within the envelope change as the keying speed is changed, but this does not alter the bandwidth of the composite signal.

The really important thing here is the shape of the keying signal.

If we pick a certain offset from the carrier and take a dB down reading, we can have a figure of merit for comparison purposes. One kHz is a good place to make this measurement as the sideband level is generally way out of the noise

and is easy to read from the plots. These numbers are posted next to the analyzer plots.

Several things are readily apparent when viewing the plots. First, the Inrad modification makes a substantial reduction in the FT-1000MP spectrum. Also, the modified MP is quite good when compared with the other radios. As a matter of fact, it's narrower than some radios for which popular opinion claims good keying.

The "bad name" which the MP has developed in recent times probably has something to do with the number of radios in the field. In a major contest there are more MPs in use than any other radio. Imagine, for example, if everyone in the last 160 meter contest was using an Omni VI+ or a K2 driving a KW amplifier. The popular press would then be saying that something has to be done about those radios. In truth, something needs to be done with most of the currently popular radios.

The Inrad mod

What is it and how does it work? The mod consists of 3 small components, two go on the IF board and one goes on the RF board. On the IF board, a 0.047 capacitor and a 100 K resistor in parallel are placed across C2148. On the RF board, a 0.1 uF cap is placed across C1004 (Mark V and Field) or C1216 in the original MP. (If you don't have a service manual, Louis, W7DZN has posted pictures on the VA3CR web site.)

In each case, these capacitors are used to slow the waveform which is used to key the gate voltage on FETs. These stages are doing the CW keying. The resistor on the IF board is required to keep the duty cycle of the keyed waveform at 50% by rebiasing the gate of the FET.

Some people have asked about routing the RF through the 500 Hz filter instead of the SSB filter. It seems like a good idea, however, the keying is done beyond the filters and this change would have no effect on the keyed waveform. Note that this is done in the Omni VI+ and the keying is distorted by the ALC loop. Another way to improve the keying would be to use a gausian or a transitional filter to shape the keying waveform. In a perfectly linear system this would work very well. However, the FETs being keyed are far from linear. Thus it is not possible to improve the output spectrum beyond what the Inrad mod does without substantial changes in the radio.

Beverage Antenna Products

This equipment provides the best possible receiving system performance of any design! This is the same equipment design proven to make top scores in 160m contests year after year. Fully isolated feeds prevent common mode noise and unwanted signals. This equipment has excellent reliability and is housed in metal cases for improved life and shielding. Units use RF tight type F connectors for superior reliability and weather characteristics.

W8JI Beverage Antenna Construction Article

Reversable Beverage System

The RBS-1 is a two-direction, reversable Beverage array designed and used by W8JI. It consists of the reversable feed point matching system (RBS-1FP) and a reflection transformer (RBS-1RT). The unit can switch directions of reception by having a 10-18 Vdc voltage applied through the coaxial feed. The antenna between the two units is standard 450 Ohm ladder line (not included). Operating range is a broad 0.2-30 MHz. Fully isolated grounds are used to prevent common-mode noise and unwanted signals.

Specifications:
Power Requirement: 9-10 Vac or 12-15 Vdc
Switching Current: less than 80 mA
Antenna Impedance: 300-600 Ohms (450 Ohms recommended)
Feedline Impedance: 50-75 Ohms (75 Ohm recommended)
Reflection Transformer Ratio: 1:1

Metal housings are used for shielding and improved life.

DXE-RBS-1P	$129.00	

superstar!

Receiver Preamplifier, 0.3-35 MHz

This is the best HF low-noise amplifier available. The RPA-1 is optimized for 0.3-35 MHz operating range. It's push-pull amplifier design and robust components enable it to with stand high signal levels and operate when you need it most.

Gain: 16 dB, 0.3-35 MHz (+1.5-0 dB over this range)
Input Third Order Intercept: 23 dBm
Noise Figure: 3.5 dB
One dB Compression: +26 dBm (~0.4 W output)
500 Hz BW IM3 Dynamic Range: 110 dB or greater
Power Requirement: 10-18 Vdc @ 140 mA maximum

Suitable for indoor or outdoor installation with the option of being powered through the coaxial feed. Metal housing provide shielding and improve life. RCA and Type F connectors are used on the input and output of the RPA-1. The unit comes with a relay that automatically bypasses the amplifier when dc power is removed.

DXE-RPA-1	$109.00	

Beverage Feed System

This Beverage Feed System is designed and used by W8JI. This receive only antenna pulls signals out of the noise that most antennas don't even pick up. The BFS-1 has fully isolated feeds to prevent common mode noise. The transformer used in this receive only antenna handles 25 watts of power so it won't go into saturation even with the strongest of signals.

Specifications:
Operating Frequency: 0.1-30 MHz
Antenna Impedance: 400-500 Ohms
Feedline Impedance: 30-100 Ohms (75 Ohms recommended)
Common Mode Isolation: 20-30 dB (antenna to feedline)
Power Handling: 20 watts continuously or 200 watts for 5 seconds
Termination Resistance: 400-500 Ohms

Utilizes stainless steel hardware and metal housing for long life. Utilizes type F connectors for superior reliability and weather characteristics.

470-Ohm Non-Reactive 2 Watt Resistor
Pack of 10 Resistors

This non-inductive resistor can absorb extreme amounts of power for short periods without damage. It has the highest surge immunity of any 2-watt leaded (with leads) carbon or metal resistor. Metal-film and carbon-film resistors easily fail from even minor electrical disturbances. When used as a Beverage termination, the DXE resistor withstands nearby lightning strikes significantly better than hard-to-find carbon composition resistors. It is superior to carbon composition resistors in real life, retaining resistance value despite exposure to heat and power surges.

Applications:

- Beverage Antenna Terminations
- Parasitic Suppressors
- Dummy Loads

Sold Only as a Pack of 10 resistors

Part #	Price	Add to Cart
DXE-ECM-R470-2	$20.00

Downloadable Files

NOTE: I place no restrictions on the use of any of these files except that they may not be sold. I do not warrant the programs in any way, and no support is available for them.

All downloadable files with .EXE extensions are self-extracting ZIP files. After downloading a file, go to the directory containing the file (first starting DOS if you're using a Windows system). Then type the name of the file. (You don't need to type the '.EXE'.) This will cause the file to expand into two or more other files. One of these will be a documentation file such as READ.ME or INFO.TXT containing instructions. Windows users can generally read these files with Notepad. Files with extension .ZIP must be un-ZIPped with PKWare's PKUNZIP program, widely available as shareware. Again, a documentation file will appear when the file is un-ZIPped.

The "Field Day Special" Antenna

The Field Day Special is a two-element wire beam with a unidirectional pattern. It's similar to the "ZL" special, except that its elements are the same length. This makes it easy to reverse the pattern by using two feedlines, one at the center of each element. The original antenna was described in June 1984 QST. An antenna like this can't directly be scaled for other bands unless the size of the twinlead it's made from is scaled in proportion. However, using the program available here, you can design your own for the frequency band of interest. By changing the various dimensions, you can trade gain/beamwidth, feedpoint impedance, and bandwidth. Improvements in the program have been made since the article was published, so an optimal design for 20 meters will have dimensions slightly different than the ones shown in the article. The currents in the elements of one design were measured and found to agree very closely with those predicted by the program. Quite a number of these have been built by various people for several bands, with universal reports of operation as predicted. I use a 20 meter version nearly every year for Field Day, and occasionally 15 and 40 meter versions as well. 20 and 15 meter Field Day Specials have been my primary home QTH antennas for these bands for a number of years. Download **FDSP~.EXE**, then follow the directions under "Downloadable Files", above. More information about the antenna, including construction and feeding, is included in one of the expanded files. The program is a DOS program and can be run from the Windows 95/98/NT DOS prompt.

Current Baluns

Baluns are a continuing source of discussion on the Internet newsgroups. In response to some questions about "current" or "choke" baluns, I wrote an analysis of their operation. In the past, I had believed that placing the balun at the input of an unbalanced tuner would allow the balun to work properly when the output of the tuner sees a high impedance load. The analysis shows this to be incorrect. A brief analysis is given in **IBALBRF.TXT**, and a more detailed analysis in **IBALUN.TXT**. Both are plain ASCII text files and can be viewed with Notepad or a similar application.

RF — Test and Measurement

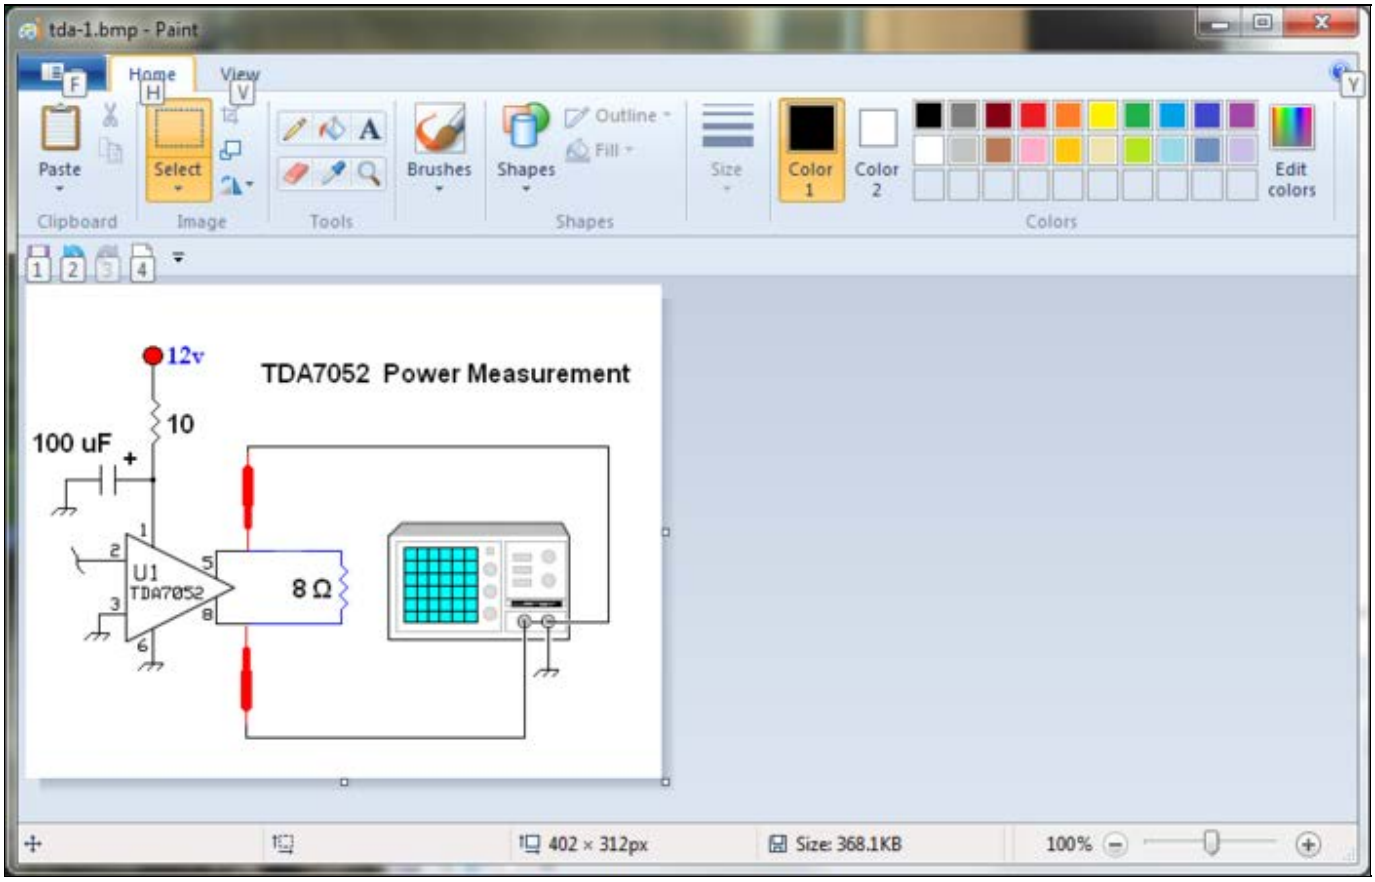
Frequently Asked Questions

1. How to you make your schematics?

I hand draw my schematics using the Paint Program that ships with all Microsoft Windows(tm) operating systems.

I strive to make schematics as clear and as small in file size as possible.The Windows Clipboard is used extensively to copy and paste the desired components from previous schematics to new schematics — very few new components are ever drawn; rather they are recycled from schematic to schematic. My system allows me to paste color 3-D labels and small photographic bitmaps into schematics.

The raw 24-bit bitmap drawings are compressed to 16-bit png files. Prior to May 17, 2010, bitmaps were compressed as 8-bit gif files. An example drafted circuit using the Windows 7 Paint program follows.



At least 25 people have sent or recommended software for making schematics. Thank you for this kind gesture, but I prefer my current method and after 15 years — make schematics quickly.

2. How come you don't supply parts lists? Other people do.

The answer is simple; lack of time. It takes considerable time and effort to put up a new web page and also to maintain a large web site. I save time by leaving the parts list up to the builder. In addition, this site is about experimentation and using what parts you have on hand.

3. Why didn't you answer my email?

I answer all legitimate emails as soon as possible. Our POP3 server gets an average of 2016 spam emails per month (December 2013 data), however, our software removes 99.27% of these and I never see them. Occasionally, legitimate emails are filtered in error and I apologize. I've received as many as 83 legitimate emails in a single day so can get behind. Please keep emailing — when readers stop emailing, I'll know the site has fallen totally obsolete [it may already be obsolete] and delete it.

Our mail server software logs and analyzes the network information of all spammers and may automatically filter and/or block their addresses or even their entire ISPs at the router level. Analysis indicates that 90% of our SPAM comes from just 3 countries and if you happen to live in one of these countries, the filtering will be especially sensitive.

This sounds dogmatic and unfriendly, however, until you've set up a domain and must handle ++ spam emails, endure and then develop router control software and other strategies to handle DDoS attacks and so forth, your completely naive about the 'dark side' of running a homebrew web server. Massive amounts of bandwidth might be otherwise wasted by allowing unwanted server use unless we actively counter these activities to keep the site running well for legitimate hobbyists. Not to mention all the wasted time. Further:

The 3 host web servers, the power, the server software, the security apps, the internet bandwidth etc.are owned or purchased by my family, and as you know, nothing is free. Despite many offers by companies to place ads on my pages, I've kept the site advertisment free and running pops.net costs us a few thousand dollars each year. We ask you to please respect our site for the sake of the experimenters who visit.

Pops.net server rack in our warehouse.

While I appreciate that some people might want to email invite me onto their social networks, I do not have time to participate. All email traffic from or involving social networks see this page for a list is deleted automatically by our POP3 server control software.

I **never** buy or sell parts via email, nor exchange hyperlinks. Never. I do give free parts to those in need though.

All email with the .info domain is blocked.

The number of people selling kits has jumped up by ~4 dB in the past 5 years. Increasingly, builders who need help with kits were emailing me for support. I rarely build kits and my knowledge regarding kit building is nearly 0. Please contact your kit seller for help.

You may wish to enquire with the kit seller about their online support polices and promptness prior to purchase. Additionally you might try the "support" email address provided and see if and how promptly they reply. Most of the popular kit sellers (AADE, Kits and Parts, etc.) provide excellent support to their customers. Like anything else online; buyer beware.

4. How come you didn't link to my web site - I linked to yours?

A big thanks to the folks who link to this web site! The QRP/SWL HomeBuilder site focus is content, not web links. Making a lot of links means spending time testing for and tracking down dead links - the so called "link rot". Time spent on the web site is time away from the electronics work bench. In addition, it is not logistically possible to reciprocate in kind, as hundreds of web sites and blogs have linked this site.

5. I see the word "popcorn" used a lot on this site- what's this all about?

Popcorn connotes the essential theme of the web site; simple, frugal, without fuss and over use of technical jargon, or complex math and engineering techniques. The QRP/SWL HomeBuilder web site is referred to as the popcorn site by many. The site targets hobbyists. The emphasis is fun. The hope is that it will attract new people to electronic design, measurement and experimentation. Hopefully, this site stimulates interest in QRP homebrew electronics.

Soon after I began building electronic circuits, my teachers and the popular electronic-related media of the day pushed me towards etched, printed circuit boards. I complied and this killed my passion for electronics. For me, habitually stuffing circuit boards lacks creativity and freedom.

Later, I discovered people were building guitar and bass amps using point to point wiring techniques with terminal strips and partial circuit boards. I became interested in building and repairing guitar amps and this passion continues today. In 1992, the discovery of 2 QST articles changed everything *for me (complete reference provided):* The Ugly Weekender: parts 1 and 2 by Roger Hayward, KA7EXM and Wes Hayward, W7ZOI; published in QST for August 1981 and June 1992. This was my first exposure to Ugly Construction and it was immediately adopted as the defacto standard bread boarding method in my electronics work shop. In fairness, etched circuit boards are a great tool, but not essential for the experimenter.
After working with Ugly Construction over time, considerable progress was made in understanding RF circuits and one output was the launch of this web site in 1998.

Currently, little has changed, I continue to prefer scratch-homebrew rather than kit-homebrew electronics. My interest in Short Wave radio and analog electronics has grown considerably. For me, electronic circuits hold a certain mystique which arouses my curiosity to learn, enjoy and share. As a lay person, this web site has facilitated meeting some awesome people through email from all continents and it has been a privilege to learn from them, my mentors, book and web authors and often enough; from my mistakes.

5. What do you mean by a 5K1 or 3K3 resistor value?

For E24 or 5% tolerance resistors 5K1 = 5.1K, 3K3 = 3.3K and so on. For E96 or 1% resistors 31.6K is written as 31.6K. All resistors are 1/4 watt unless otherwise specified.

6. How do you measure audio amp output power?

Please see Figure 4 on this web page. Any amp when cranked, outputs much greater power than when it is providing a clean sine wave. The quoted power for any audio power amp on this web site is the maximum average power it will give before the pure sine wave becomes distorted.

7. I noticed a new web page appears and then it is edited for 1-2 weeks. When is the web page completed?

When a new web page is added, it takes a week or so to find and change some of the grammar and spelling errors. Sometimes new ideas or feedback will cause me to further edit a web page at any point in time. This whole web site is a work in progress. The last date any given web page was edited is posted on the bottom of the web page.

8. Do you buy or sell stuff?

No and no. I receive numerous emails from people asking me to sell them stuff. I do not sell anything - no parts, books, coffee cups, ball caps, tee-shirts, ad space — nothing. I do not buy parts in commercial-quantity volumes and have no need to make contracts for obtaining any electronic components. Every week, Asian companies email to ask about buying their parts — please note, my answer is *always* the same: no thank you.

9. Questions and concerns about printing and printability

Each year, a few readers email to complain how poorly the web pages print. This is true and I apologize.

Some people prefer pdf files for easy printing. I have resisted going to pdf format for 3 main reasons:

1. The web site audience is international and many are using web translators. PDF files are 8-bit graphic image files and do not translate.
2. More and more readers are using mobile computer devices and pdf files are a pain for them.
3. We should all print less often to save resources

As an experimenter, I dislike crammed, small-size schematics and feel they should be drawn for *maximum* clarity. Therefore, my schematics tend to have a lot of white space and color contrast. I try to make them no wider than 700 pixels, although sometimes it's impossible to do this. Big schematics are *not* printer friendly. The only practical solution is to click on and open them in a separate browser window for easier sizing and printing.

I also feature big photos which burn up a lot of printer paper. Project photos are important to me; they provide a more intimate glimpse into the bench work and promote the real purpose of the site — building stuff.

A potential printing solution for Microsoft Explorer 8 users; Click

10. I have noticed in your CMOS logic photographs, you don't always ground unused input gates. Isn't this bad?

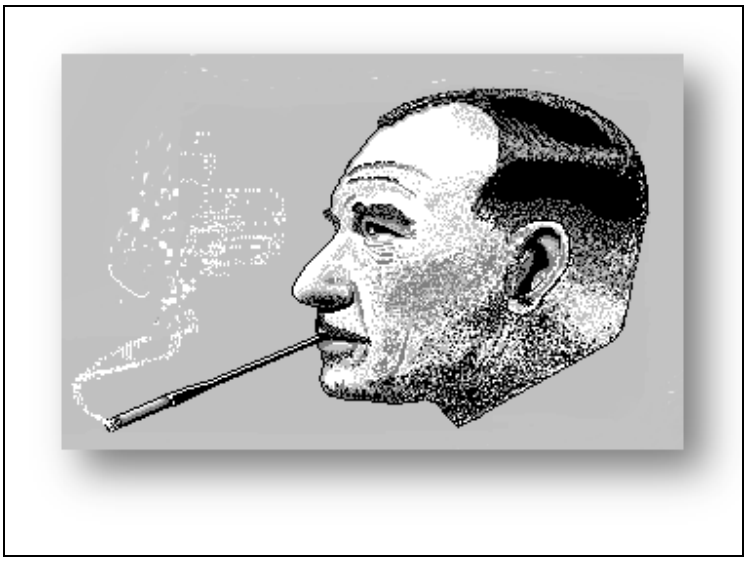
Proper CMOS logic practice mandates the grounding of all unused input gates. In prototypes and experiments, I don't always do this as I generally want to re-use the IC in other experiments. This is a cost saving measure. When you build a lot of stuff, it can get expensive and recycling parts makes sense. In keeper circuits or critical prototypes, unused input gates are directly soldered to the copper clad board. This also anchors the IC very well.

11. What is the proper URL of the home page?

http://www.qrp.pops.net

The following pre-2006 URL was decommissioned August 6, 2010: http://www.qrp.pops.net/default.htm

12. What are the QRPHB Design Centers and Professor Ivanenko character about?



This web site is about design and not just providing circuits to copy; I'm hopeful that the QRPHB Design Center concept initiated in 2011 will invigorate the site. Design Centers are the presentation of simple, but useful algorithms for amateur builders to advance their skills on the bench.

Professor Vasily Ivanenko ( ), a *fictitious* retired Russian physics professor wants to share his knowledge and give back to society. He signifies each Design Center. Professor Ivanenko was drawn for me by Rod Adams in 1996 using the Paint program that ships with Windows (the same app I make my schematics with). Rod did all of the other original bitmap art for this website including the coil guy and junk box pictures. This character was inspired by one of my favorite photographers: Irving Penn — this photograph, which is all over the web.

A new character; Dr. Natasha Petrovna appeared in late Summer 2012.

The professors are just a good bit of fun — add intrigue, characters on whom to focus and a means of identifying Design Centers. Electronics with just math and physics bores us all. Adding splash, color, clear photographs and characters such as the coil guy or the Professors boosts the site's appeal and provides a creative outlet for me.

13. Why did you kill your blog?

Time mostly. *My* blog wasted *yours* and my time. I carefully analyzed my personal yield from blogs in 2012 to 2013 — for the most part, blogs just entertain + share trivia, or rehash someone elses idea(s), or 'innocently' attract you in hope to sell stuff — and sometimes, just fulfill the author's need for attention. I don't seek, nor have time for entertainment or spectacle within my RF hobby and I certainly don't wish to waste *your* time. Each to his own, I suppose.

My analysis showed that unfortunately, blogs rarely boosted my understanding of electronic design or measurement practices. My ardent focus is to learn + improve and then pay some of this knowledge forward on a web site. Of course, everything in context — many exceptional people blog. For example, Dave AA7EE, or Jason, NT7S.

Most of the RF design and measurement people I follow keep old fashion web sites and provide generous email support. Design and measurement web sites, plus reputable and/or peer-reviewed industry and hobbist books, journals and multimedia work best for me.

Further, great elmers don't just publicly hang-out on blogs, or web server groups, or publish Utube videos — some just check their emails and when asked — give wonderful support without fanfare. Hats off to these humble folks. Thank you!

14. What oscilloscope should I buy?

Yikes — a tough question I get nearly every month. Please do your research. My best answer is buy the best 'scope you can afford. Are you a casual experimenter, or sit in your lab a lot? I prefer DSO's , however, made due with a old boat- anchor CRT for my first 10 years. The Rigol 1052/1152 seem popular entry-level choices due to their cost versus performance ratio. On the other hand, view this video to see how much Rigol DSO technology has changed.

I owned and sold my 1052 to a builder in Michigan — a worthy choice like many other 'scopes. IMHO, the FFT and math functions on the 1052 and 1152 suffer due to low memory depth and clock jitter.

Even if you only work at HF, a bandwidth 5X higher than your main frequencies of interest works better for showing harmonics. Again, I advise people to simply buy the best 'scope they can afford since it will form the heart of your test bench.

15. I'm a beginner — what toroids should I buy?

Opinions will vary, but here's what I recommend. Buy any quantity you wish, but sometimes minimum quantities apply and shipping to some countries costs dearly, so I tend to order enough parts to last me for awhile.

A basic HF toroid starter kit might look like:

Quantity	Part#	Type
10-25	FT37-43	ferrite
10-25	T50-6	powdered iron

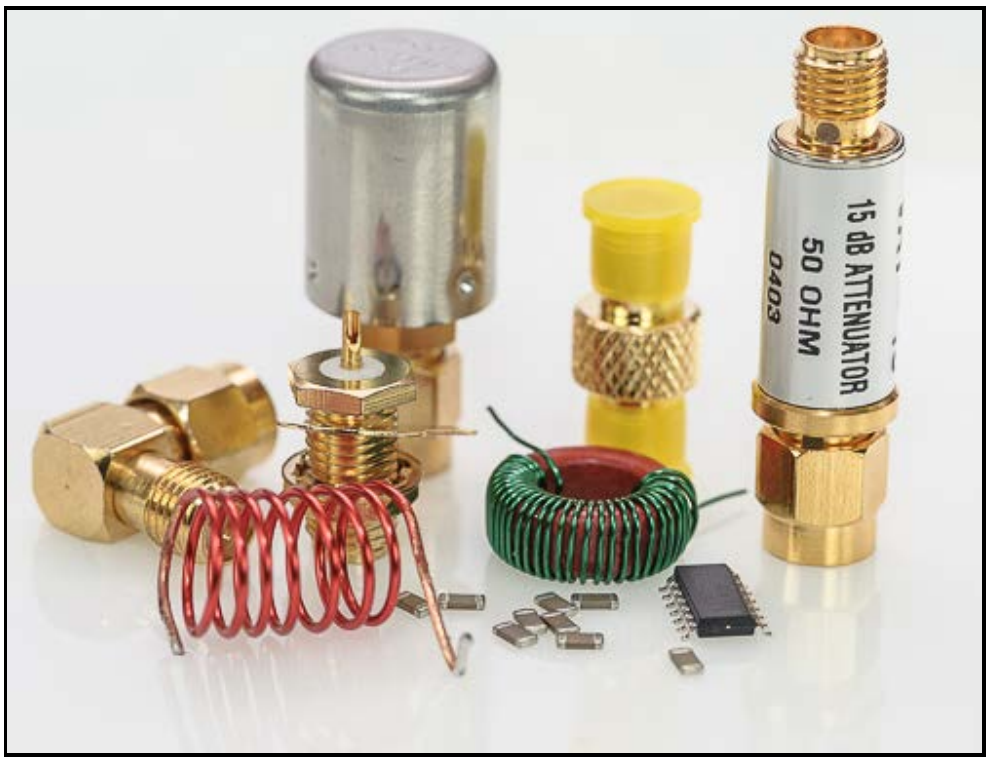
Above that, perhaps add these toroids.....

10-25	T68-6	powdered iron
10-25	T37-2	powdered iron
10-25	T50-2	powdered iron
10-25	FT50-61	ferrite

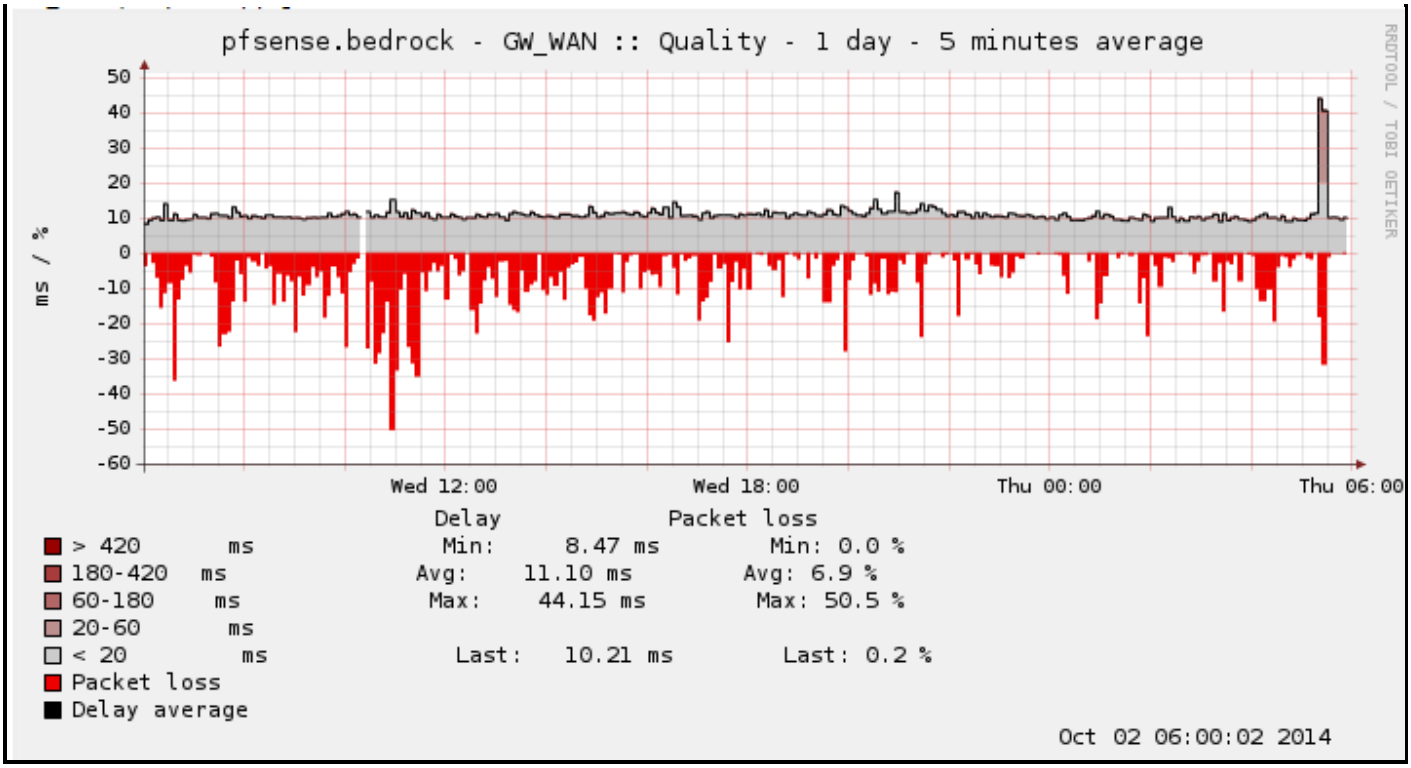
That's about it -- These will build most things RF on a HF beginner bench

RF — Test and Measurement

QRP — Log: Updates To Permanent Content



Oct 5, 2014 --- The end of QRPHB? Expect the Qrp site to go down each day for 1-4 hours. As I wrote before, we're losing an average of 10% of the outgoing packets and this peaks as high as 40% when many people are accessing the site. See an example graph below.



On Oct 2, 1 of our ISP's techs came and tested our WAN -- "it's better than most" he said. Hopefully they can do something to boost the performance on their side. Wave bought out all the local competition and we're stuck with them [this is happening everywhere]. Click for 1 of the many links writing about the emerging internet cable company monopoly.

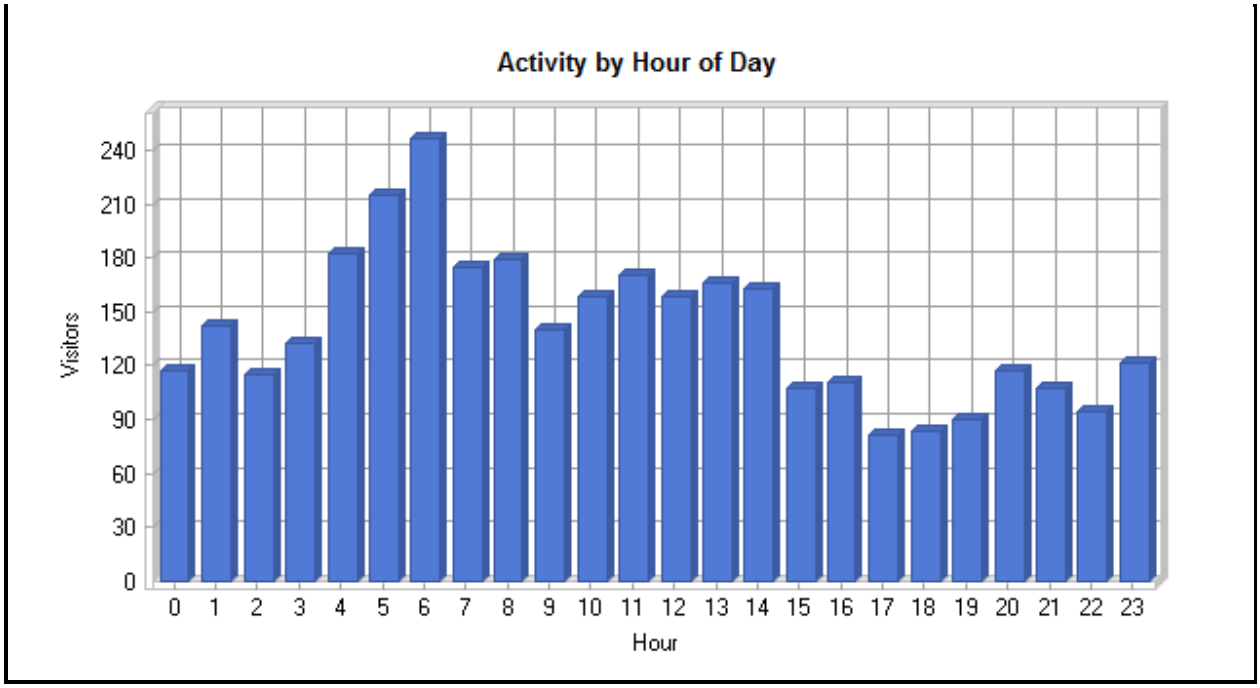
You'd think that in 2014 we could properly host a web site like we've done since 1998? To boot, Stuart is paying for a high bandwidth business account and getting less than 1% of the promised bandwidth. We chatted today and will wait patiently for Wave to improve our outflow - but only for so long.

If Wave can't or won't boost performance, I am leaning towards taking this web site down as opposed to moving it -- it's been a good run. QRPHB creates a lot of work and I could get way more done without the web site hassles. So, 2014 might be it for me. If so, thanks for coming here all these years and best of luck with your experiments!

--- Sep. 19 --- Wave Broadband, our Internet provider suffered major problems recently and I shut the site down for 4 days rather than have it limp along pathetically. Well the Wave saga *continues*: the site loads slowly and pictures are missing etc.

Our email server remains working even when the main site is down. You can always email me if the site is not working for you -- or if you have a comment or question.

Vistor volume rose this Summer so we added a better router that provides bit by bit data performance collection and new features to help throughput. At minimum user bandwidth, a unique visitor hits the site every ~0.7 minutes. I'll start formal bench experiments on October 3 --- to kick off the sites' 16th season.



August 31, 2014 — Kit to upgrade my HP frequency counter to 3 GHz added as Section 5 on Caitlyn 310 — UHF Beginnings.

August 18, 2014 — QRP-POS Data on the Sundry Web Page. Look at the end of Section 8: Popcorn AF Amps For Receivers — Reprise. This new, all-discrete AF stage will go into the Funster Line receiver and ranks as 1 of my best in terms of power and headroom.

August 12, 2014 — Funster Line: a QRP 40M band CW trans-receiver added to HF Embarcadero web page as Menu item 4. Click here for Funster. Only the transmitter is presented for now.

June 18, 2014 — I tweaked the page now called About... on the top level menu. Also, on this web page, I added a new essay for 2014 just under the essay for 2010. I'm off the bench until Fall, but hope to add a little content on rainy days or such. I'm about 2 years behind in presenting some of my experiments.

May 22 and 26, 2014 — New Supplemental Web Page for VHF-FM launched. This page and another supplement will house some new receivers over time. The new supplement is linked on the original VHF-FM web page in section number 4.

May 5, 2014 — Section 7: NE612 Mixer Diddy added to VHF Veronica

April 14, 2014 — Completion of Return Loss Bridge Experiments [added Bridge #4] on Caitlyn 310.

April 7, 2014 — Return loss and VCO experiments added to Caitlyn 310.

March 7, 2014 — Section 3 added to VHF-FM. A DC Converter for VCOs. **March 25** QRP-POSDATA for March 2014 Poor Hams Scalar Network Analyzer (PHSNA) added to Section 1 of Sundry.

February 14, 2014 — Caitlyn 310 — New repository web page for my venture into UHF. Click. Surprisingly, the site averages ~ 3000 unique visitors every 24 hours. Click for the Feb 25 tally

January 15, 2014 — The FAQ was often missed and therefore moved to the top level menu + editted/augmented.

January 4, 2014 — A follow-on version of the K3NHI QEX power meter added to RF Workbench 5 as section 6.

December 15, 2013 — I added Section 3 to HF Embarcadero. VXO and VCXO Notes. I significantly updated the VFO-2011 web page on Dec 17, 2013.

November 7, 2013 — Section 6 added to VHF — Véronique. 1 photo added to the end of the Ugly Construction page. Severe Fall weather

conditions took down the server for ~1 hour today.

November 1, 2013 — I added Section 2 to HF Embarcadero. A vestigal set of notes regarding my attempts to update the Popcorn Superhet receiver.

October 31, 2013 — Section 5 added to VHF — Véronique.

October 27, 2013 — VHF-FM re-formatted and Section 2 added. I imagine this page will disinterest many.

October 18, 2013 — 3 rarely accessed web pages removed from drop down menu, but not deleted from the server. New QRP-Posdata added to HF-Ragbag (near the end). Section 3 edited and Section 4 added to VHF — Véronique.

October 11, 2013 — Build Season 15 begins [I bench experiment Oct to May]. I added HF Embarcadero to hold all my HF and perhaps AF experiments this season. I'll also add content to VHF FM, VHF — Véronique and RF Workbench 6 over the next 12 months. Thanks.

September 9, 2013 — Blog deleted.

August 8, 2013 — Section 2 of RF Workbench 6 added. Measuring PA collector V and I to calculate efficiency. On August 16 — I added a new essay on the Ugly Construction page called Is Ugly Construction Less Reproducible than Manhattan?

June 25, 2013 — I started RF Workbench 6. It will take 1 year to complete

April 14, 2013 — I added Section 3: 50 Ω MMIC Bench Amplifer to the VHF 2013 Veronica web page.

March 31, 2013 — I started a new content page called Pin Outs

March 25, 2013 — Section 9: an essay about the 1981 Progressive Receiver, plus the final section — 10: Miscellaneous Pictures and Figures added to Sundry 2012-13

March 18, 2013 — Section 8. Popcorn AF Amplifier for Receivers — Reprise added to Sundry 2012-13

March 10, 2013 — I added a new VHF content page for 2013: VHF-2013 - Veronica

February 16, 2012 — I added Section **7** -- A Journey Above HF -- to the Sundry Experiments 2012-13 web page.

February 14, 2012 — I added Section **6** -- Non-Mechanical Iambic Paddle -- to the Sundry 2012-13 web page.

February 1, 2013 — A seperate QRP—POSDATA added to RF Workbench 4. Now QRP— POSDATA 1, 2 and 3.

December 15, 2012 — I added Section 4 to Sundry Experiments 2012 - 2013 . A PLL circuit from EMRFD.

January 5, 2013 — I added Section 5 to Sundry Experiments 2012 - 2013 . A simple AF feedback amp. An essay concerning L-C meters was also added on RF Workbench 5. Section **5.**

December 22, 2012 — I deleted the web page ***Tuning VFOs with a PN Junction*** since some of the experiments were poor quality and performed back in 1998 when I was more ignorant than now. I've learned much since then and my new VCOs from the past 1-2 years reflect this knowledge. The ***Selected QRP Reading list*** and ***Cascode 7 Receiver*** web pages were also wiped.

December 15, 2012 — I added Section 4 to Sundry Experiments 2012 - 2013 . A PLL circuit from EMRFD.

December 3, 2012 — I added Section 3 to Sundry Experiments 2012 - 2013 . Interview with Jason from Etherkit

November 13, 2012 — QRP — Posdata added to the VHF to the Max web page. Section 5: Z-Comm VCO.

November 1, 2012 — Sundry Experiments 2012 - 2013 web page added.
QRP — PosData added to Section 2 of **Power Meter Calibrators** on RF Workbench 5 and updated again on Nov 22, 2012.

October 16, 2012 — VHF FM web page added. Already, it has spawned a first supplemental web page

Sept 24, 2012 — QRP — Posdata added to the end of the HF Ragbag web page. I added a bypass and decouple network for HF to lower VHF.

August 17, 2012 — QRP — Posdata #2 added to bottom of the Receiver Band-pass Filters web page.

August 6, 2012 — Section 5: **Some Experiments with RF Bypass Capacitors** added to the HF Ragbag web page. Also a new QRP — Posdata added to the bottom of the Crystal Parameter Checker web page.

August 1, 2012 — QRP — Posdata added to the Receiver Band-pass Filters web page.

July 12, 2012 — I added a corrected schematic on the Wee Willy page: Wayne. M0WAY — 14 MHz PA under August 25, 2011. Also, added a new essay on **Microphonics in DC Receivers**. See Section 4 on the HF Ragbag Page

June 23, 2012 — RF Workbench 5 added. Click here.

May 31, 2012 — Galina discovered that I neglected to publish the proper version of the Hobby and Fun 2011 page and corrected my error. A fine-tuneable Wien Bridge Oscillator idea from Ken Kuhn now appears at the page bottom.

April 21, 2012 — I heavily edited RF Workbench 1 and 2.

April 13, 2012 — Web site purge. I removed RF Filters, VFO 1998, QRP Workshop Ideas, Miscellaneous Schematics and Photos, Base-biased VFO, Funster Transceiver, Miscellaneous Circuits and Ideas 2005 and Crystal Oscillator Offsets. **Reason:** substandard.

April 6, 2012 — 50 MHz Receiver Pre-amp and Filter added to VHF to the Max web page .Section 4.

March 26, 2012 — HF Ragbag web page added to top-level menu. Non-VHF experiment repository for 2012.

March 19, 2012 — VHF to the Max web page added to top-level menu. 50 MHz VCO experiments added to this page in Section 3.

March 14, 2012 — EMRFD review edited.

February 29, 2012 — Minor edits to the Audio Transistor Input Impedance Experiments web page. Also, I updated the calculation of the common emiiter amplifier base input resistance using the better formula: **Rin = (B+1)*(re + RE')** [while ignoring REB]. This is my favorite web page on the site.

February 26, 2012 — QRP— Posdata added to the bottom of the 2nd NDB web page

February 17, 2012 — I introduced a new miscellaneous VHF page: VHF to the Max — I'll slowly add stuff over 2012. Major editing done to the Broadband Transformer web page.

February 4, 2012 — RF Workbench 1 and 2 significantly edited. 2 new photos added.

January 28, 2012 — QRP — Posdata added to Crystal Parameter Checker web page and to QRP Modules 2011 under 7 MHz VCO Experiments on this web page. I re-wrote the temperature compensation section of the VFO-2011 web page and added 3 photographs.

January 3, 2012 — Web site change: I update web essays with an "epilogue section". In 2012 and on, they will be called QRP — Posdata (Spanish for post-script or epilogue). Posdata #2 added to the RF Workbench 4 web page.

December 17, 2011 — The Butler Did It ! - First VHF Experiments 2011 web page added. A 50 MHz frequency doubler added Dec 26, 2011.

Nov 12, 2011 — Our server went down for 16 hours. Both AC power and cable Internet to the warehouse failed after a rain storm and wind gusts knocked down some trees that severed the hydro and cable wires. Expect more weather-related down time as Winter approaches.

Oct 15, 2011 — VFO-2011 added.

Oct 2, 2011 — RF Workbench Page 4 added. On **Oct 17, 2011** I added an epilogue.

Sept 20, 2011 — Double Stacked Toroid VFO 2008 web page pulled off. It was substandard and some of the material will re-emerge on a VFO 2011 page this Winter.

Sept 19, 2011 — I updated the SWL essay since it was 6 years old and much has changed with respect to Internet radio. Over time I have received ++ emails expressing different views. I am more a SWL than a Ham and offer just 1 opinion and live by a "each to his own" mantra. Context is everything - this is a radio electronic experimenters site that recognizes SWL'ers are important members of the radio community. Click. Wee Willy web page updated again!

Sept 12, 2011 — Design Center concerning popcorn receiver band-pass filters added. Click.

Aug 26, 2011 — Minor update at the end of Wee Willy DSB transceiver. ***New Junk Box Blog format***. Change is good.

July 30, 2011 — New web page QRP Modules listed on the main menu. Currently under construction.

March 31, 2011 — 2 photos added to the Ugly Construction web page

March 19, 2011 — New content; Hobby and Fun 2011 . I'll slowly add more stuff over the year.

Feb 12, 2011 — New content. Miscellaneous RF Experiments 2011

Dec 29, 2010 — New content. RF Workbench Page 3

Dec 12, 2010 — Final additions to the the 2010 Hobbyist Page added — these concern matching FETs, BJTS and diodes.

Nov 10, 2010 — Some editing and 2 photos added to RF Workbench page 2.

Oct 9, 2010 — This October marks the 12th season of experiments for the site. I have 4 partially completed web pages on the go — pure craziness. I decided to finish them 1 at a time and then add them sequentially. Today, a new web page was added and is 1 of 2 supplements to a future main QRP audio page: Audio Transistor Input Impedance Experiments. The first new "permanent" content since March 2010.

Oct 7, 2010 —The Junk box page lay out was simplified: Accommodating the various modern Web devices plus screen resolutions proved difficult with the old html code. Although less impressive, the new format updates quickly and looks the same on every computer.

Aug 15, 2010 — The cable supplying the Internet connection failed. The site went down for 25 hours. Expect more shut downs over the next couple of days as we resolve any remaining problems.

August 6, 2010 — I decommissioned the historic home page URL http://www.qrp.pops.net/default.htm. This page was a html hard-coded parallel version of the the *correct* home page URL http://www.qrp.pops.net. It was just too much work to continue to update the old (pre-2006) home page in addition to the proper home page.

June 28, 2010 — Web subtitle change : **Amateur Radio Electronic Design** to shorten the name and reflect the site's main purpose.

Effective May 17, 2010 — Schematics now use the 16-bit png format. I have abandoned the 8-bit gif format

May and June 2010: The pops.net net control crew rest up for the next big wind storm. The servers lost power for many hours on May 4 and June 12 due to bad weather. Severe storms arising from the Pacific Ocean threaten our AC power lines each Spring.

March 2010

Wide Range L-C Oscillator added to Hobbyist 2010 page. Link **March 7**

JavaScript Applet **K** added to the QRP Tools page **March 11**

RF Workbench Page 2 added. Link **March 15**

February 2010

JavaScript Applet **J** added to the QRP Tools page **Feb 6**

Editing of the Low Noise Crystal Oscillator web page **Feb 22**

RF Workbench Page 1 added. Link **Feb 18**

January 2010

Experiment #6 added to the Hobbyist page **Jan 2**

New content Low Noise Crystal Oscillator **Jan 10**

2 photos added to the bottom of the Ugly Construction web page. **Jan 12**

1 photo added to the Broadband Transformers page **Jan 12**

New content Hobbyist Page 2010 **Jan 13**

New content: Supplement to JavaScript Applet G which is located on the QRP Tools page **Jan 11**

Additions to the Low Noise Crystal Osc page: the DSO versus CRO essay, plus 5 MHz crystal oscillator added **Jan 31**

JavaScript Applets H and I added to the QRP Tools web page **Jan 31**

December 2009

It has been brought to my attention that the email replies I am sending are not compatible with some of the latest email software such as Thunderbird etc. The reason was that I was using a homebrew email program written over 10 years ago. It is now obsolete. A new email platform is now in place along with a completely **new email address**. Consult the email web page for more information. **Dec 30**

Experiment #5 added to the Hobbyist page FAQ updated and edited. **Dec 30**

Experiment #4 added to the Hobbyist page **Dec 26**

Experiment #3 added to the Hobbyist page **Dec 23**

What does the output of a diode ring mixer look like in your oscilloscope? This has become a FAQ. The question is answered in a contribution by Wes, W7ZOI. Big thanks to Wes for this content. **Dec 22**

I am very pleased to present the **Mike, KL7R Memorial Receiver Experiments**. Click here **Dec 19**

New bulleted list format added to this page to improve readability **Dec 19**

A minor addition was added to the bottom of the Ugly Construction web page. Flux pen photo and text. **Dec 19**

Minor updates to the VFO 2008 "Stacked Toroids" web page under **Epilogue - December 19, 2009**

Update to JavaScript applet **Item E: Calculate Cut off Frequency for an RC Low Pass Filter**. Now has a capacitor range from 0.1 nF to 1500 nF. QRP tools page. **Dec 19**

Editing plus a photo added to the broadband transformer page. This page was improved to support an upcoming project. **Dec 17**

Drafting errors on this schematic corrected (fuse position+ negative rail LED polarity). From this web page. Thanks to Paul, K0EET and Tom for the good eyes and their emails. **Dec 16**

VFO Experiments 2009 updated again; 3 images added. Supplemental web page added and updated **Dec 13**

New JavaScript applet added to QRP Tools page; **Item F: dBm calculator. Dec 12**

Nov 22-27, 2009

1 Hertz Precision Time Base added to the Hobbyist Page.
VFO Experiments 2009 added
The top level menu item "Java Tools" was renamed **QRP Tools.** This menu provides a link to my Webmaster's page and some basic JavaScript applets. Some new material will appear on the Junk Box page during this time.

Nov 20, 2009

Finally; Fall-Winter experiments begin. A small update on the VFO 2008 web page under A 3.5 MHz VFO for Diode Ring Mixers was added.

The RF Preamp page was updated with some content that was first presented on the Junk Box web page. I have received a lot of email about these amps and decided to permanently add them to the site.

The W7ZOI file linked on this page is now in pdf format.

Nov 1, 2009

The Ugly Construction web page was augmented and re-written. 2 new photos were added. This term actually came from Wes and Roger Hayward.

A new Electronic Hobbyist page was added to the drop down 2009 menu.

Oct 25, 2009

Some small updates to the Junk Box page were made. I don't ever think I have been so excited about upcoming Fall and Winter experiments as there are a number of cool, new ideas in my notebook. Extra work and travelling have kept me off the bench, but this will cease in mid November. After that, it's back to the work bench. The Fall-Winter experiments will include some HAM, SWL, general electronics and tube guitar amp experiments. Thanks for your feedback and ideas!

Oct 19, 2009

RSS feed. Click on the **orange RSS icon** above to establish a feed. I will only show 1 item; the latest addition of major new content to the site. Additions to the Junk Box page will occasionally be counted as "new content" and will be included on the feed.

Can anyone guess what brand of beer is in the tool box ? Yes.... its

Oct 12, 2009

Fall weather has come to Western North America! Thanks to Cor, PA3COR for debugging the JavaScript code on this page. Apps number D and E now work in Firefox. Rediscover the fun and learning of scratch homebrew electronics!

RF — Test and Measurement

About My Web Site

Welcome Friends!

Introduction

Welcome to the QRP and SWL Homebuilder web site. I write about my experiments with relatively simple and primitive electronic circuits.

Avoiding excessive algebra and obscure parts, I emphasize and show fundamental bench practices.

Through real experiments I examine topics to challenge and intrigue amateur designers — providing examples and describing ways to plan, problem solve, breadboard and measure your circuits.

As amateur experimenters we ought to advance in our hobby; not just perform cookbook electronics. Designing and improving your circuits requires considerable knowledge and effort. Fortunately, others selflessly share their ideas to teach us.

In time, you may recognize your electronics workbench as your greatest teacher. Bench experiments involve us thinking about and measuring our circuits so we know what's happening instead of relying too much on folklore, guessing and copying others. Designing and/or simulating circuits with software can enhance your learning but does not obviate the need to spend time in the trenches with meters, wires and solder.

People often learn skills by modeling others. We need sound examples of how other builders work and think to inform our own designs — inspired, creative and active learning driven by experience and reflection.

At some level, our bench experiences are stories of growth and realization sparked by going and doing. For example, why did the designer choose a particular resistor value? You try different resistor values while measuring the results and increase your knowledge. Collecting schematics, kit building or just thinking do not provide as intimate a learning experience as soldering your ideas on a bare copper board. Talking, tweeting or day dreaming about design is not the same as *doing it*.

Russian novelist Fyodor Dostoyevsky describes the contrast between real life and passivism; "love in action is a harsh and dreadful thing compared to love in dreams", The Brothers Karamazov, Братья Карамазовы. Dare to dream, but better yet, dare to innovate — to design and build *your own* circuits. You may start by just modifying a favorite circuit or scaling a stage to another frequency. We need more innovators and less imitators to grow and sustain our great hobby.

Electronic design produces more than a completed circuit. On the bench, even joy is experiential – a moment of discovery (or several discrete moments) yields more pleasure than stuffing a circuit board or operating a piece of gear. Creativity trumps process every time!

I hope this site demonstrates my passion for building basic, "popcorn" circuits and sharing ideas. Please remember I am just a lay person experimenter and not an electrical engineer.

Regards, Todd, VE7BPO

Essay for 2010

Building or buying test equipment and acquiring a good reference library are important to your experiments. Spurred by the realization that sound bench measurement practices are at the heart of good design, test equipment receives greater focus in 2010 and on.

A reference library is vital to our electronic experiments; good examples lead to better experiments. Poor circuits are everywhere and some builders can't tell a good design from a bad one. Minimalism and simplicity aren't excuses for sloppy design when your goal is to learn. Collecting and sharing well designed circuits helps us avoid wasting time and experiencing frustration. Circuits with attributes like well defined input or output impedances, low noise or harmonic distortion are desirable to fuel experimentation. Look for better quality circuit examples in 2010 and on.

The Internet is changing how we read and write. The prevalence of small portable web devices such as iPhones, ever increasing numbers of web sites and blogs, and the use of search engines create fierce competition among sites. Modern sites attract your attention with varied visual, aural and textural media and unfortunately, hype and pseudo-journalism. Narrative writing is more skimmed than read. Brief is in — bullets, subtitles, lists and graphics replace long lines of narrative prose which no one seems to have time for anymore.

Have you noticed the changes on this website? New content still contains lots of narrative writing, but assumes an active voice, with emphasis on brevity, clarity and speaking directly to you, the reader. Sharing mostly obsolete, analog 1970's-style circuits, QRP/SWL HomeBuilder attracts a tiny, niche audience. I believe the success of this website depends on providing good and diverse content — not Tags, RS feeds, adopting net-speak, or self promotion. You be the judge.

Essay for 2014

The Internet of Everything?

Bucking the trend, my contribution to amateur RF homebrew remains informational and not social. Why?

Social media information represents a Pandora's Box of good science and opinion, mediocre thought, or trash potentially created and/or disseminated by anyone who's connected. We accept that much of our social media content doesn't come from the best or brightest — some people are just plain interesting, or express themselves vigorously, seem like-minded, or touch our hearts.
